Hypoproteinemia

The most common cause of a low serum calcium level in hospitalized patients is a reduction in the concentration of serum proteins (particularly albumin). In these patients, the ionized calcium is unaffected, and signs and symptoms of hypocalcemia are absent. Low serum albumin concentrations are often seen in patients with nephrotic syndrome, chronic illness, malnutrition, cirrhosis, and volume overexpansion. One commonly cited rule of thumb for correcting the effects of decreased serum albumin on total serum calcium concentration is to add 0.8 mg/dL to the total serum calcium for every 1 g/dL decline in serum albumin to less than 4 g/dL. However, this estimate is somewhat inaccurate, and it is preferable to determine the ionized calcium concentration directly in this setting.

Vitamin D Deficiency

Vitamin D synthesis in the skin requires adequate exposure to ultraviolet light. Thus, vitamin D deficiency is less common where sunlight exposure is abundant. In extremes of latitude (e.g., northern climates in North America) and where industrial pollution can interfere with the transmission of ultraviolet light, normal vitamin D status depends on adequate dietary intake. Supplementation of milk products with vitamin D has reduced the incidence of vitamin D deficiency in North America. Elderly persons in particular are at risk for this complication because of their general nutritional compromise and limited sunlight exposure.

Overt hypocalcemia is seen only in severe vitamin D deficiency. PTH levels are high in this setting. Serum levels of alkaline phosphatase (of bone origin) can be elevated as a result of associated osteomalacia, which is manifested by painful pseudofractures, particularly in weight-bearing long bones. The best way to assess vitamin D status is to measure circulating levels of 25(OH) vitamin D. Levels of this metabolite are low in vitamin D deficiency. Levels lower than 20 ng/mL indicate frank vitamin D deficiency; levels below 30 ng/mL are considered insufficient. However, hypocalcemia is usually not seen until serum levels are very low, often less than 10 ng/mL. Circulating $1,25(OH)_2$ vitamin D levels may be low, normal, or elevated in the setting of vitamin D deficiency. This finding may appear paradoxical, but $1,25(OH)_2$ vitamin D circulates in 1000-fold lower concentrations than 25(OH) vitamin D.

Because vitamin D is a fat-soluble vitamin, generalized fat malabsorption can also lead to vitamin D deficiency. Gastrointestinal diseases such as Crohn's disease, celiac sprue, and pancreatic insufficiency can be accompanied by hypocalcemia resulting from vitamin D malabsorption. Interruption of the enterohepatic circulation of both 25(OH) vitamin D and $1,25(OH)_2$ vitamin D may lower body vitamin D stores in these diseases. Mild hypocalcemia and secondary hyperparathyroidism are also seen in cholestatic liver diseases such as primary biliary cirrhosis. Circulating levels of 25(OH) vitamin D are reduced in this setting because of impaired hydroxylation of vitamin D in the liver and intestinal malabsorption of vitamin D.

Hyperphosphatemia

Oral or parenteral phosphate can induce a decline in serum calcium concentrations, and hyperphosphatemia can lead to frank hypocalcemia. Clinical settings in which this can occur include excessive enteral or parenteral phosphate administration, the tumor lysis syndrome, and rhabdomyolysis-induced acute renal failure. Hypocalcemia induced by either oral or parenteral phosphate administration is often associated with soft tissue calcifications. Such ectopic calcification has been observed during the treatment of hypophosphatemia resulting from either diabetic ketoacidosis or acute alcoholism. Adults receiving phosphate-containing enemas may also become hypocalcemic. Under most circumstances, with the discontinuation of exogenous phosphate intake, the serum calcium level promptly returns to normal. Hypocalcemia in the setting of massive tumor lysis results from the release of intracellular phosphate as a consequence of chemotherapy-induced cell death, usually during the treatment of rapidly proliferating neoplasms. The hypocalcemia may continue beyond the period of hyperphosphatemia and appears to be aggravated by suppressed $1,25(OH)_2$ vitamin D levels. Rhabdomyolysis-induced acute renal failure occurs with trauma and drug or alcohol abuse. Marked hypocalcemia can occur in the early oliguric phase, and moderate to severe hypercalcemia is noted in the subsequent polyuric phase. The appearance of hypercalcemia and high serum $1,25(OH)_2$ vitamin D levels during the diuretic phase may result from the rapid development of secondary hyperparathyroidism during the initial hypocalcemic period.

Pancreatitis

Hypocalcemia and tetany were first reported in patients with pancreatitis (Chapter 146) in the early 1940s. Pancreatic lipase released from the damaged gland is believed to liberate free fatty acids that chelate calcium, thereby removing it from the ECF. Hypomagnesemia resulting from poor oral intake, alcohol use, or vomiting may contribute to the hypocalcemia. Hypocalcemia in the setting of pancreatitis often suggests a poor clinical course. Treatment consists of parenteral calcium and magnesium when indicated.

Chronic Kidney Disease

Progressive renal disease (Chapter 132) is associated with a decline in serum calcium resulting from several factors. Important among these are a rise in serum phosphate as the kidneys' ability to clear absorbed phosphate declines, and a fall in serum levels of $1,25(OH)_2$ vitamin D because of both diminishing renal production of this metabolite and a rise in circulating levels of fibroblast growth factor 23, which directly suppresses 1α-hydroxylase activity. Hypocalcemia leads to chronic parathyroid stimulation, which can lead to severe secondary and even tertiary hyperparathyroidism. Early intervention with phosphate binders and calcitriol or calcitriol analogues is now the standard of care for patients with significantly impaired renal function. The challenges of managing hypocalcemia in a patient treated with dialysis are beyond the scope of this chapter (Chapter 133).

Sepsis

Up to 20% of septic patients (Chapter 108) have reductions in ionized serum calcium. Hypocalcemia is associated with a worse prognosis. This phenomenon is most often reported with gram-negative sepsis, but it has occurred in toxic shock syndrome caused by staphylococcal infection. The pathophysiology of hypocalcemia in this setting is unknown.

CLINICAL MANIFESTATIONS

Manifestations of hypocalcemia are related primarily to increased neuromuscular irritability. Tetany is the classic sign of hypocalcemia, but it is not always present. Paresthesias are more common and often occur around the mouth or in the fingertips. They may progress to overt muscle spasm in the face and extremities, the latter typified by carpopedal spasm. The term *latent tetany* refers to signs elicited by provocative stimuli such as ischemia or percussion. A positive Trousseau's test is the induction of carpal spasm within 3 minutes of inflating a sphygmomanometer above systolic blood pressure. A positive Chvostek's sign is percussion of the facial nerve to induce involuntary contraction of the facial muscles, including the corner of the mouth, nose, and eye. Neither the degree of hypocalcemia nor the rapidity with which it develops necessarily correlates with clinical manifestations, although the frequency of overt signs increases when serum calcium falls to less than 7.5 mg/dL.

Patients with hypomagnesemia or hyperkalemia may present with similar findings, which can be exacerbated by hypocalcemia. In contrast, hypermagnesemia or hypokalemia can mask symptoms in a hypocalcemic individual. Abnormalities of cardiac repolarization are seen in hypocalcemic individuals, reflected by a prolonged QT interval on the electrocardiogram.

Basal ganglia calcifications are typical findings in long-standing hypoparathyroidism. Osteopetrosis and dental abnormalities have also been reported in chronic untreated hypoparathyroidism. Dry skin, coarse hair, and a form of psoriasis that responds to correction of hypocalcemia have all been described in this clinical setting.

DIAGNOSIS

The initial step in evaluating hypocalcemia is to confirm that the ionized calcium level is low (Fig. 253-5). If the serum albumin concentration is within the normal range, total serum calcium can be considered an accurate reflection of the ionized fraction. Otherwise, ionized serum calcium must be measured. Once it has been established that the patient is hypocalcemic, a serum PTH level should be measured. A low or undetectable PTH level in the presence of hypocalcemia confirms the diagnosis of hypoparathyroidism. The diagnostic focus in this setting is on destructive, infiltrative, and autoimmune diseases of the parathyroid glands, as well as genetic disorders leading to the absence of the parathyroid glands or (as in the case of activating mutations of the CaR) their functional absence. If the serum PTH level is elevated, the differential diagnosis should focus on factors inducing resistance to the actions of PTH. The presence of hyperphosphatemia suggests concomitant renal failure or excessive ingestion or administration of phosphate salts. A low serum phosphorus level in the setting of hypocalcemia and an elevated PTH

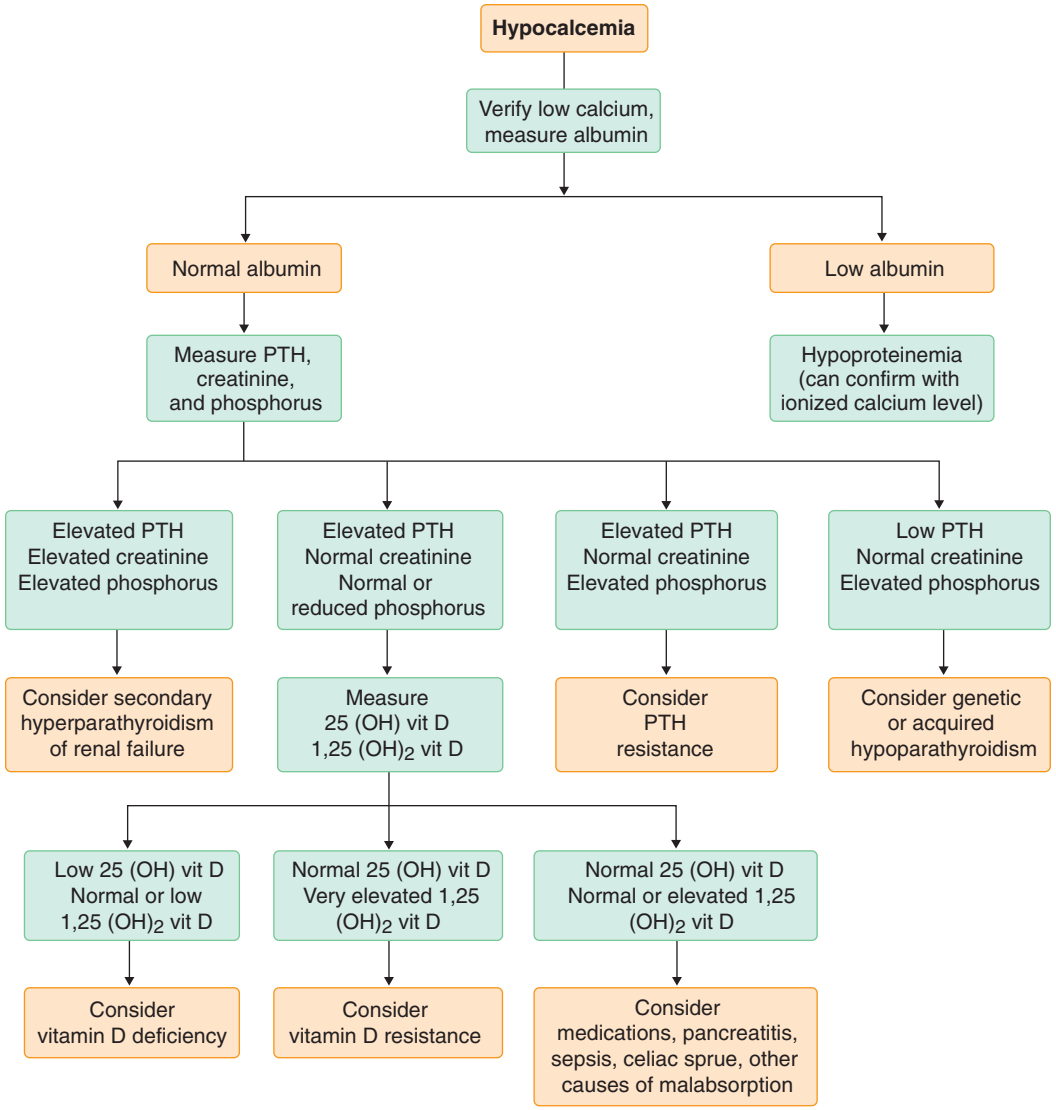

FIGURE 253-5. Algorithmic approach to the diagnosis of hypocalcemia. PTH = parathyroid hormone; vit = vitamin.

suggests the possibility of vitamin D deficiency, and a serum 25(OH) vitamin D level should be checked early in the evaluation. The presence of vitamin D deficiency indicates nutritional deficiency or intestinal malabsorption. The diagnosis of hypomagnesemia should be excluded. In the absence of any of these accompanying changes, phenotypic abnormalities such as those seen in Albright's hereditary osteodystrophy should be sought because PHP is a likely diagnostic possibility.

TREATMENT

Acute Management

Hypocalcemia-induced seizures, laryngospasm, and tetany are examples of clinical settings in which the immediate correction of hypocalcemia is required. In these emergencies, 10 to 20 mL of 10% calcium gluconate should be infused over a 10- to 15-minute period. This treatment can be followed, if necessary, by an infusion of calcium. For this purpose, 10 ampules of calcium gluconate can be diluted in 1 L of 5% dextrose, and, beginning at a rate of 50 mL/hour, the infusion rate can be titrated to maintain the serum calcium in the low-normal range.

In patients with hypomagnesemia, magnesium therapy may be required to restore PTH secretion and peripheral activity. Before the administration of magnesium salts, adequate renal function and urinary output should be ensured. In the acute setting, elemental magnesium can be infused slowly, with up to 2.4 mg/kg body weight given over a 20-minute period (to a maximum of 180 mg). The length of parenteral therapy must be individualized, and maintenance with oral magnesium salts should be implemented when ongoing hypomagnesemia is anticipated.

The administration of intravenous calcium or magnesium should be carefully monitored. The patient's cardiac status should be followed and the infusions stopped if electrocardiographic changes occur. Deep tendon reflexes can be used to monitor for magnesium toxicity, and therapy should be halted if reflexes diminish. Intravenous calcium gluconate is a useful antidote for magnesium intoxication and should be available at the bedside.

Long-Term Treatment

Many of the causes of hypocalcemia discussed earlier are corrected by treating the underlying disorder (e.g., vitamin D deficiency, tumor lysis syndrome). However, some patients require maintenance therapy for hypocalcemia, including those with hypoparathyroidism, PHP, and vitamin D–resistant states.

Hypoparathyroidism, whether primary or secondary to trauma or surgery, is the most frequently encountered condition that requires long-term therapy to support circulating calcium concentrations. In these individuals, the goal is to maintain serum calcium in the low-normal range (8.5 to 9.2 mg/dL). This approach reduces the likelihood of symptoms such as circumoral tingling, signs such as carpopedal spasm, and long-term complications such as cataracts. Increasing the serum calcium level to the middle to high-normal range can result in significant hypercalciuria, nephrocalcinosis, and nephrolithiasis.

There is no single best way to achieve target calcium levels, although the combination of a vitamin D metabolite and calcium supplements is generally preferred. Many different preparations of both are available. Because of the prolonged toxicity that occurs with excessive ingestion of either ergocalciferol or 25(OH) vitamin D, the use of rapid-acting preparations of vitamin D is generally preferred for the treatment of hypoparathyroidism. Calcitriol [$1,25(OH)_2D_3$] and dihydrotachysterol are two preparations suited to this purpose. Both are fully active in vivo. In general, it is best to establish a stable dose for one of these agents and refine the serum calcium level by adjusting the intake of supplemental calcium, rather than by making repeated changes in vitamin D metabolite therapy. Calcitriol can be used in most patients. The dose of calcitriol can range from as little as 0.25 up to 2.0 µg/day. The biologic half-life of the drug is 12 to 14 hours. When hypercalcemia develops during therapy with calcitriol, it usually resolves within 3 to 4 days after discontinuing the drug, although it can persist for more than 1 week. In addition to a

high-calcium diet, calcium supplements are important for the treatment of hypoparathyroidism, and doses of 1000 to 2000 mg/day may be necessary. Calcium preparations including the carbonate, citrate, lactate, gluconate, and glucobionate salts are suitable for this purpose. In some patients with hypoparathyroidism, a thiazide diuretic may be useful in augmenting serum calcium levels and reducing the hypercalciuria that can occur with the institution of treatment. Long-term treatment of hypoparathyroidism with synthetic human PTH is not yet practical, although therapy for up to 3 years was well tolerated in a clinical trial. Various stresses such as trauma, infection, and pregnancy can increase the therapeutic requirements of patients with chronic hypocalcemia, and the clinician should be alert to this possibility.

SAMUEL A. WELLS JR.

MEDULLARY THYROID CARCINOMA

DEFINITION

Medullary thyroid carcinoma (MTC) is a relatively uncommon form of thyroid cancer that occurs either sporadically or as part of multiple endocrine neoplasia (MEN) type 2.

EPIDEMIOLOGY

MTC accounts for 5 to 10% of thyroid cancers, and there are 1500 to 3000 new cases in the United States each year. In 25% of cases, MTC occurs as a uniform component of MEN 2 or related syndromes: MEN 2A, (80%), MEN 2B (5%), and familial MTC (15%) (Table 254-1). The incidence of the hereditary forms of MTC is 1 in 30,000 persons.

PATHOBIOLOGY

MTC originates from the neural crest–derived C cells, which localize within the upper poles of the thyroid lobes during embryogenesis as the lateral thyroid complex closes. Even though MTC occurs within the thyroid parenchyma, it is actually a neuroendocrine tumor, as it does not arise from the thyroid follicular cells. Sporadic MTC occurs as a solitary tumor, whereas in the hereditary forms of MTC, the tumor involves both thyroid lobes and is multifocal. In patients with hereditary MTC, the first manifestation of this C-cell disorder is C-cell hyperplasia, which progresses over time to microinvasive MTC and then invasive MTC.

The C cells have diverse biosynthetic activity and secrete calcitonin, carcinoembryonic antigen (CEA), chromogranin-A, histaminase, somatostatin, gastrin-releasing peptide, and adrenocorticotropin. Of these markers, calcitonin and CEA are the most useful clinically, and both are excellent serum markers for MTC. The hormone calcitonin was once thought to be important in calcium homeostasis; however, its physiologic importance has recently been called into question. Histologically, the MTC cells are spindle shaped, and special staining demonstrates calcitonin and CEA. With age, the central portion of the tumor calcifies, which can be seen on radiographic imaging studies.

Dominant-negative, activating, germline, missense, and point mutations in the *RET* proto-oncogene are present in virtually all cases of hereditary MTC. Somatic *RET* mutations are demonstrated in at least half of sporadic MTCs. *RET* is located in the pericentromeric region of chromosome 10q11.2 and spans 21 exons, including more than 60 kb of genomic DNA. *RET* is highly conserved, and homologues have been found in lower vertebrates and the fruit fly. *RET* plays a central role in various intracellular signaling cascades that regulate cellular differentiation, proliferation, migration, and survival. The RET protein is expressed in developing neuroendocrine cells (including thyroid C cells; adrenal medullary cells; parathyroid cells; neural cells, including parasympathetic and sympathetic ganglion cells; and cells of the testis and urogenital tract).

MEN 2A, MEN 2B, and familial MTC (FMTC) are inherited as autosomal dominant traits with near-complete penetrance and, in the case of MEN 2A and MEN 2B, variable expressivity. Approximately 75 *RET* mutations have been reported in association with MEN 2A, MEN 2B, and FMTC, and 95% of families with one of the forms of hereditary MTC have demonstrated *RET* mutations. The mutations for MEN 2A are located mostly in the extracellular, cysteine-rich region of exon 10 (including codons 609, 611, 618, and 620) and exon 11 (including codons 630 and 634). Approximately 85% of the mutations associated with MEN 2A involve *RET* codon 634, approximately half of which are *C634R RET* mutations. The mutations characteristic of FMTC also occur in exons 10 and 11; however, noncysteine point mutations have also been found in exon 8 (codons 532 and 533), exon 13 (codons 768, 790, and 791), exon 14 (codons 804 and 844), exon 15 (codon 891), and exon 16 (codon 912).

Unlike the mechanism in MEN 2A and FMTC, MEN 2B mutations occur in the kinase domain and cause constitutive RET activation in a monomeric form of RET, thereby altering substrate specificity, presumably due to a conformational change in the binding pocket of the kinase. Approximately 95% of mutations causing MEN 2B are in codon 918 (exon 16), and 5% are located in codon 883 (exon 15).

It is estimated that the disease arises de novo in 50% of patients with MEN 2B and in 10% of patients with MEN 2A and FMTC. In all founder cases studied thus far, the de novo mutation arose from the paternal allele.

CLINICAL MANIFESTATIONS

The peak incidence of sporadic MTC is in the fifth decade of life, and most patients present with a solitary thyroid nodule and lymph node metastases, although the latter may not be evident on physical examination. Clinically,

the tumors are more aggressive than papillary thyroid carcinoma and follicular thyroid carcinoma, and overall, the 10-year survival rate is 75%.

MTC occurs in virtually all patients with MEN 2A, MEN 2B, and FMTC and is the most common cause of death in affected patients. Approximately 50% of patients with MEN 2A and MEN 2B develop pheochromocytomas (Chapters 235 and 239). An undiagnosed pheochromocytoma, which makes itself known during induction of anesthesia for thyroidectomy or childbirth, can be catastrophic and often lethal. Thus, pheochromocytoma must be excluded in all patients with a confirmed or presumptive diagnosis of hereditary MTC (Chapter 235).

Parathyroid hyperplasia occurs in 30% of patients with MEN 2A and usually involves all four glands. The disease is frequently asymptomatic, with the only abnormality being an elevated serum calcium concentration.

There is a strong relationship between genotype and phenotype in patients with MEN 2A. For example, pheochromocytomas are most common in patients with mutations in exon 11 (particularly codon 634). Also, the presence of hyperparathyroidism is associated with codon 634 mutations, especially the *C634R* mutation. The clinical aggressiveness of MTC (age of onset, tumor size, frequency of regional and distant metastases) is related to the form of hereditary MTC. For example, MTC associated with MEN 2B is much more aggressive than that occurring with MEN 2A or FMTC. The primary basis for the difference is that MEN 2B mutations are associated with greater basal kinase activity and thus are more highly activating compared with mutations occurring in MEN 2A and FMTC.

Patients with MEN 2A may also develop one of two associated disorders: cutaneous lichen amyloidosis or Hirschsprung's disease. Cutaneous lichen amyloidosis occurs in about 25% of patients with MEN 2A and involves the interscapular region of the back, corresponding to dermatomes T2 through T6. Pruritus, the dominant symptom, leads to repetitive scratching and secondary skin changes characterized by the deposition of amyloid. The lesion may be evident in infancy, thus serving as a precursor marker of MEN 2A. Cutaneous lichen amyloidosis is associated with a *RET* codon 634 mutation.

Hirschsprung's disease, manifested by the absence of intrinsic ganglion cells in the distal gastrointestinal tract, has been reported in 30 or more families with MEN 2A or FMTC and is associated with mutations in exon 10 of *RET* involving codons 609 (15%), 611 (4%), 618 (30 to 35%), and 620 (50%). In functional studies, the cell surface expression of RET with these codon mutations is lower than that found with codon 634 mutation, suggesting a novel mechanism whereby the mutations have a dual effect: causing the transformation of C cells, leading to MTC, and interfering with transportation of the protein to the plasma membrane, resulting in the absence of ganglion cells and the development of Hirschsprung's disease.

Patients with MEN 2B develop mucosal neuromas, ganglioneuromatosis throughout the aerodigestive tract, hypotonia, and medullated corneal nerves. They also develop colonic dysfunction manifested by abdominal pain and occasionally intestinal obstruction requiring surgery. Patients have a characteristic physical appearance, which may not be evident very early in life. The failure to diagnose MEN 2B at a young age can be catastrophic because MTC develops early; it is often evident soon after birth, and regional or distant metastases occur soon thereafter.

Patients with FMTC develop only MTC, which, relative to the tumors in patients with MEN 2A and MEN 2B, is slow growing. There has been some question whether FMTC is a distinct disease entity or a form of MEN 2A.

DIAGNOSIS

Once it was discovered that C cells secrete calcitonin, the measurement of serum levels of this hormone, either in the basal state or following the intravenous administration of the secretagogues calcium or pentagastrin, became the primary method of establishing the diagnosis of a C-cell disorder. With the discovery that MEN 2A, MEN 2B, and FMTC are caused by mutations in the *RET* proto-oncogene, direct DNA analysis to detect a mutated *RET* allele replaced serum calcitonin measurement as the method of choice for identifying affected family members. At present, the measurement of serum calcitonin is used to evaluate disease progression, either after thyroidectomy for MTC or during the course of medical treatment for advanced disease. In European countries it is common practice to measure basal serum calcitonin in patients with nodular thyroid disease; this technique has proved more effective than fine-needle aspiration cytology in detecting patients with MTC.

The Gene Tests directory currently lists 38 laboratories that perform DNA analysis for *RET* in MEN 2A, MEN 2B, FMTC, and sporadic MTC (*http://www.genetests.org*). Almost all the laboratories use direct sequence analysis to evaluate mutations in exons 10, 11, 13, 14, 15, and 16, and some laboratories include exon 8. If no mutations are found in these exons, the entire coding region of *RET* can be sequenced. *RET* mutations in exons 10 or 11 are identified in more than 95% of families demonstrating a germline transmission of MEN 2A or FMTC.

Approximately 7% of patients with presumed sporadic MTC actually have MEN 2A or FMTC; therefore, it is important to perform direct DNA analysis on all patients with "sporadic" disease. The diagnosis of hereditary MTC widens the disease spectrum to be considered by the responsible physician, and it also creates the obligation to screen family members, some of whom will have early-stage MTC.

TREATMENT Rx

The primary treatment for patients with MTC is total thyroidectomy and resection of lymph nodes in the central compartment of the neck, an area bounded by the hyoid bone superiorly, the thoracic inlet inferiorly, and the carotid sheaths laterally (levels I through VI). Total thyroidectomy is indicated because the incidence of intrathyroid lymphatic spread is 10 to 20%, and even though the disease appears to be sporadic, the patient's hereditary status is usually unknown at the time of thyroidectomy. If lymph nodes are palpable in the ipsilateral or contralateral neck or are evident on preoperative ultrasound examination, the respective lymph node compartments (levels II through V) are cleared. During the procedure, great care must be taken to preserve the parathyroid glands, the recurrent laryngeal nerve, and the external branch of the superior laryngeal nerve.

The preoperative serum levels of calcitonin and CEA are important predictors of nodal metastases. Half of patients with serum calcitonin levels greater than 3000 pg/mL and 30% of patients with CEA levels greater than 10 ng/nL have lymph node metastases. Spread to regional nodes is associated with treatment failure, indicated by normalization of the serum calcitonin in only 10% of patients with node-positive disease, compared with 60% of patients with node-negative disease. Even though surgical resection seldom cures patients with regional lymph node metastases, many have a good prognosis, with 5- and 10-year survival rates of 80 and 70%, respectively.

Repeat neck operation following initial thyroidectomy is indicated in patients with serious complications from recurrent tumor compressing or invading vital structures, such as the spinal cord, airway, or esophagus. Relief often follows tumor excision or debulking. Also, patients who have intractable diarrhea due to markedly elevated tumor hormone secretions, presumably calcitonin, may obtain symptom relief by tumor ablation. Rarely, patients with MTC develop Cushing's syndrome due to the inappropriate secretion of adrenocorticotropin or corticotropin-releasing hormone. Such patients usually have advanced disease, and bilateral adrenalectomy may be required if steroidogenesis inhibitors are ineffective. This is a poor prognostic sign and is associated with an average survival of 2 years.

Patients who develop persistent or recurrent MTC following thyroidectomy, as indicated by elevated serum levels of calcitonin or CEA, are also candidates for reoperation; however, the benefit of such surgical procedures is open to question, with a lack of long-term data on quality of life and survival.

The treatment of pheochromocytoma is adrenalectomy, as described in Chapter 235. Hyperparathyroidism is managed by either three-and-a-half-gland parathyroidectomy or total parathyroidectomy and heterotopic autotransplantation.

For patients with locally advanced or metastatic MTC, single-agent or combined chemotherapeutic regimens have been minimally effective, and chemotherapy does not play a major role in those with advanced disease. Similarly, external beam radiotherapy has little effect on primary tumors or soft tissue metastases and is indicated only for the treatment of central nervous system or bone metastases.

With the demonstration that the tyrosine kinase inhibitor imatinib induced remissions in patients with chronic myelogenous leukemia and gastrointestinal stromal tumors, there was hope that similar small-molecule therapeutics would be developed for patients with MTC. The tyrosine kinase inhibitor vandetanib inhibits vascular endothelial growth factor signaling, angiogenesis, tumor growth, KDR tyrosine kinase activity, and oncogenic RET kinases. A phase II clinical trial of vandetanib in locally advanced or metastatic hereditary MTC resulted in partial remissions in 20% of patients and a disease control rate of 80%. Similar results have been observed with other tyrosine kinase inhibitors. Thus, there is hope that effective systemic therapies will be available for patients with advanced disease and perhaps for patients with minimal disease after primary thyroidectomy for MTC.

PREVENTION

There are several hereditary cancer syndromes for which the causative abnormality has been identified. In many of these syndromes, removal of the organ at risk for malignancy is considered a preventive strategy. Patients with MEN 2A, MEN 2B, and FMTC are ideal candidates for prophylactic thyroidectomy because the genetic mode of inheritance is characterized by near-complete penetrance, and direct DNA analysis identifies carriers of a mutated *RET* allele who are destined to develop MTC. Furthermore, the thyroid is easily

removed, with minimal morbidity and virtually no mortality; there is a suitable replacement for the organ's function; and there is a reliable serologic test to determine whether the patient has been rendered disease free.

Apparently normal, young members of kindreds with hereditary MTC who are found to have a mutated *RET* allele on genetic screening have the greatest likelihood of being cured by prophylactic thyroidectomy. Surgeons in several countries have reported success with this operative procedure, and the question is no longer should it be done but at what age.

The Consensus Committee of the 7th International Workshop on MEN, the EUROMEN group, and the International Guideline Committee of the American Thyroid Association have all proposed guidelines for the timing of prophylactic thyroidectomy in patients with MEN 2A, MEN 2B, and FMTC. The recommendations of the three groups are similar, in that children with MEN 2B (or with mutations in codons 918 or 882) should have thyroidectomy at the time of diagnosis, even during the first months of life. Children with mutations in codons 611, 618, 620, or 634 should have the thyroid removed at or before 5 years of age. In children with mutations in other *RET* codons, the recommended timing of thyroidectomy is less clear but is generally between 5 and 10 years of age. Some clinicians use basal or stimulated calcitonin levels to determine the timing of thyroidectomy.

PROGNOSIS

A poor prognosis is associated with the following findings: a large primary tumor, metastases to regional lymph nodes, markedly elevated serum levels of calcitonin and CEA preoperatively, extrathyroidal invasion of the trachea or soft tissues intraoperatively, elevated and increasing serum levels of calcitonin and CEA postoperatively, and radiographic evidence of distant metastases. Generally, MTC is more aggressive in patients with sporadic disease than in those with hereditary disease. Also, patients with MEN 2B and patients with MEN 2A who have *RET* mutations in codon 634 have a poorer prognosis than those with *RET* mutations in other codons. Patients apparently cured by thyroidectomy are followed at 6-month intervals by the measurement of serum levels of calcitonin. The doubling time of serum calcitonin is very useful in predicting the course of the disease; calcitonin doubling times less than 6 months (vs. those >24 months) are associated with a poor prognosis.

PAGET'S DISEASE OF BONE

G. DAVID ROODMAN

DEFINITION

Paget's disease is a focal disorder of the skeleton that is the second most common bone disease, exceeded only by osteoporosis. It affects approximately 1 to 2% of adults older than 55 years in the United States and up to 4 to 6% of adults 55 years old or older in certain areas of the United Kingdom. Paget's disease is the most exaggerated form of bone remodeling, involving increases in all phases of the bone remodeling process. The initial phase is characterized by markedly increased bone resorption, followed by exuberant new bone formation. The new bone is abnormal and woven, with disorganized collagen. This increased bone formation results in bone enlargement and deformity because of the poor quality of the bone.

EPIDEMIOLOGY AND ETIOLOGY

The cause of Paget's disease is unknown. However, a genetic predisposition has been clearly established. Approximately 40% of patients with Paget's disease have an affected first-degree relative, and many families with vertical transmission of Paget's disease and an autosomal dominant pattern of inheritance have been described. At least six genetic loci have been linked to Paget's disease, and mutations in the sequestosome-1 gene *(SQSTM1)*, also known as p62, are the most frequent. *SQSTM1* mutations have been detected in 30% of patients with familial Paget's disease and in 10% of patients with sporadic Paget's disease. Although the penetrance for Paget's disease is high, it can vary in families with a genetic predisposition. Elderly patients with *SQSTM1* mutations may have no evidence of Paget's disease, even though they are homozygous for the mutation.

The primary cellular abnormality in Paget's disease resides in the osteoclast. These cells contain nuclear inclusions that resemble paramyxoviral nucleocapsids. Both measles virus and respiratory syncytial virus nucleocapsid proteins and transcripts have been detected in osteoclasts from patients with Paget's disease, but some studies have not detected paramyxoviral transcripts or proteins in pagetic osteoclasts. Furthermore, a cause-and-effect relationship between Paget's disease and paramyxovirus infection has not been definitively established. Nevertheless, in vitro studies in which normal osteoclast precursors were transfected with measles virus transcripts or infected with measles virus have demonstrated that osteoclast precursors containing the measles virus nucleocapsid gene can form pagetic-like osteoclasts. Furthermore, transgenic mice in which expression of the measles virus nucleocapsid gene was targeted to cells of the osteoclast lineage developed bone lesions and osteoclasts characteristic of Paget's disease.

Although Paget's disease is the second most common bone disease, its prevalence varies among different populations. In the United Kingdom, for instance, Paget's disease affects up to 6% of the population older than 55 years. Further, the frequency of symptomatic Paget's disease increases with age. Paget's disease occurs with similar prevalence in western Europe and in the white populations of New Zealand and Australia. However, Paget's disease is extremely rare in Scandinavia and the Far East, and it does not affect indigenous populations in either Australia or New Zealand. The prevalence of Paget's disease appears to have decreased since the early 1980s. Its prevalence has reportedly decreased from approximately 8 to 4% in England and from 5 to 3% in New Zealand. In addition, the severity of Paget's disease in these populations has decreased. The basis for these changes is unknown.

PATHOBIOLOGY

Bone remodeling is increased 5- to 10-fold in patients with Paget's disease. Paget's disease is highly localized, with focal areas of involvement. In pagetic lesions, osteoclast numbers are increased, and the osteoclasts are hyper-multinucleated, with up to 100 nuclei per cell. In contrast, normal osteoclasts contain 3 to 20 nuclei per cell. The bone resorbing capacity of pagetic osteoclasts on a per nucleus basis is decreased compared with normal osteoclasts. However, because of the large numbers of osteoclasts in the pagetic lesion, overall bone resorption is markedly increased (Fig. 255-1). The increased bone resorption phase is followed by new bone formation. As the disease progresses, bone formation begins to predominate, and the bones become enlarged (Fig. 255-2). Large numbers of osteoblasts are often found near areas of resorbed bone, and they may even be prominent in a lesion that appears to be purely osteolytic by roentgenogram. The osteoblasts contain abundant rough endoplasmic reticulum, mitochondria, and a well-developed Golgi zone. These features of heightened cellular activity are consistent with the increased bone formation in active lesions. In addition to the increased numbers of osteoclasts and osteoblasts, the marrow in pagetic lesions is often grossly abnormal. The normal hematopoietic elements are usually absent and are replaced by mononuclear cells of indeterminate origin, intermixed with highly vascular connective tissue. The bone matrix structure in Paget's disease is extremely abnormal and arises as a consequence of disordered bone resorption and formation. The matrix consists of a "mosaic" of irregularly shaped pieces of lamellar bone with an erratic pattern of cement lines. The matrix is interspersed with numerous foci of woven bone, which, in adults, is ordinarily associated with fracture healing. After a long time, the lesions become sclerotic. This rapid and abnormal deposition of bone results in the characteristic irregular cement lines that give rise to the mosaic appearance on radiographs and in tissue sections. Marrow vascularity is markedly increased in pagetic

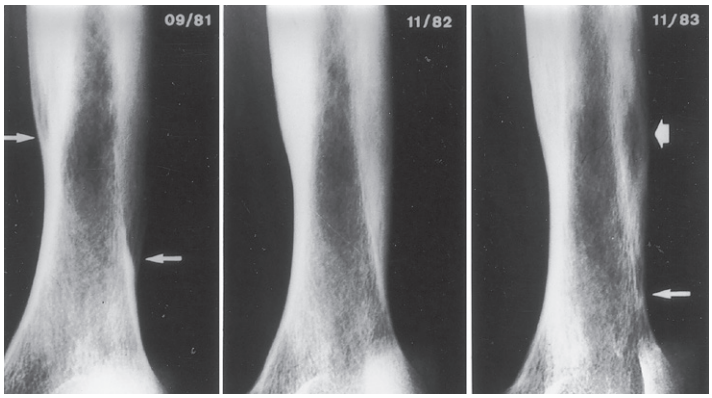

FIGURE 255-1. Sequential radiographs of the distal end of the femur at the dates shown. A, Distinction between pagetic and normal bone *(arrows)*, the osteolytic front, and expansion of bone diameter at the affected site. **B,** Treatment with a bisphosphonate induced filling in of the resorption front. **C,** Relapse after treatment was associated with a new area of osteolysis *(thick arrow)* and progression of the resorption front. (From Kanis JA. *Pathophysiology and Treatment of Paget's Disease of Bone*, 2nd ed. London: Martin Dunitz; 1998.)

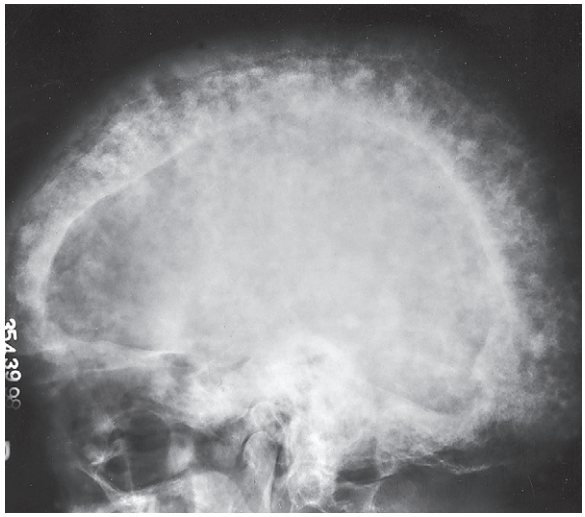

FIGURE 255-2. Advanced involvement of the skull with Paget's disease. Note the marked thickening of the entire vault, areas of osteolysis, and patchy new bone formation, resulting in a "cotton-wool" appearance.

lesions, such that involved bones often feel warm to the touch. Electron microscopy studies of pagetic osteoclasts show nuclear inclusions that resemble paramyxovirus nucleocapsids. However, these nuclear inclusions are not unique to Paget's disease and have been reported in rare cases of osteopetrosis and other bone diseases, such as giant cell tumors of bone.

CLINICAL MANIFESTATIONS

Most patients with Paget's disease are elderly, and the age at diagnosis is usually older than 50 years. Paget's disease affects both men and women, with a slight male predominance. Although Paget's disease is often asymptomatic, 10 to 30% of patients experience pain, skeletal deformity, neurologic symptoms, pathologic fractures, or deafness. Patients may have only one affected bone or pagetic lesions in multiple bones. Patients with familial Paget's disease tend to have more bones affected and more deformity than those with sporadic Paget's disease. Paget's disease remains highly localized, and patients rarely develop new lesions in previously unaffected bones after diagnosis. Table 255-1 lists the common clinical features and complications of Paget's disease.

DIAGNOSIS

The biochemical findings in Paget's disease reflect the cellular events occurring throughout the skeleton of affected patients. Measurement of collagen cross-link degradation products in urine provides a specific measure of skeletal matrix degradation. Urinary *N*-telopeptide, pyridinoline, and deoxypyridinoline have all been used as measures of skeletal matrix resorption.

TABLE 255-1 CLINICAL FEATURES AND COMPLICATIONS OF PAGET'S DISEASE

COMMON
Pagetic or articular bone pain
Fracture of long bones and vertebral bodies
Neurologic deafness
Deformity and enlargement of bones
UNCOMMON
Spinal neurologic syndromes
Hypercalciuria of immobilization or fracture
Vascular bleeding from bone during surgery
Extraskeletal (aortic) calcification
Osteosarcoma and other bone tumors
RARE
Cardiovascular disease
Cranial nerve lesions (except VIII)
Brain stem and cerebellar lesions
Hypercalcemia of immobilization
Extramedullary hematopoiesis
Epidural hematoma
SIGNIFICANCE UNCERTAIN
Gout
Pseudogout
Angioid streaks
Hyperparathyroidism
Urolithiasis

Serum tartrate-sensitive acid phosphatase, released by osteoclasts, is another index of bone resorption in Paget's disease.

Osteoblast activity can be assessed by measuring total serum alkaline phosphatase activity, serum bone-specific alkaline phosphatase concentration, serum osteocalcin concentration, and serum type 1 carboxy-terminal procollagen peptide concentration. The most useful are total serum alkaline phosphatase and bone-specific alkaline phosphatase determinations. Total serum alkaline phosphatase measurements are routinely used to monitor disease activity in the clinic.

TREATMENT Rx

Medical Therapy

Symptomatic patients with Paget's disease require treatment. No data support the treatment of asymptomatic patients, except in the presence of rapidly advancing osteolytic lesions in weight-bearing long bones, in which case the risk of pathologic fractures is increased. Because the osteoclast is the primary cell involved in Paget's disease, medical treatment that inhibits osteoclast activity—in particular, the use of bisphosphonates, calcitonin, and mitomycin—has been successful. Salmon calcitonin by injection, which has been used since the early 1980s, is an effective treatment for Paget's disease, suppressing the biochemical parameters of the disease by 50%. Bisphosphonates can inhibit osteoclast formation, but they predominantly induce osteoclast apoptosis; they are the most frequently used treatment for Paget's disease. Bisphosphonates, which contain nitrogen, are pyrophosphate derivatives with a high affinity for bone. They are incorporated into sites of bone resorption, released during the resorption process, and taken up by osteoclasts. This process results in the death of osteoclasts. Osteoclasts were recently reported to be angiogenic, and bisphosphonates affect angiogenesis as well as cytokine production by osteoclasts. Because biochemical markers strongly correlate with disease activity, following serum alkaline phosphatase levels is a simple method for monitoring the activity of Paget's disease. Some treatments may result in a high degree of normalization of both skeletal abnormalities and bone scan findings in these patients. With the availability of more potent bisphosphonates, the prognosis has greatly improved (Table 255-2). A single intravenous dose of 5 mg of zoledronic acid can provide a 96% response rate for the next 6 months and is more effective than 2 months of oral risedronate.■

Patients treated with bisphosphonates can usually attain remission. Symptomatic bisphosphonate treatment for pagetic bone pain unresponsive to analgesics or anti-inflammatory drugs is as good as repeat courses of bisphosphonates, irrespective of symptoms, in reducing and maintaining normal alkaline.■ However, after variable periods of time, patients suffer relapse and require further treatment. Bisphosphonates by themselves have not been shown to "cure" Paget's disease. However, treatment with zoledronate can result in very long remissions.

TABLE 255-2 BISPHOSPHONATES USED IN THE TREATMENT OF PAGET'S DISEASE

AGENT	ROUTE	DOSE (mg/day)	DURATION OF EFFECT
Alendronate	Oral	40	6 mo
Clodronate*	Oral Intravenous	1600 300	3-6 mo 5 days
Etidronate	Oral	400	6 mo
Pamidronate	Intravenous	30-60†	3 days
Risedronate	Oral	30	2 mo
Tiludronate	Oral	400	3 mo
Zoledronate	Intravenous	5 mg as a single injection	>2 yr

*Has not been approved by the Food and Drug Administration at the time of publication.
†Lower dose has been approved; higher dose is used by investigators.

Surgical Therapy

Surgery is used to treat fractures, correct the deformity of bowed bones, and treat bone disease in the hip. In addition, surgical treatment may relieve the neurologic complications of the overgrowth of pagetic bone, with resultant nerve root compression. Before elective surgery, patients with Paget's disease are usually treated with bisphosphonates to decrease the vascularity and activity of the bone and to prevent increased bleeding.

PROGNOSIS

Pagetic bone pain responds to medical treatment. Much of the bone pain associated with the disease results from arthritis or joint pain arising from the bone deformity, rather than pain from the pagetic bone per se. Unless treated, pagetic lesions continue to increase in size, but patients rarely if ever develop new lesions in previously unaffected bones. In patients for whom analgesic or other specific treatments are unsuccessful, joint replacement can be performed. The most dreaded complication in Paget's disease is the development of osteosarcoma in the pagetic lesion. Although it is an extremely rare complication, affecting less than 1% of patients, Paget's disease is the most common cause of osteosarcoma in adults. Once patients develop osteosarcoma, their prognosis is extremely poor, and the outcome is usually fatal. Active treatment of Paget's disease decreases the biochemical abnormalities, with near normalization of alkaline phosphatase activity, and improves the neurologic syndromes associated with this disease.

OSTEONECROSIS, OSTEOSCLEROSIS/HYPEROSTOSIS, AND OTHER DISORDERS OF BONE

MICHAEL P. WHYTE

OSTEONECROSIS

DEFINITION

Osteonecrosis (aseptic, avascular, or ischemic necrosis of bone) refers to skeletal infarction. Bone infarcts may be asymptomatic, cause self-limited discomfort, or engender painful collapse of subarticular bone that leads to joint destruction.

PATHOBIOLOGY AND PATHOGENESIS

Many conditions are associated with osteonecrosis (Table 256-1). In adults, the most common causes are ethanol abuse and long-term glucocorticoid therapy, both of which have dose-dependent effects.

Skeletal infarction may result from blood vessel destruction (e.g., joint dislocation, fracture), obstruction (e.g., thromboemboli, sickle cell disease, fat emboli, caisson disease), or, hypothetically, compression from local expansion of fatty tissue (e.g., ethanol abuse, glucocorticoid treatment, diabetes mellitus). However, symptoms may not occur unless, weeks later, resorption of dead bone during skeletal repair leads to pathologic fracture. Certain skeletal sites (often subarticular) are predisposed to osteonecrosis, but the sites differ for traumatic and nontraumatic processes and for children and adults. *Osteochondrosis* refers to necrosis of ossification centers; more than 50 eponymic types have been recorded. The susceptibility of children to osteochondrosis and its pathogenesis are poorly understood. At all ages, however, the femoral head is especially prone to infarction. Nontraumatic osteonecrosis commonly affects the femoral condyles, distal end of the tibia, humeral head, and talus.

CLINICAL MANIFESTATIONS

Pain occurs acutely on skeletal collapse. Chronic arthralgia results from desquamated necrotic tissue and articular destruction. Although the pathogenesis is uncertain, intravenous administration of amino-bisphosphonates, especially to patients with malignancy, has been associated with osteonecrosis of the jaw (Fig. 256-1).

TABLE 256-1 CAUSES OF ISCHEMIC NECROSIS OF CARTILAGE AND BONE

Endocrine/metabolic
Ethanol abuse
Glucocorticoid therapy
Cushing's disease
Diabetes mellitus
Hyperuricemia
Osteomalacia
Hyperlipidemia
Bisphosphonate therapy (osteonecrosis of the jaw)
Storage diseases (e.g., Gaucher's disease)
Hemoglobinopathies (e.g., sickle cell disease)
Trauma (e.g., dislocation, fracture)
Human immunodeficiency virus (HIV) infection
Dysbaric conditions (e.g., caisson disease)
Collagen vascular disorders
Irradiation
Pancreatitis
Organ transplantation
Hemodialysis
Burns
Intravascular coagulation
Idiopathic, familial
Pregnancy

FIGURE 256-1. Exposed dead bone characterizes osteonecrosis of the jaw.

DIAGNOSIS

Magnetic resonance imaging (MRI) that demonstrates bone marrow edema is especially sensitive for detecting early osteonecrosis. Bone scintigraphy discloses skeletal reconstitution with or without fracture. Relatively late in the pathologic process, radiographs first show patchy areas of osteopenia and osteosclerosis that reflect skeletal repair. A linear subchondral radiolucency (crescent sign) indicates bony collapse.

TREATMENT

Rx

Non–weight bearing is advisable for the affected limb. Decompression by trephine insertion is used at some sites. Arthrotomy to remove debris, transpositional osteotomy, arthroplasty, or joint replacement may be necessary.

OSTEOSCLEROSIS/HYPEROSTOSIS

Many conditions are associated with radiographic evidence of increased bone density. Skeletal dysplasias, metabolic disturbances, and various other disorders can cause generalized or focal increases in bone mass (Table 256-2). Aberrations in skeletal growth, modeling (shaping), and/or remodeling (turnover) may be at fault. *Osteosclerosis* refers to thickening of trabecular (spongy, cancellous) bone. *Hyperostosis* describes widening of cortical (compact) bone. Increases in trabecular bone, cortical bone, or both may augment skeletal density.

Osteosclerosis

Neoplastic, hematologic, and metabolic disorders may preferentially cause sclerosis in trabecular bone because it houses marrow and remodels more rapidly than cortical bone.

FIBROGENESIS IMPERFECTA OSSIUM

DEFINITION

This rare, sporadic condition features generalized osteopenia, but coarsening of the remaining trabeculae places it among disorders of increased bone mass.

PATHOBIOLOGY

The cause is unknown. Subperiosteal bone formation and collagen synthesis in nonosseous tissues seem to be normal.

CLINICAL MANIFESTATIONS

Typically, intractable skeletal pain begins gradually during middle age or later and then rapidly increases, with a debilitating course and eventual immobility. Spontaneous fractures are a prominent complication. Physical examination reveals marked bone tenderness.

TABLE 256-2 DISORDERS THAT CAUSE DENSE BONES

DYSPLASIAS
Central osteosclerosis with ectodermal dysplasia
Craniodiaphyseal dysplasia
Craniometaphyseal dysplasia
Dysosteosclerosis
Endosteal hyperostosis
Van Buchem's disease
Sclerosteosis
Worth type (LRP5 activation)
Frontometaphyseal dysplasia
Infantile cortical hyperostosis (Caffey's disease)
Juvenile Paget's disease
Lenz-Majewski syndrome
Melorheostosis
Metaphyseal dysplasia (Pyle's disease)
Mixed sclerosing bone dystrophy
Oculodento-osseous dysplasia
Osteodysplasia of Melnick and Needles
Osteopathia striata
Osteopetrosis (several types)
Osteopoikilosis
Progressive diaphyseal dysplasia (Engelmann's disease)
Pyknodysostosis
METABOLIC CONDITIONS
Carbonic anhydrase II deficiency
Fluorosis
Heavy metal poisoning
Hepatitis C–associated osteosclerosis
Hyperparathyroidism, hypoparathyroidism, pseudohypoparathyroidism
Hypervitaminosis A, D
Hypophosphatemic rickets or osteomalacia
Milk-alkali syndrome
Renal osteodystrophy
OTHER DISORDERS
Axial osteomalacia
Fibrogenesis imperfecta ossium
High bone mass (with or without torus palatinus): LRP5 activation
Ionizing radiation
Lymphoma
Mastocytosis
Multiple myeloma
Myelofibrosis
Osteomyelitis
Osteonecrosis
Paget's bone disease
Sarcoidosis
Skeletal metastases
Tuberous sclerosis

From Whyte MP. Skeletal disorders characterized by osteosclerosis or hyperostosis. In: Avioli LV, Krane SM, eds. *Metabolic Bone Disease*, 3rd ed. San Diego: Academic Press; 1998.

DIAGNOSIS

On radiography, only the skull is spared. Initially, osteopenia and a slightly abnormal appearance of trabecular bone are noted. Subsequently, the changes suggest osteomalacia. Corticomedullary junctions become indistinct as compact bone is replaced by an abnormal cancellous pattern. Generalized osteopenia causes the remaining spongy bone to appear coarse and dense, in a fishnet pattern of mixed lytic and sclerotic areas. Alkaline phosphatase activity in serum is increased.

The skeletal lesion is a localized form of osteomalacia that varies considerably in severity from area to area.

Hyperostosis

PROGRESSIVE DIAPHYSEAL DYSPLASIA (CAMURATI-ENGELMANN DISEASE)

PATHOBIOLOGY

Progressive diaphyseal dysplasia (Camurati-Engelmann disease) affects all races and is inherited as an autosomal dominant trait with variable penetrance. New bone formation gradually envelops both the periosteal and endosteal surfaces of long bone diaphyses. In patients with severe disease, osteosclerosis also occurs in the axial skeleton.

Mutations alter the gene that encodes transforming growth factor-β1. Osteoblast differentiation may be deranged.

CLINICAL MANIFESTATIONS

During childhood, limping or a broad-based, waddling gait is noted. Muscular dystrophy can be diagnosed erroneously. Severely affected individuals may have a characteristic body habitus featuring an enlarged head with a prominent forehead, proptosis, and thin limbs with little subcutaneous fat or muscle mass and tender, thickened bones. Cranial nerve palsies and raised intracranial pressure can occur. Some patients have hepatosplenomegaly and Raynaud's phenomenon. Symptoms may remit after puberty.

DIAGNOSIS

Irregular hyperostosis of the diaphyses of the major long bones slowly develops as a result of periosteal and endosteal new bone formation. The femur and tibia are most commonly affected. Metaphyses may be involved. The age of onset, rate of progression, and severity are variable. Clinical, radiographic, and bone scan findings are generally concordant. Serum alkaline phosphatase activity, urinary hydroxyproline levels, and erythrocyte sedimentation rate may be elevated. Histopathologic study reveals newly formed woven bone that matures and becomes incorporated into cortical bone. Electron microscopy of muscle may show myopathic changes and vascular abnormalities.

TREATMENT Rx

Glucocorticoid therapy (typically a low dose of prednisone on alternate days) can relieve bone pain and may normalize skeletal histology. Bisphosphonates are sometimes useful.

ENDOSTEAL HYPEROSTOSIS

PATHOBIOLOGY

Sclerosteosis and van Buchem's disease, autosomal recessive disorders, are the principal types of endosteal hyperostosis. Sclerosteosis and van Buchem's disease both map to chromosome 17q12-q21. Sclerosteosis is caused by deactivating mutations in a gene called *SOST*. Van Buchem's disease involves a downstream deletion. Enhanced osteoblast activity with failure of osteoclasts to compensate for the increased bone formation seems to explain the skeletal changes.

CLINICAL MANIFESTATIONS

Sclerosteosis (cortical hyperostosis with syndactyly) occurs primarily in patients of Dutch ancestry. The gender distribution appears to be equal. Patients are tall and heavy beginning in childhood; have a prominent, square mandible; and are deaf and experience facial nerve palsy from cranial nerve entrapment. Raised intracranial pressure and headache may reflect a small cranial cavity that can shorten life expectancy. Van Buchem's disease causes progressive asymmetrical enlargement of the jaw during puberty. Patients may be symptom free, or, beginning as early as infancy, they may have recurrent facial nerve palsy, deafness, and optic atrophy from the narrowing of cranial foramina. Long bones may hurt with applied pressure but are not fragile.

DIAGNOSIS

In sclerosteosis, the skeleton is radiographically normal in early childhood except for syndactyly, which is common and most often involves the index and third fingers. Progressive bony thickening widens the skull and causes prognathism. Long bones have thickened cortices. The pelvis, vertebral pedicles, ribs, and tubular bones may become dense. Computed tomography has shown fusion of ossicles and narrowing of the internal auditory canals and cochlear aqueducts. Endosteal thickening homogeneously widens diaphyseal cortices and narrows medullary canals. Osteosclerosis involves the skull base, facial bones, vertebrae, pelvis, and ribs. Serum alkaline phosphatase activity can be increased from enhanced skeletal formation.

TREATMENT Rx

Surgical decompression of narrowed foramina may alleviate cranial nerve palsies.

PACHYDERMOPERIOSTOSIS

PATHOBIOLOGY

Pachydermoperiostosis (hypertrophic osteoarthropathy, primary or idiopathic) is an autosomal dominant disorder that features clubbing of the digits, hyperhidrosis with thickening of the skin (especially of the face), and periosteal new bone formation, most prominently in the distal ends of the limbs. Autosomal recessive inheritance also seems to occur. Not all patients manifest all three principal features. A loss-of-function mutation is found in the gene that encodes 15-hydroxyprostaglandin dehydrogenase.

CLINICAL MANIFESTATIONS

Men seem to be more severely affected than women, and blacks more commonly than whites. Symptoms typically begin during adolescence, intensify during the next decade, but then become quiescent. Arthralgia and fatigue are common. Stiffness and limited mobility occur in both the appendicular and the axial skeleton. Clubbing, with slowly progressive enlargement of the hands and feet, results in a pawlike appearance. Cutaneous changes include thickening, furrowing, pitting, and oiliness, especially of the scalp and face.

DIAGNOSIS

Periostitis thickens the distal portions of the tibia, fibula, radius, and ulna. Clubbing is obvious, and acro-osteolysis can occur. Periosteal proliferation is exuberant, with an irregular texture, and it often involves the epiphyses, whereas secondary hypertrophic osteoarthropathy (pulmonary or otherwise) typically causes a smooth and undulating periosteal reaction. Ankylosis of the joints, especially in the hands and feet, may trouble older patients. Bone scanning reveals symmetrical, diffuse, regular uptake along the cortical margins of long bones, especially in the legs—the "double-stripe" sign.

TREATMENT Rx

Patients with painful synovial effusions may respond to nonsteroidal anti-inflammatory drugs. Contractures or neurovascular compression by osteosclerotic lesions may require surgical intervention.

OSTEOSCLEROSIS WITH HYPEROSTOSIS

Osteopetrosis

DEFINITION

Osteopetrosis (marble bone disease) is a group of rare disorders characterized by an increase in bone mass due to dysfunction in or lack of osteoclasts. There are two major clinical forms: the autosomal recessive or "malignant" type, which results in death during early childhood if untreated; and the autosomal dominant or "benign" type, which causes fewer problems. Other autosomal recessive types feature intermediate severity, neuronal storage disease, stillbirth, or renal tubular acidosis with cerebral calcification secondary to carbonic anhydrase II isoenzyme deficiency. Bisphosphonate-induced osteopetrosis has been reported.

PATHOGENESIS

The defective gene causing autosomal dominant osteopetrosis encodes a chloride channel important for osteoclast activity. Abnormalities in this gene or one that encodes a subunit of a vacuolar proton pump can also result in malignant disease. Carbonic anhydrase II deficiency is caused by deactivating mutations in the gene that encodes this isoenzyme. Rare autosomal recessive cases involve loss-of-function mutations within the genes that encode either receptor activator of nuclear factor kappa-B (RANK) or its ligand (RANKL).

Histopathologic studies show that all true forms of osteopetrosis feature profound deficiency of osteoclast action. Primary spongiosa (calcified cartilage deposited during endochondral bone formation) persists away from growth plates and constitutes the pathognomonic finding. Defective endosteal bone resorption impairs the formation of marrow space. Quiescent skeletal remodeling leads to bone fragility from the diminished interconnection of osteons and the delayed conversion of immature (woven) bone to mature (compact) bone. Neuronal storage disease (ceroid-lipofuscin) could reflect a lysosomal defect. Deficient superoxide production (necessary for bone resorption) may also be a pathogenetic factor.

FIGURE 256-2. Osteopetrosis. Anteroposterior radiograph of the distal end of the femur shows a widened metadiaphyseal region, with characteristic alternating dense and lucent bands. (From Whyte MP, Murphy WA. Osteopetrosis and other sclerosing bone disorders. In: Avioli LV, Krane SM, eds. *Metabolic Bone Disease*, 2nd ed. Philadelphia: WB Saunders; 1990.)

CLINICAL MANIFESTATIONS

Malignant osteopetrosis can manifest during infancy as nasal "stuffiness" from underdeveloped mastoid and paranasal sinuses. Small cranial foramina may cause optic, oculomotor, or facial nerve palsy. Failure to thrive, delayed dentition, and fractures are common. Hypersplenism and recurrent infection, bruising, and bleeding reflect myelophthisis. Short stature, large head, frontal bossing, nystagmus, hepatosplenomegaly, and genu valgum are characteristic physical features. Untreated children usually die during the first decade of life of hemorrhage, pneumonia, severe anemia, or sepsis. Benign osteopetrosis occasionally causes fracture, facial palsy, deafness, mandibular osteomyelitis, bone marrow failure, impaired vision, psychomotor delay, carpal tunnel syndrome, or osteoarthritis. Carbonic anhydrase II deficiency can result in failure to thrive, fracture, developmental delay, mental subnormality, and short stature. Cerebral calcification develops during childhood, but defective skeletal modeling and osteosclerosis may correct spontaneously. Both proximal and distal renal tubular acidosis have been described.

DIAGNOSIS

A generalized increase in bone density is the radiographic hallmark. In severe disease, modeling defects in long bones produce an "Erlenmeyer flask" deformity (Fig. 256-2). Alternating dense and lucent bands commonly occur in the metaphyses and pelvis. The cranium is usually thickened and dense, especially at the base, and the paranasal and mastoid sinuses are underpneumatized. Vertebrae may show, on a lateral view, a "bone-in-bone" (endobone) configuration or end plate sclerosis causing a "rugger jersey" appearance. Skeletal scintigraphy can disclose fractures and osteomyelitis. MRI helps monitor the response to bone marrow transplantation.

Serum levels of acid phosphatase and creatine kinase (brain isoenzyme) are often increased. In malignant osteopetrosis, hypocalcemia with secondary hyperparathyroidism and elevated serum concentrations of calcitriol can accompany radiographic changes that resemble rickets. In benign osteopetrosis, biochemical indices of mineral homeostasis are typically unremarkable, although serum parathyroid hormone levels may be elevated.

TREATMENT Rx

Because the origin, pathogenesis, and prognosis of the osteopetroses differ, correct classification is crucial. It may be necessary to evaluate disease progression and to study the family. For the malignant form, human leukocyte antigen (HLA)–identical bone marrow transplantation to supply functional osteoclasts has remarkably benefited some children. Calcium-deficient diets have been tried, but their use may be limited by hypocalcemia and rickets. Massive oral doses of calcitriol (1,25-dihydroxyvitamin D_3), together with dietary calcium restriction (to prevent hypercalciuria and hypercalcemia) or human interferon-γ, which enhances superoxide production, have successfully stimulated osteoclast activity. Prednisone alone or with a low-calcium, high-phosphate diet may also be effective. Glucocorticoid therapy stabilizes pancytopenia and hepatosplenomegaly. Hyperbaric oxygenation helps in the treatment of osteomyelitis. Surgical decompression of optic and facial nerves can be beneficial. Mutation analysis is recommended for nearly all patients.

Pyknodysostosis

EPIDEMIOLOGY

Pyknodysostosis is believed to have affected French impressionist painter Henri de Toulouse-Lautrec (1864–1901). Most descriptions have come from Europe and the United States, but the disorder seems to be especially common in Japan.

PATHOBIOLOGY

This autosomal recessive condition is caused by defects in *CTSK*, the gene that encodes cathepsin K. Diminished rates of collagen degradation and skeletal turnover are reported. In chondrocytes and osteoblasts, abnormal inclusions have been described.

CLINICAL MANIFESTATIONS

Characteristic features seen during infancy or early childhood are disproportionate short stature, relatively large cranium, fronto-occipital prominence, proptosis, bluish sclerae, beaked and pointed nose, small facies and chin, obtuse mandibular angle, high-arched palate, and dental malocclusion with retention of primary teeth. Cranial sutures remain open. Fingers are short and clubbed from acro-osteolysis or aplasia of the terminal phalanges, and the hands are small and square. Repeated fractures cause knock-knee deformity. Mental retardation is noted in approximately 10% of patients. Adult height ranges from 4 feet 3 inches to 4 feet 11 inches. Life expectancy can be shortened by recurrent respiratory infections and right-sided heart failure from chronic upper airway obstruction secondary to micrognathia.

DIAGNOSIS

Osteosclerosis is uniform, first becoming apparent in childhood and increasing with age. Skeletal modeling defects do not occur, although long bones appear to have thick cortices because of narrow medullary canals. Clavicles are gracile and hypoplastic at their lateral segments. The calvaria and base of the skull are sclerotic, orbital ridges are dense, and wormian bones are present.

TREATMENT Rx

No effective medical therapy has been documented. Fractures of the long bones usually mend satisfactorily. Internal fixation of long bones is formidable because of their hardness. Tooth extraction is difficult. Osteomyelitis of the mandible may require antibiotic, surgical, and/or hyperbaric therapy.

Hepatitis C–Associated Osteosclerosis

Rarely, achy and tender limbs develop in individuals who are infected with hepatitis C virus. Radiographic studies reveal a marked generalized increase in bone mass from osteosclerosis and hyperostosis. Disturbances in the insulin-like growth factor system may explain the enhanced bone formation. Calcitonin or bisphosphonate therapy has benefited some patients.

FOCAL OSTEOSCLEROSIS/HYPEROSTOSIS

Osteopoikilosis

Osteopoikilosis ("spotted bones") is a radiologic curiosity inherited as a highly penetrant autosomal dominant trait resulting from a deactivating mutation of the *LEMD3* gene. The bony lesions are asymptomatic. However, incorrect diagnosis may lead to confusion with serious conditions, including metastatic disease. Some patients have connective tissue nevi called *dermatofibrosis lenticularis disseminata* (or Buschke-Ollendorff syndrome). Radiologically, numerous small, round or oval foci of bony sclerosis appear in cancellous bone in the tarsal, carpal, pelvic, and metaepiphyseal regions of tubular bones.

Osteopathia Striata

This autosomal dominant curiosity features linear striations in the metaphyseal regions of long bones and in the ilium. Clinically important syndromes

include osteopathia striata with cranial sclerosis or with focal dermal hypoplasia (Goltz's syndrome). Goltz's syndrome is an X-linked dominant disorder featuring widespread linear areas of dermal hypoplasia and various bony defects in the limbs of female patients due to mutation in the *PORCN* gene.

Melorheostosis

DEFINITION

Melorheostosis causes bony changes likened to wax that has dripped down a candle. No mendelian basis for this disorder has been established. The anatomic distribution suggests a segmentary embryogenic defect.

CLINICAL MANIFESTATIONS

Usually, monomelic involvement is noted; bilateral disease is generally asymmetrical. Cutaneous changes over affected bones are common (e.g., linear scleroderma-like areas and hypertrichosis). Soft tissue abnormalities often appear before the hyperostosis. Symptoms typically begin during childhood, with pain and stiffness as the major complaints. Joints may become contracted and deformed. Leg length inequality results from soft tissue contractures and premature fusion of epiphyses. Skeletal changes seem to progress most rapidly throughout childhood. During adult life, melorheostosis may or may not gradually spread, but pain is especially common.

DIAGNOSIS

As seen radiographically, irregular, very dense, eccentric periosteal and endosteal hyperostosis affects a single bone or several adjacent bones. The lower limbs are most commonly involved. Endosteal thickening predominates during infancy and childhood, and periosteal new bone formation is prominent during adulthood. Ectopic bone formation may occur, particularly near joints.

TREATMENT Rx

Surgical correction of contractures is difficult. Recurrent deformity is common.

Mixed Sclerosing Bone Dystrophy

This typically sporadic disorder features combinations of osteopoikilosis, osteopathia striata, melorheostosis, cranial sclerosis, and other skeletal defects in one individual. Problems are associated with the individual patterns of osteosclerosis or hyperostosis, such as nerve palsy with cranial sclerosis and bone pain with melorheostosis.

OTHER DISORDERS OF BONE

Fibrous Dysplasia

This sporadic developmental disorder features an expansile fibrous lesion within bone. Polyostotic disease (with multiple bone lesions) is typically seen before age 10 years; monostotic disease (with solitary bone lesions) begins in adolescence or early adulthood. *McCune-Albright syndrome* refers to a condition characterized by polyostotic fibrous dysplasia, cafe au lait spots (Fig. 256-3), and endocrine hyperfunction.

PATHOBIOLOGY

Postzygotic mosaicism for an activating mutation in the gene that encodes the α subunit of the receptor subunit/adenylate cyclase–coupling G protein, *GNAS*, causes fibrous dysplasia and McCune-Albright syndrome. Imperfect bone forms because mesenchymal cells do not fully differentiate to osteoblasts.

CLINICAL MANIFESTATIONS

Monostotic fibrous dysplasia is more common than polyostotic disease. The skull and long bones are affected most often. The skeletal lesions can deform bones, cause fractures, and occasionally entrap nerves. Sarcomatous degeneration is rare (<1%), but it typically occurs within the facial bones or femur and is more frequent with polyostotic disease. Pregnancy may reactivate previously quiescent lesions. McCune-Albright syndrome usually causes pseudo–precocious puberty in girls. Less commonly, one sees pseudo–precocious puberty in boys or thyrotoxicosis, Cushing's disease, acromegaly,

FIGURE 256-3. McCune-Albright syndrome. Typical rough-border ("coast of Maine"), pigmented cafe au lait spots. (From Whyte MP. Metabolic and dysplastic disorders. In: Coe FL, Favus MJ, eds. *Disorders of Bone and Mineral Metabolism*. New York: Raven Press; 1992.)

FIGURE 256-4. Fibrous dysplasia. A characteristic expansile lesion with a ground-glass appearance has caused thinning of the cortex in the mid-diaphysis of the fibula. (From Whyte MP. Fibrous dysplasia. In: Favus MJ, ed. *Primer on the Metabolic Bone Diseases and Disorders of Mineral Metabolism,* 3rd ed. Philadelphia: Lippincott-Raven; 1996.)

hyperprolactinemia, or hyperparathyroidism. In some patients, acquired renal phosphate wasting causes hypophosphatemic rickets or osteomalacia.

DIAGNOSIS

As seen radiographically, lesions are found in either the metaphysis or diaphysis of long bones. They are typically well defined, with thin cortices, and have a ground-glass appearance (Fig. 256-4). Occasionally, the defects are lobulated, with trabeculated areas of radiolucency.

TREATMENT Rx

In patients with mild disease, bone lesions may not expand. In severe cases, individual defects can progress, and new ones may appear. Spontaneous healing does not occur, but pathologic fractures generally mend well. Stress fractures, however, can be difficult to detect and treat. When the skull is involved, nerve compression may require surgical intervention. In McCune-Albright syndrome, pharmacologic control of pseudo–precocious puberty can be beneficial in girls. Intravenous infusions of the bisphosphonate pamidronate can help some patients.

Hereditary Multiple Exostoses

This relatively common, highly penetrant autosomal dominant disorder features irregular bony excrescences that protrude from expanded metaphyses. Osteocartilaginous exostoses arise from growth plates and increase in size until linear growth ceases. Lesions may or may not become detached from the parent bone. Their structure is relatively unremarkable, with an outer cortex and an inner spongiosa. Disability results primarily from limb length discrepancies when linear bone growth suffers at the expense of transverse expansion. Compression of nerves, the spinal cord, or the vascular system occurs occasionally. Sarcomatous degeneration (0.5 to 2% of patients) should be suspected when an exostosis enlarges rapidly, especially in an adult.

Enchondromatosis (Dyschondroplasia, Ollier's Disease)

This sporadic disorder features cartilaginous masses within the trabecular bone that arise from growth plates. The condition begins in childhood with localized swelling and interferes with linear bone growth. At puberty, expansion of cartilage masses ceases, and these masses can be replaced by mature bone. Enchondromas appear radiographically as lucent defects in flat bones or in metaphyses of tubular bones, often with central calcific stippling. When enchondromatosis occurs with multiple hemangiomas (Maffucci's syndrome), the enchondromas or hemangiomas undergo malignant transformation in 15% of cases.

Achondroplasia

Chondrodystrophies are disorders of cartilage growth that result in disproportionate short stature. Achondroplasia is the most common. A defect occurs in the gene that encodes fibroblast growth factor receptor type 3; 80% of cases are the result of new autosomal dominant mutations, which increase in frequency with increasing paternal age. Short tubular bones form because of abnormal endochondral ossification in the limbs. In the chondrocranium, membranous ossification is undisturbed; hence the skull vault is normal. However, the cranial base and foramen magnum are small. Lumbar lordosis is greatly exaggerated, and the spinal canal narrows from the upper to lower segments of the vertebral column. This disturbance is revealed radiographically by a decreasing interpediculate distance. The head is large, with frontal bossing and midface hypoplasia. The trunk length is relatively normal, but the limbs show rhizomelic shortening, and the hands have a trident configuration. The long bones appear massive owing to their disproportionately normal width. Growth plates are not grossly disorganized, and chondrocytes appear normal. Complications can include hydrocephalus or compression of the brain stem, spinal cord, or nerve roots. Minimal impingement by a disc or osteophyte on the small spinal canal can cause neurologic disturbances. Despite these problems, achondroplasia is compatible with good health and a normal lifespan.

257 APPROACH TO THE PATIENT WITH ALLERGIC OR IMMUNOLOGIC DISEASE

STEPHEN I. WASSERMAN

Allergic diseases and disorders of the immune system affect multiple organ systems and may arise in a variety of manners. The reader is directed to Section VII for a detailed discussion of the immune system and specific autoimmune and acquired immune disorders. This chapter addresses allergic disorders, the most common manifestation of immune system dysfunction, and primary immune deficiencies, which are uncommon manifestations of immune dysfunction. For clarity, these two issues are treated separately.

ALLERGIC DISEASE

DEFINITION

Allergic disorders are common, and their prevalence is increasing, particularly in urbanized, Western societies. It is said that allergic diseases are the most common disorders seen by primary care physicians. Moreover, even in nonallergic patients, consideration of allergy frequently enters the differential diagnosis of a problem under consideration. Therefore, an appreciation of how to approach the diagnosis and treatment of allergic patients is of major importance to the practice of internal medicine. Allergic disorders are those caused by the interaction of a sensitized host (one who has made immunoglobulin E [IgE] antibody recognizing a specific antigen) with a specific allergen. Not all patients possessing specific IgE antibody react adversely on interaction with the allergen, and such individuals are termed *sensitized* but not *allergic*. The primary allergic conditions are seasonal allergic rhinoconjunctivitis (hay fever), perennial allergic rhinitis or sinusitis, asthma, anaphylaxis (especially secondary to foods, medications, and hymenopteran stings), urticaria or angioedema, atopic dermatitis (eczema), and food allergy.

EPIDEMIOLOGY

It is currently estimated that more than 50% of the population is atopic (i.e., able to mount an IgE immune response and to exhibit an immediate positive prick-puncture hypersensitivity response to common aeroallergens). Clinically, 10 to 20% of the general population will develop allergic rhinoconjunctivitis, 5 to 7% will have active asthma, and 20% will experience urticaria at some time.

The increase in allergic diseases noted in the past 2 decades is thought to result from better hygienic conditions, decreases in infant and childhood infections, and an increasingly sedentary and indoor lifestyle. These changes appear to be associated with a less effective activation of the innate immune system, thereby altering the protective maturation of the acquired immune system. The immune bias in utero and in infancy is toward a type 2 helper T-lymphocyte (T_H2)–directed immune response, which is the immune pathway required for the expression of allergic disease. Ineffective generation of regulatory T lymphocytes underlies the genesis and persistence of allergy. It is therefore postulated that without sufficient early childhood infection to induce a switch to an effective and protective T_H1 immune response, allergic disease is more likely to emerge during childhood. Substantial epidemiologic evidence has been gathered to support this concept, now termed the *hygiene hypothesis*. Thus, allergy is more prevalent in individuals of higher socioeconomic status, among those living in urban areas, in less polluted communities (e.g., western Germany), in first-born children compared with later siblings, in multiply immunized individuals, and in those free of mycobacterial disease. Conversely, children living on farms, in rural communities, and in more highly polluted areas (e.g., eastern Germany), as well as children with mycobacterial infection and those who have experienced multiple early childhood infections, are less likely to develop allergic disorders. A concentration-effect relationship appears to exist between exposure to endotoxin (as a marker for hygiene) and the incidence of allergic sensitization. Low and very high levels of exposure to endotoxin are associated with abnormal immune maturation and allergic expression, whereas moderate levels of exposure predispose to a nonallergic phenotype.

PATHOBIOLOGY

The persistence or aberrant activation of T_H2 lymphocytes leads to the generation of cytokines (e.g., interleukins-4, -5, -13), which stimulate B-lymphocyte synthesis of IgE antibody and the production of eosinophilic polymorphonuclear leukocytes. The expression of allergic disorders results from the interaction of a specific allergen with allergen-reactive IgE bound to high-affinity receptors on mast cells and basophils. This interaction leads to activation of these target cells and to their release of preformed, granule-associated mediators (exemplified by histamine); the synthesis of lipid mediators from membrane lipids (sulfidopeptide leukotrienes); and the transcription and secretion of cytokines, including tumor necrosis factor-α and interleukins-4, -5, and -13. These mediators directly induce smooth muscle contraction, vascular dilation, and endothelial leakage; they also cause vascular adhesion molecule expression, and they attract and activate inflammatory leukocytes, particularly $CD4^+$ T lymphocytes, basophils, and eosinophils. These and other IgE-dependent mediators are thought to be responsible for stimulating smooth muscle proliferation and tissue remodeling.

DIAGNOSIS

Allergy is a systemic immune disorder, so its expression can be multifocal. It is essential to remember this fact when examining a patient with suspected allergic problems because a focus on only the major presenting symptom may be insufficient to identify all the pertinent medical issues in a given patient.

History

Allergic disease has a high degree of heritability, with a great degree of concordance in identical twins. The risk of expressing allergic disease is highest if both parents are atopic. The inheritance of specific manifestations of allergy and of the specific allergen to which a patient is sensitized is less simple. Quite often, the diagnosis of allergic disorders is straightforward and can be made by asking about the nature of the patient's complaints, when and where reactions occur, and what exposures the patient believes are relevant to symptom induction or exacerbation (Table 257-1).

Seasonal and Perennial Rhinitis

Patients with seasonal and perennial rhinitis (Chapter 259) commonly present with complaints of itchy nose and palate; sneezing; watery rhinorrhea; itching, watery, and burning eyes; and nasal obstruction, which, when severe, may cause anosmia. In the evaluation of possible causes of seasonal rhinoconjunctivitis or sinusitis, the time of the year when symptoms occur is pertinent. Symptoms may be associated with the pollination of trees (early spring), grasses (late spring and summer), or weeds (fall). In some patients with perennial symptoms, the multiple overlapping pollen seasons are responsible for their symptoms. Indoor exposures at home, school, work, or

TABLE 257-1 SYMPTOMS, SIGNS, AND TREATMENT OF ALLERGIC DISEASE

SYMPTOMS AND SIGNS	APPROACH TO TREATMENT
SYMPTOMS	
Cutaneous: itch, rash Ocular: gritty sensation, itch Upper respiratory: palatal pruritus, clear rhinorrhea, sneeze, nasal obstruction Lower respiratory: wheeze, cough, dyspnea Gastrointestinal: nausea, vomiting, cramping pain	H_1-antihistamine Topical H_1-antihistamine or mast cell stabilizing agent Topical corticosteroid, oral H_1-antihistamine, leukotriene receptor antagonist, topical nasal H_1-antihistamine β_2-agonist, inhaled corticosteroid, inhaled β_2-agonist, leukotriene receptor antagonist, oral methylxanthine, parenteral corticosteroid, parenteral anti-IgE Epinephrine (if caused by anaphylaxis), oral corticosteroid, oral cromolyn
SIGNS	
Cutaneous: flushing, urticaria, angioedema, eczema Ocular: conjunctival erythema, chemosis Upper respiratory: pallor, edema, clear rhinorrhea, polyps Lower respiratory: wheeze	

recreational sites to furred animals, dust mites or insects, and mold should be addressed in the search for additional causes of perennial symptoms. Mold and mites are to be expected in humid environments, and mites are nearly ubiquitous in bedding and in homes with pets, carpeting, and overstuffed furnishings. Additional occupational or recreational exposures may be pertinent in selected situations (e.g., bakers, health care workers, food handlers, horse fanciers, laboratory animal handlers) in which specific inciting allergens may be identified. Because many patients with rhinitis have concomitant asthma, it is important to obtain information about the presence of this disease in patients with rhinitis.

Asthma

Patients with asthma (Chapter 87) may present with cough or wheeze with dyspnea, which is reversible spontaneously or with treatment. In addition to the association with rhinitis, the influence of exercise, exposure to tobacco smoke, effect of respiratory infection (particularly viral), occupational exposures (e.g., ≤30% of atopic animal handlers develop asthma), and medication use (e.g., β-adrenergic blocking drugs) are pertinent. Because most patients with asthma have concurrent rhinitis, it is essential that the physician evaluate this issue in all asthmatic patients. Wheezing may accompany other disorders, including pulmonary edema in congestive heart failure.

Urticaria and Angioedema

Patients with urticaria (Chapter 260) describe pruritic, erythematous cutaneous lesions with regular or irregular borders occurring anywhere on the body; they may vary in size from small (1 × 1 mm) to extremely large. Skin lesions are often preceded by intense intertriginous pruritus. Individual urticarial lesions generally persist for a few hours and rarely last for more than 24 hours. However, many disorders can cause a sensation of itching; skin and systemic diseases associated with pruritus are listed in Table 443-1 in Chapter 443. Angioedema (Chapter 260) is most frequently appreciated in the face, hands, and other soft tissues and is generally accompanied by symptoms of stretching, tingling, and tightness of the skin rather than pruritus. Lesions, especially in the face, typically last 24 to 36 hours. Although most cases of urticaria or angioedema are not IgE mediated, it is important to identify foods and medications used by patients with acute urticaria or angioedema, particularly those substances ingested within 2 to 4 hours of the development of lesions, and to inquire about insect stings. Chronic urticaria is less often IgE mediated; questions about medications, especially nonsteroidal antiinflammatory drugs, recent infection (especially with Epstein-Barr virus), and the presence of autoantibodies to the IgE receptor must be addressed. Approximately one half to two thirds of patients with such autoantibodies also have antibodies to thyroid antigens. In angioedema, the use of angiotensin-converting enzyme inhibitors must be sought. Atopic dermatitis is another allergic cutaneous disorder in which patients complain of intense pruritus, especially in flexural surfaces. In adults, foods (IgE mediated) and cutaneous infection with *Staphylococcus aureus* (superantigen mediated) are the most commonly identified precipitating events for atopic dermatitis.

Anaphylaxis

Anaphylaxis (Chapter 261) is the most important allergic emergency and is potentially fatal. It is an acute allergic response associated with cutaneous (urticaria, angioedema, flushing), respiratory (laryngeal edema, asthma), cardiovascular (arrhythmia, hypotension, extravascular fluid loss), gastrointestinal (nausea, vomiting, abdominal pain, diarrhea), and nonspecific symptoms (metallic taste, sense of impending doom) that may occur singly or together. Historical information of note includes all medications, foods, and other encounters occurring within 2 hours of the reaction. Epidemiologic data suggest that foods (especially peanuts, tree nuts, shellfish, milk, and eggs), hymenoptera stings, and medications (antibiotics, muscle relaxants, radiocontrast media) are the most frequently identified causes of this important problem.

Food Allergy

Patients presenting with food allergy often complain of oral pruritus and nausea, vomiting, diarrhea, and abdominal pain. Eczema, urticaria, and anaphylaxis, as noted previously, may also be consequences of food allergy. In general, allergic symptoms consequent to foods occur within minutes to 2 hours of ingestion of the causative food; delayed symptoms are unlikely to be mediated by an IgE-allergen interaction. Other symptoms attributable to foods are less easily explained by allergic mechanisms and are termed *food intolerance*.

Physical Examination

The physical examination of a patient with suspected allergic disease should emphasize the organ systems pertinent to the patient's complaints. The skin should be examined for the presence of urticarial or angioedematous lesions and for signs of atopic dermatitis, including flexural papules, excoriations, and lichenification. Keratosis pilaris, particularly on the outer aspect of the upper arm, commonly accompanies atopic dermatitis. Urticaria typically consists of small, pink, irregular lesions that blanch on pressure and then clear, leaving normal skin. In a patient with urticaria, a simple test for dermatographism should be undertaken. Angioedematous lesions are larger, more diffuse, and pale, and they are found most often on the face and in acral areas.

The eyes, ears, nose, and throat should be examined in all patients suspected of having allergic disease, particularly those whose symptoms suggest seasonal or perennial allergic rhinoconjunctivitis-sinusitis or asthma. In allergic disease, the conjunctivae are often injected and may be edematous. "Cobblestoning" of the epithelium may be present. The periorbital tissues may be swollen and darkened. Examination of the nares may show pale and edematous nasal mucous membranes and swollen turbinates, and polyps may be seen. Secretions, generally clear, may be seen in the nasal passages or in the posterior pharynx. Such secretions generally contain copious numbers of eosinophils (see later), and their absence is a point against an allergic cause. Fever and discolored secretions, particularly those that are thick and yellow or green, in the presence of neutrophilic polymorphonuclear leukocytes suggest infection. Percussion over the maxillary or frontal sinuses may elicit tenderness in acute sinusitis, and in this case, transillumination of the sinus (albeit a test of low sensitivity) may be impaired. In chronic sinusitis, the physical examination may be unrevealing. In acute otitis media, patients may have erythema and bulging or perforation of the tympanic membrane, with fluid in the canal; in chronic cases the drum may be scarred and retracted. Alteration in airborne conduction may be noted as well.

Patients with acute asthma may display tachypnea and auditory wheezes, and they may be unable to speak in full sentences because of shortness of breath. Use of accessory muscles of respiration and evidence of cyanosis should be sought. Examination of the chest includes inspection for evidence of chronic hyperinflation and auscultation for wheezing (which, if unilateral, may suggest a foreign body or tumor). In mild asthma, the examination may be normal, or the only physical finding may be wheezing on forced expiration and a slight prolongation of the expiratory phase.

Patients experiencing acute anaphylaxis usually demonstrate flushing, and concomitant urticaria and angioedema are often present. Assessment of vital signs may disclose hypotension and tachycardia. In some situations, hoarseness or stridor related to laryngeal edema or wheezing secondary to asthma can be identified. Hyperactive bowel sounds may be noted. Progressive hypoxia and cyanosis may ensue. In severe anaphylaxis, cardiovascular collapse secondary to hypoxia and hypotension may result in death.

Laboratory Evaluation

In the evaluation of patients with allergic disorders, the laboratory may be of assistance in both the identification and the quantification of specific organ dysfunction, as well as in the assessment of the presence and specificity of IgE antibody.

Assessment of Total and Allergen-Specific Immunoglobulin E

Essentially all (>95%) IgE antibody is bound to specific high-affinity receptors on tissue mast cells and circulating peripheral blood basophils. The small amount of free serum IgE antibody circulates in nanogram quantities and can be identified only with techniques of sufficient sensitivity. A large proportion of IgE in a given individual may be directed toward a single antigen, so total IgE levels may be normal in the presence of allergic disease. Therefore, the measurement of total serum IgE is rarely of help in making a diagnosis. In a few situations, such as adult atopic dermatitis or allergic bronchopulmonary aspergillosis, measurement of total serum IgE levels may provide insight into disease severity or risk of disease exacerbation.

Of more importance is the identification of allergen-specific IgE in a patient with suspected allergic disease (Table 257-2). Such specific IgE may be identified in vitro or in vivo. A search for allergen-specific IgE is particularly useful in the evaluation of patients with suspected allergic rhinitis, asthma, eczema, food reactions, and anaphylaxis. In vitro assessment is similar to the quantification of total IgE, except the initial capture reagent bound to a solid phase is a specific pollen, mold, insect, venom, food, or other allergen. Development of the assay is identical to that used to quantify total

TABLE 257-2 ADVANTAGES AND DISADVANTAGES OF DIFFERENT ALLERGY TESTING METHODS

METHOD	PATIENT SELECTION	CLINICAL ADVANTAGES	CLINICAL DISADVANTAGES
Skin testing	Clinical indication suggesting allergic disease	Rapid (15-30 min) turnaround Sensitive and specific; prick-puncture for aeroallergens, prick-puncture followed by intradermal testing for drugs, sera, and venoms	Patient must not be taking H_1-antihistamine agents for 5-7 days Not interpretable in the presence of dermatographism Requires sufficient normal skin to enable testing
In vitro testing	Clinical indication suggesting allergic disease	Antihistamine therapy not contraindicated Dermatographism not a problem Sensitive and specific; equal to prick-puncture skin testing	Requires blood drawn Slow turnaround (7-14 days)

IgE, and results are generally reported in a semiquantitative manner. The magnitude of the reaction is weakly correlated with the degree of sensitization and expression of allergy, although for certain foods, more precise correlative data exist on the risk of allergy and the amount of allergen-specific IgE detected. To assess allergen-specific IgE in vivo, a minute quantity of the allergen in question is introduced into the skin by a prick-puncture technique, and the cutaneous response is assessed 15 to 30 minutes thereafter. A positive response is one in which a wheal and flare at least 2 mm larger than those caused by a saline control occur at the injection site. In vivo tests are rapid and inexpensive; their use requires the absence of dermatographism, that patients not be taking antihistamine medications, and that patients exhibit a positive response to a control using histamine. In some situations (e.g., penicillin allergy or hymenopteran sting), a more diluted allergen is injected intradermally, and wheal and flare responses are assessed similarly. The presence of allergen-specific IgE antibody and a clear temporal correlation between exposure to allergen and genesis of symptoms are required to conclude that a patient is allergic to a specific allergen. In the absence of symptoms, a patient with allergen-specific IgE is termed *sensitized* but not allergic.

Specific in vivo challenge tests can also be used to identify allergen responsiveness. Such tests in the presence of specific IgE antibody may be useful in research settings, or they may be used clinically to clarify the exact relationship between exposure and symptoms. Such tests can be dangerous, however, because they introduce the allergen to which the patient is presumed allergic. In the case of food allergy, such challenges are best done in a double-blind and placebo-controlled manner; they may be useful to distinguish allergy from sensitization or to eliminate a suspect food from consideration. However, food challenge tests are unnecessary in the case of anaphylaxis and a positive test for IgE antibody to the putative allergen. Because many patients falsely believe that foods are responsible for their symptoms, such double-blind challenges may be useful in directing patients' concerns to more productive areas. Inhalation tests employing specific allergens or chemicals have been helpful in elucidating some cases of occupational allergy or asthma.

Other Laboratory Aids in Allergic Disease

In a patient with acute asthma, chest radiographs generally demonstrate hyperinflation. In some instances, evidence of bronchiectasis may be present, a finding that raises the specter of allergic bronchopulmonary aspergillosis. The presence of a tumor or radiopaque foreign body may be noted on a chest radiograph and should be sought in a patient with unilateral localized wheezing. In the examination of a patient with asthma, assessment of both airflow and volumes can provide a clear picture of the severity of asthma and its response to treatment. Flow-volume loops can also identify the presence of vocal cord dysfunction. When patients with airway obstruction are evaluated, their response to an inhaled β_2-adrenergic agonist medication can be helpful in elucidating the reversible nature of their disorder. Essentially all asthmatic patients exhibiting bronchoconstriction display a bronchodilatory response to the inhalation of such agents. In suspected cases of asthma in which pulmonary function is normal, a histamine or methacholine challenge can be performed. These agents take advantage of the nonspecific bronchial hyperresponsiveness that is characteristic of patients with asthma. Failure to develop bronchoconstriction on inhalation of either of these agents strongly argues against the diagnosis of asthma.

Other laboratory tools may be of clinical benefit in the identification and classification of allergic disorders. Audiometry may clarify the degree of hearing loss caused by otitis media in a patient with allergic rhinitis. When sinusitis is suspected, computed tomography of the sinuses provides the most complete image and has the highest degree of sensitivity for the identification of mucosal thickening, opacification of air spaces, and presence of polyps and bone erosions. Computed tomography is particularly useful in the examination of the ethmoid and sphenoid sinuses, which are often affected in chronic allergic disease and are difficult to assess on physical examination or with plain radiographs.

The quantification of blood, sputum, nasal mucus, or tissue eosinophilia and the response to corticosteroid therapy are useful correlates in the identification and management of allergic disease. The quantification of tryptase, a mast cell–specific protease with a serum half-life of 2 hours, can assist in the diagnosis of anaphylaxis if performed on serum or plasma obtained within hours of a systemic response with associated hypotension.

IMMUNOLOGIC DISEASE

EPIDEMIOLOGY

Diseases related to disordered immune function (immunodeficiency) are far less common than allergic disorders. The most frequent is IgA deficiency, which occurs in approximately 1 in 1000 individuals and is often asymptomatic. Next most frequent are disorders of B and T lymphocytes, such as common variable hypogammaglobulinemia, and other disorders, including DiGeorge syndrome and severe combined immunodeficiency (Chapter 258). Much less common are defects in neutrophil function or complement.

DIAGNOSIS

The clinical expression of immunodeficiency disorders is primarily infection, related to impaired host defense. Thus, the diagnosis of suspected immunodeficiency involves the evaluation of recurrent, persistent, severe, and otherwise unexplained infections. Many, but not all, immune disorders arise in early childhood, and with improved management, many patients presenting in childhood live into adulthood. It is important for the general internist and internal medicine subspecialist to be cognizant of the presentation of these disorders.

History

The most important historical information includes the following: age at onset of the problem in question; family history of frequent infection or death at an early age from infection; number, site, and type of infections; and presence of other physical abnormalities (Table 257-3). The earlier the onset of infections, the more severe the immune defect is likely to be. T-lymphocytic defects, with or without B-cell deficiencies, usually arise in the first 3 to 5 months of life, whereas B-cell function is supported by maternal antibody until after 6 months of age. Many of the immune disorders are X-linked, and a careful family history is critical in such situations. Infection-related death of a patient's male sibling or the patient's mother should lead to the search for such an X-linked disorder.

In a patient with a T-cell disorder, viral, fungal, mycobacterial, and other opportunistic infections (*Pneumocystis jirovecii, Toxoplasma gondii*) are most commonly noted, and live virus vaccination may be associated with disseminated and progressive viral disease. Persistent thrush, diarrhea, malabsorption, and failure to thrive occurring in early childhood may suggest the presence of T-cell abnormalities.

In B-cell or antibody deficiency, pyogenic bacterial infections predominate, particularly infections involving encapsulated microorganisms. Usually such infections affect the upper and lower respiratory tract and the skin and are severe and persistent. Infections with unusual organisms, with unexpected complications, or involving multiple sites (lung, sinus, joint, bone, or

TABLE 257-3 KEY POINTS REGARDING IMMUNOLOGIC DISORDERS

ANTIBODY DEFICIENCY DISORDERS
Onset after 6 mo of age
Recurrent respiratory infection
Infection with bacteria, especially encapsulated organisms
Absence of isohemagglutinins
Evaluation of B-cell function, not numbers
CELLULAR IMMUNE DEFECTS
Onset before 6 mo of age
Recurrent viral, fungal, or parasitic (opportunistic) infection
Defective delayed hypersensitivity skin responses
Malabsorption or diarrhea
COMPLEMENT DEFICIENCIES
Recurrent bacterial infection
Recurrent neisserial infection (deficiency of late components)
Associated rheumatic disorder (especially systemic lupus erythematosus)
FACTORS SUGGESTING NEUTROPHIL DYSFUNCTION
Late separation of umbilical cord
Persistent neutrophilic leukocytosis
Recurrent or persistent gingivitis or periodontitis
Recurrent bacterial infection with granuloma formation

meninges, with abscess formation or sepsis) should raise the index of suspicion. In adults, the most common disorder in this class is termed *common variable immunodeficiency.*

As in any patient with infection, information should be sought about exposure to ill individuals or to irritants such as tobacco smoke, the hygiene of the environment to which the patient has been exposed, and the presence of an anatomic abnormality or allergy that could predispose to infection.

Physical Examination

Physical examination beyond that necessary to assess the extent and severity of a particular infection should focus on immune organs. Assessment of tonsillar tissue and determination of the presence and size of lymph nodes, spleen, and liver are important. Patients with common variable immunodeficiency often present with hepatosplenomegaly and lymph node hyperplasia, whereas in X-linked hypogammaglobulinemia, lymph tissue is absent. Telangiectasia (ataxia-telangiectasia), cardiac defects (DiGeorge syndrome), chronic eczema (Wiskott-Aldrich syndrome), and chronic periodontitis (neutrophil defects) all suggest immunodeficiency syndromes.

Laboratory Evaluation

The proper use of the laboratory is essential to elucidate a suspected immunodeficiency disorder. Screening tests appropriate to the generalist's initial approach include complete blood count, total neutrophil and lymphocyte enumeration, quantitative immunoglobulin levels, and assessment of isohemagglutinins (especially when common variable immunodeficiency is suspected). In some situations, quantification of IgG subclasses may be warranted to identify a specific subclass deficiency. When considering T-lymphocyte defects, it is important to enumerate total T cells and specific T-cell subsets. Delayed hypersensitivity skin testing to recall antigens is also helpful in assessing cellular immunity. When neutrophil defects are suspected, a nitroblue tetrazolium test or measurement of phagocytic potency can be performed. Complement defects are best addressed by obtaining a CH_{50} level. CH_{50} is the amount of patient serum required to cause lysis of 50% of test erythrocytes. It is compared with the amount of pooled normal serum required to cause the same degree of lysis. Tests for specific individual components of complement, or of complement regulatory proteins, can also be obtained under special circumstances.

Additional tests of antibody production in response to defined stimuli, including vaccinations, may be helpful when selective antibody deficiency is suspected or when borderline immunoglobulin levels are encountered in the presence of frequent infection. In some situations, assessment of T-cell proliferation to mitogens or antigen may be of benefit. Further testing might include the assessment of natural killer–cell function and the production of cytokines by activated lymphocytes. In general, such additional laboratory tests should be performed in consultation with an expert in immune disorders.

PRIMARY IMMUNODEFICIENCY DISEASES

MARK BALLOW

DEFINITION

Although immunodeficiency diseases are relatively uncommon, more than 165 primary immunodeficiency diseases have been described. Immunodeficiencies are generally divided into several categories: B-cell or antibody immunodeficiencies (55% of all immune deficiencies), T-cell or cellular immunodeficiencies (20%), immunodeficiencies associated with the phagocytic system (20%), immune defects of the innate immune system, and immune abnormalities associated with the complement system (5%). Although many primary immunodeficiencies are first noticed in infants and young children, the most frequent B-cell (humoral) immunodeficiencies become evident later in life, especially in young adults; the characteristic presentations of these diseases should be recognized by the physician so diagnosis and treatment can be initiated. The purpose of this chapter is not to present an encyclopedic list of all the known immunodeficiencies but to identify the most common presenting clinical characteristics, define the initial laboratory evaluation, and briefly discuss the approach to treatment.

PATHOBIOLOGY

Genetics

Many of these disorders are caused by mutations of genes required for the development of T cells or B cells or genes needed for the development of precursor cell lineages that differentiate into various types of immune cells. Other genetic abnormalities are widely expressed in many tissues, resulting in complex multisystem disorders along with the immunodeficiency. Some gene mutations that occur in the same immunologic pathway (e.g., cytokine receptor and signaling pathway) result in similar clinical phenotypes and laboratory findings. Conversely, depending on the nature and location of the mutation, defects in other genes may result in immune defects associated with compound heterozygous mutations with complex variable (hypomorphic) clinical phenotypes.

CLINICAL MANIFESTATIONS

This chapter presents the important details of the history and physical examination and the common clinical signs when evaluating a patient with recurrent infections. The association of particular sites of infection and specific pathogens with certain immunodeficiencies is also helpful in directing the physician toward a differential diagnosis and the appropriate screening laboratory tests.

Clues from the Infecting Pathogen and the Organ System Involved

The organ systems affected by infection and the identity of the isolated pathogens provide clues to the nature of the possible defect. A patient presenting with lymphadenitis or recurrent abscesses caused by low-virulence gram-negative organisms such as *Escherichia coli, Serratia,* or *Klebsiella* may have an abnormality in phagocyte function (Chapter 172). Infections with unusual pathogens such as *Staphylococcus epidermidis* or *Pseudomonas* species, especially *Burkholderia cepacia,* also suggest a phagocytic disorder. Another characteristic presentation of patients with a phagocyte defect is a history of recurrent skin infections with catalase-positive *Staphylococcus aureus,* a finding underscoring the importance of effective phagocytosis and intracellular superoxide-mediated killing in controlling these infections. A history of delayed separation of the umbilical cord exceeding 6 to 8 weeks or poor wound healing suggests the diagnosis of a leukocyte adhesion defect. Suppurative adenitis is common in patients with chronic granulomatous disease, and it can be an important clue in the diagnosis when gram-negative bacteria are recovered from the tissues. Gingivostomatitis and dental erosions are characteristic of patients with a phagocytic cell defect such as leukocyte adhesion deficiency (Chapter 172). Recurrent oral ulcers are characteristic of patients with cyclic neutropenia (Chapter 170). Defects in the late complement components C5 through C9 (Chapter 49) are associated with infections caused by *Neisseria* species, such as meningitis caused by *Neisseria meningitidis* or septic arthritis caused by *Neisseria gonorrhoeae.* Patients with C3 deficiency can present with overwhelming septicemia, especially with gram-negative organisms; this finding is consistent with the important role of complement, particularly C3b, in opsonization and the facilitation of phagocytosis.

B-cell abnormalities most commonly lead to recurrent sinopulmonary infections that are frequently caused by encapsulated bacteria such as *Streptococcus pneumoniae* or *Haemophilus influenzae.* Examination of the pharynx and nasal cavities for signs of sinusitis, including posterior pharyngeal cobblestoning, postnasal drainage, or purulent nasal discharge, is important. Tympanic membranes can appear scarred and disfigured as a result of recurrent or chronic infection of the middle ear. Rales on auscultation of the chest may suggest bronchiectasis as a complication of recurrent lung infections. Digital clubbing points to significant lung disease. A characteristic feature of patients with X-linked agammaglobulinemia (XLA) is an unusual susceptibility to a viral meningoencephalitis caused by enteroviruses (e.g., coxsackievirus, echovirus). Chronic gastrointestinal symptoms caused by *Giardia lamblia* are likely related to impaired mucosal immunity and lack of secretory immunoglobulin (Ig) A. Small bowel bacterial overgrowth and infections with *Yersinia* and *Campylobacter* can lead to chronic gastrointestinal symptoms; diarrhea and occasionally malabsorption may be presenting symptoms in patients with common variable immunodeficiency (CVID).

T cells are essential not only in controlling viral, fungal, mycobacterial, and protozoal infections but also in providing crucial signals to help B cells produce immunoglobulins. Extensive mucous membrane candidiasis suggests a T-cell defect. Patients with cellular immune defects often present with opportunistic infections such as *Mycobacterium avium-intracellulare* and *Pneumocystis jirovecii.*

Lymphatic System in Patients with Immunodeficiency

Assessing the lymphatic system for hepatosplenomegaly and for the presence or absence of lymphoid tissue is an important aspect of the physical examination in a patient suspected of immunodeficiency (Chapter 171). Patients with severe combined immunodeficiency disease (SCID) or infantile XLA do not have palpable lymphoid tissue or visible tonsils. However, the presence of lymphoid tissue can be misleading: adult patients with CVID or IgA deficiency may actually have enlarged lymphoid tissue and even hepatosplenomegaly. This occurs because the reticuloendothelial system undergoes hyperplasia in the absence of opsonic antibody.

Immunodeficiency and Autoimmunity

Deficiencies of the early complement components, such as C4 and C2, often present in adults as an associated autoimmune disease that manifests first with arthritis, frequently in conjunction with dermal vasculitis. A lupus-like rash with negative or low-titer antinuclear antibodies may occur in deficiencies of the early components of the classical complement pathway. Patients with some primary immunodeficiencies present with features of autoimmunity involving hematopoietic or other organ systems. For example, the diagnosis of CVID can be preceded by autoimmune hemolytic anemia (Chapter 163).

Immunodeficiency and Gastrointestinal Disease

Many patients with primary immunodeficiency disease have symptoms and clinical findings referable to the gastrointestinal tract. In a survey of 248 patients with CVID, 21% had significant gastrointestinal disease. Liver disease occurred in an additional 12%. Bacterial overgrowth of the small bowel, including infections with *Yersinia* and *Campylobacter,* parasitic infestations with such organisms as *G. lamblia,* and chronic viral enteritis caused by enteroviruses and cytomegalovirus are relatively common in patients with B- or T-cell immune defects. The incidence of lactose intolerance is high in patients with immunodeficiency. Similarly, patients with IgA deficiency often present with gastrointestinal manifestations.

Immunodeficiency and Family History

A detailed family history in patients with suspected immunodeficiency can add valuable information. Numerous immunodeficiencies are X-linked; therefore, a family history of maternal male relatives with unusually frequent infections or who died in early infancy should suggest the possibility of an X-linked form of immunodeficiency. The mother in these cases would be expected to be a carrier, although the rate of new mutations for X-linked disorders is significant; therefore, a negative family history may not exclude this inheritance pattern. CVID and IgA deficiency are familial disorders and often occur in a setting of other family members with autoimmune disorders.

DEFECTS IN THE INNATE IMMUNE SYSTEM: COMPLEMENT AND PHAGOCYTE DEFICIENCIES

Deficiencies of Complement Proteins

DEFINITION

The complement (C) system is important in host defense and is composed of a complex system of plasma proteins and cell surface receptors (Chapter 49). Important functions of the complement system include opsonization to enhance phagocytosis, clearance of immune complexes, induction of the humoral immune response, and clearance of apoptotic cells.

EPIDEMIOLOGY

Approximately 5% of patients with primary immunodeficiency diseases have complement deficiencies. Although rare, C2 deficiency is the most common of the early complement component diseases; it occurs in 1 in 10,000 whites. C6 deficiency is the most common of the late complement component disorders. The frequency of complement deficiency in sporadic cases of systemic meningococcal infection has been estimated at 15%. In patients with recurrent meningococcal disease, the prevalence is as high as 40%.

CLINICAL MANIFESTATIONS

These disorders are usually inherited as autosomal codominant traits: the parents of the patient have half-normal levels of the involved complement component, and the patient has a complete absence of the component in question. The complement deficiencies can be broadly divided into those of the early classical complement pathway (C1, C2, and C4), the components of the alternative complement pathway (factors B, D, and P), the mannose-binding proteins and their associated proteases (MASP-1 and MASP-2), and the late complement components (C5, C6, C7, C8, and C9). Persons deficient in C3 share characteristics of both early and late complement component deficiencies. Patients lacking one of the early complement components frequently present as adults with a rheumatologic disease. These patients may exhibit the typical features of systemic lupus erythematosus, except they often are seronegative; that is, anti-DNA antibodies are absent, and antinuclear antibodies are present in only low titers. Individuals with C2 deficiency may have either systemic lupus erythematosus or discoid lupus. Other rheumatologic disorders associated with early complement component deficiencies include dermatomyositis, scleroderma, vasculitis, and membranoproliferative glomerulonephritis. Homozygous deficiency of factor H, a complement regulatory protein, may manifest as hemolytic-uremic syndrome (Chapter 175). Likewise, deficiencies of the late complement components are occasionally associated with vasculitis or other lupus-like illnesses. Less frequently, patients with late component deficiencies develop Raynaud's syndrome, scleroderma, or dermatomyositis.

Patients with deficiencies in the late complement components usually present with recurrent, invasive meningococcal or gonococcal infections caused by *Neisseria* species, such as meningococcal meningitis, gonococcal arthritis, or gonococcal septicemia. However, patients with deficiencies of early or alternative pathway complement components, such as properdin deficiency, may also present with recurrent or invasive neisserial infections.

DIAGNOSIS

Individuals with recurrent blood-borne infection with encapsulated bacteria (e.g., *S. pneumoniae, H. influenzae,* invasive meningococcal or gonococcal disease) or immune complex disease should be screened for complement deficiency by determining the total hemolytic complement activity (CH_{50}) in the serum, a test of classical pathway activity. The CH_{50} should be undetectable. If the CH_{50} is normal, alternative pathway function should be tested with the AH_{50}. Hemolytic activity is very sensitive to heat degradation, so blood samples must be handled appropriately, and the serum should be separated and frozen at −70° C as soon as possible. Abnormalities in CH_{50} or AH_{50} may be followed by a determination of specific component concentrations in serum.

TREATMENT Rx

Patients with late complement defects should be immunized with the conjugate meningococcal vaccine. There is controversy over the use of prophylactic antibiotics because this could lead to the emergence of resistant strains of *Neisseria*.

Phagocytic Cell and Other Innate Immune Defects

Patients with defects in phagocyte function (Chapter 172) experience repeated infections where the body surface interfaces with the environment. Because of defective phagocyte function, the manifestations of infection may be blunted; erythema, swelling, and pus formation may be limited or absent. Phagocyte defects frequently manifest as infections caused by bacteria of relatively low virulence, such as *S. aureus;* fungi; and gram-negative enteric bacteria, including *Klebsiella, E. coli, B. cepacia,* and *Serratia* species. These infections often fail to respond optimally to the usual courses of antimicrobial agents. Many patients also have a history of poor wound healing, reflecting the critical role of phagocytes in tissue repair. The clinical features of phagocytic cell defects are shown in Table 258-1.

Normal function of the phagocyte compartment requires adequate numbers of neutrophils and monocytes, as well as the full performance of a number of closely integrated functions that result in the effective killing of a pathogen by the leukocyte. Defects in neutrophil number (severe congenital neutropenia, cyclic neutropenia, Kostmann's syndrome, Shwachman-Diamond syndrome; Chapter 170), adherence, deformability, locomotion, chemotaxis, recognition of foreign particles, phagocytosis, oxidative respiratory metabolism, and intracellular microbial killing (Chapter 172) have all been reported. Data from the history and physical examination can help the clinician focus on which phagocyte function is most likely defective.

A critical aspect of host defense is the accumulation of neutrophils at the site of infection. Absence of pus at the site of infection, for example, suggests that the patient has a decreased number of granulocytes or that these cells have an impaired ability to concentrate at the site of bacterial invasion, that is, defective chemotaxis or adhesion. Conversely, a history of persistent abscesses with exudates suggests that the phagocytes can migrate to the appropriate site but are defective in intracellular bacterial killing. A history of recurrent gingivitis, skin infections with furunculosis, abscesses of the viscera or perirectal tissues, and lymphadenitis should prompt an evaluation of the phagocyte host immune defenses.

INTERFERON-γ/INTERLEUKIN-12 PATHWAY DEFICIENCIES

These patients have increased susceptibility to infections with nontuberculous mycobacteria, *Salmonella,* and certain viruses, as well as disseminated infection following bacille Calmette-Guérin vaccination. Several genetic defects of the monocyte-macrophage-T_H1 T-cell pathway have been identified. Patients with complete interferon-γ receptor defects have severe impairment in interferon-γ signaling and fail to form tuberculoid granulomas. Patients with a partial defect have a better prognosis. Other patients with a similar clinical phenotype have an interleukin (IL)-12p40 deficiency or a mutation in the IL-12 receptor.

There is significant redundancy in the innate immune system, such that mutations in genes that are important in host defense, such as the defects in the interferon/IL-12 pathway, lead to an increased susceptibility to a variety of pathogens. In contrast, mutations in UNC-93B and TLR3 lead to a pathogen-specific predisposition to herpes simplex viral encephalitis. Undoubtedly there will be more discoveries of primary immune deficiencies associated with gene mutations that lead to specific single-pathogen–associated diseases.

DEFICIENCIES OF T-CELL IMMUNITY

DEFINITION

Profound defects in T-lymphocyte function, or defects arresting the development of T cells early in ontogeny, not only affect cell-mediated immunity but also impair the development of B-lymphocyte function (humoral immunity) owing to the absence of T-cell help and T-cell–derived cytokines. The clinical syndromes resulting from these more profound immune defects are referred to as SCID. Recurrent infections with organisms of relatively low virulence in an immunologically normal host (i.e., opportunistic infections) occur. Patients with T-cell immunodeficiency may develop infection with *Candida albicans* involving the mucous membranes and skin, but this infection is not invasive. Other fungal infections, severe viral diseases, and infection with opportunistic pathogens such as *P. jirovecii* or *M. avium-intracellulare* should prompt an evaluation for disorders in T-cell function. Graft-versus-host disease can be a significant problem in patients with severe T-cell immunodeficiency, either after the transfusion of lymphocyte-containing blood products or as a result of intrapartum or prenatal maternal-fetal transfusion. The clinical characteristics of patients with T-cell deficiency are shown in Table 258-2.

DIAGNOSIS

Patients are evaluated for T-cell deficiency by enumerating peripheral blood T-cell subsets and natural killer (NK) cells by flow cytometry; in addition, lymphocyte proliferative responses to mitogens and specific antigens can be assessed in vitro. Delayed hypersensitivity skin testing can be an initial screening test for T-cell immunity, using the intracutaneous injection of 0.1 mL of recall antigens (i.e., *Candida*) at 1:100 dilution weight/volume, tetanus toxoid at 1:100 dilution weight/volume, or *Trichophyton* at 1:30 dilution. Negative results are seen in patients with impaired T-cell responses, but they can also occur because of the lack of prior antigen exposure. Severe illness or the use of immunosuppressive drugs or systemic corticosteroids can also diminish delayed hypersensitivity responses (anergy).

TABLE 258-1 CLINICAL CHARACTERISTICS OF DISEASES OF PHAGOCYTIC CELL DYSFUNCTION

Can range from mild skin infections to severe systemic infections
Skin infections, furunculosis, visceral or perirectal abscess with granuloma formation, lymphadenitis, gingivitis
Poor wound healing, lack of pus
Mainly susceptible to low-grade virulent bacterial infections
Staphylococcus species
Gram-negative organisms

TABLE 258-2 CLINICAL CHARACTERISTICS OF T-CELL DEFICIENCIES

Onset of symptoms often in early infancy (4-5 mo)
Recurrent infections with fungi (*Candida*), viruses, and mycobacterial pathogens
Infections with opportunistic organisms: *Pneumocystis jirovecii*
Failure to thrive, often fatal in childhood
Fatal infections from live virus vaccines or bacille Calmette-Guérin vaccination
Graft-versus-host disease from transfusion of blood products containing viable T lymphocytes

TREATMENT

Rx

The diagnosis of T-cell immunodeficiency needs to be established quickly, before severe infections and life-threatening complications occur; patients are best referred to established centers for bone marrow transplantation. Prophylaxis against *P. jirovecii* is recommended for patients with significant T-cell immunodeficiency. Live vaccines such as oral polio, measles-mumps-rubella, varicella, and bacille Calmette-Guérin should not be given to patients with suspected or diagnosed T-cell immunodeficiency owing to the risk of vaccine-induced infection. Inactivated polio vaccine (rather than oral polio vaccine) should be given to household members to prevent transmission of the virus, which can occur via shedding of the attenuated virus in the stool. If patients with T-cell defects need blood transfusions, only irradiated, leukocyte-poor, cytomegalovirus-free products should be used to avoid graft-versus-host disease and cytomegalovirus infection.

B-CELL IMMUNODEFICIENCIES

Unlike patients with SCID, who first manifest symptoms at 4 to 5 months of age, patients with severe B-cell deficiencies usually do not have problems with infections until 7 to 9 months of age. The onset of infection is later in this group of patients because they are protected initially by maternal antibodies that pass through the placenta during the third trimester of pregnancy. Patients with B-cell immunodeficiencies usually develop infections with encapsulated bacterial organisms such as pneumococci and *H. influenzae*. The types of infection, as discussed previously, include otitis media, meningitis, septicemia, sinusitis, pneumonia, abscess, and osteomyelitis. Occasionally, these patients have problems with fungal or viral pathogens. Male patients with infantile XLA are unusually susceptible to enteroviruses and may develop chronic enteroviral encephalomyelitis. Generally, one does not see severe growth failure in patients with B-cell deficiency, as occurs in T-cell–deficient patients. Patients with antibody deficiency can survive into adulthood and can lead normal lives with the use of replacement intravenous immunoglobulin (IVIG) therapy.

Patients with severe B-cell deficiency, such as infantile XLA, typically have a paucity of lymphoid tissue (tonsils, adenoids, and peripheral lymph nodes). In contrast, patients with CVID often have lymphoid hypertrophy or hepatosplenomegaly. The incidence of allergy and autoimmune disease is increased, particularly in patients with IgA deficiency and CVID. The clinical characteristics of patients with B-cell deficiency are shown in Table 258-3.

X-Linked Agammaglobulinemia

DEFINITION

XLA is an X-linked recessive B-cell immunodeficiency with agammaglobulinemia and absent circulating B cells.

EPIDEMIOLOGY

Worldwide, the incidence appears to be approximately 1 in 100,000 to 200,000, or 5 to 10 cases per 1 million population.

PATHOBIOLOGY

The gene responsible for XLA is located on the X chromosome, and it encodes for a cytoplasmic tyrosine kinase (i.e., Bruton's tyrosine kinase [Btk]), which is expressed mainly in lymphocytes of the B-cell lineage. Btk is critical in B-lymphocyte signal transduction pathways and B-cell differentiation. Numerous mutations of the *BTK* gene have been described in patients with XLA, most involving the kinase domain. Mutations in the *BTK* gene lead to a block in B-cell maturation from pro-B cells to pre-B cells.

Some patients with *BTK* mutations do not present until later in life. This variation may reflect different types of *BTK* mutations. In fact, the block in B-cell differentiation may be "leaky," leading to a low level of immunoglobulin synthesis. A study of one family with XLA showed marked phenotypic variation among the male members who had the same gene mutation; serum immunoglobulin levels were also variable. Investigators have estimated that approximately 10% of adult patients with a diagnosis of CVID may be misdiagnosed and may actually have XLA with deficient Btk.

TABLE 258-3 CLINICAL CHARACTERISTICS OF B-CELL DEFICIENCIES

Recurrent infections with encapsulated organisms
Sinopulmonary infections, otitis media, meningitis, sepsis, abscess, osteomyelitis, cellulitis
No problems with fungal or viral infections (except enteroviral infection in XLA)
Lymphoid tissues: absent in patients with XLA, hypertrophied in those with CVID
Increased incidence of atopy and autoimmune disease
Granulomatous lung disease in CVID
Gastrointestinal disease
Celiac disease
Lactose intolerance
Bacterial overgrowth of small bowel
Nodular lymphoid hyperplasia in CVID
Higher incidence of malignancy in CVID

CVID = common variable immunodeficiency; XLA = X-linked agammaglobulinemia.

CLINICAL MANIFESTATIONS

Infections in patients with XLA occur predominantly in the sinopulmonary tract (60% of patients) and include otitis media, chronic sinusitis, and pneumonia. Other types of infections include pyoderma (25%), chronic conjunctivitis (8%), gastroenteritis (35%), arthritis (20%), meningitis or encephalitis (16%), and, less commonly, osteomyelitis (3%) and septicemia (10%). The most common pathogens are *H. influenzae* and *S. pneumoniae.* Patients who are untreated experience repeated pulmonary tract infections, leading eventually to bronchiectasis (Chapter 90). Infections may also occur with *G. lamblia.* Because cellular immunity is intact, most viral infections, fungal infections, and tuberculosis do not present a problem in patients with XLA. Exceptions to this include viral hepatitis, disseminated polio, and chronic enteroviral encephalitis.

Physical findings are related to repeated bacterial infections of susceptible target organs, such as the middle ear, sinuses, and lungs. Patients have a paucity of lymphoid tissues (e.g., adenoids, lymph nodes, spleen), unlike patients with CVID, who often have lymphoid hyperplasia. Unusual complications of XLA include a dermatomyositis-like syndrome and enteroviral meningoencephalitis.

Arthritis occurs in less than half the patients with XLA. In some patients, joint inflammation results from infection with enteroviruses or *Ureaplasma urealyticum.* Joint symptoms usually improve or resolve with IVIG therapy. Patients with XLA are highly susceptible to poliovirus infection; vaccine-associated poliomyelitis has been reported in XLA.

Unlike patients with CVID, autoimmune disorders are not a frequent problem in patients with XLA. Although a predisposition to various cancers is common with many types of immunodeficiencies, it is unclear whether patients with XLA have the same predisposition. The primary immunodeficiency registry reported that only 4.2% of registry patients with malignancies had XLA; lymphoreticular and gastrointestinal malignant diseases were more common.

Patients with XLA have a total absence or marked deficiency of serum immunoglobulins, and they fail to make antibodies to even potent protein antigens. Circulating B cells or surface membrane immunoglobulin-positive lymphocytes are extremely low (≤2%) or absent. T lymphocytes and other lymphoid subpopulations and delayed skin reactivity to recall antigens are normal. The response of peripheral blood lymphocytes to mitogens and allogeneic cells is normal. Lymphoid tissues show an absence of plasma cells, lymphoid follicles, and germinal centers.

DIAGNOSIS

Serum immunoglobulin levels should be quantified; as noted, patients with XLA usually have a profound hypogammaglobulinemia or agammaglobulinemia and fail to make antibodies even to potent protein antigens. Flow cytometry for B-cell numbers shows absent or very low numbers of $CD19^+$ B cells (e.g., <2%). Molecular analysis for *BTK* gene mutations can be very helpful in diagnostic evaluations. T-cell number and function are normal.

TREATMENT

Rx

Early diagnosis, broad-spectrum antibiotics, and replacement therapy with IVIG have changed the outcome of this disease. Infections, especially chronic enteroviral infections and chronic pulmonary disease, are still the two major complications of XLA. Early initiation of IVIG replacement therapy, with nadir serum IgG levels higher than 500 mg/dL, is important to prevent severe acute bacterial infections. Trough serum IgG levels higher than 800 mg/dL may be necessary to prevent chronic sinusitis, bronchiectasis, and enteroviral infections.

Immunodeficiency with Hyper–Immunoglobulin M (Immunoglobulin Class Switch Defects)

DEFINITION

Immunodeficiency with hyper-IgM is characterized by severe recurrent bacterial infections and decreased serum levels of IgG, IgA, and IgE but normal or elevated levels of IgM. The X-linked form of this syndrome (type 1) is most common, but a similar phenotype with an autosomal recessive inheritance occurs in female patients (type 3).

PATHOBIOLOGY

Immunodeficiency with hyper-IgM is primarily a disorder of B-cell isotype switching. Mutations in the CD40 ligand (CD40L or CD154) on T cells are responsible for the X-linked form of hyper-IgM (type 1), whereas mutations in the CD40 ligand receptor (e.g., CD40) on B cells are responsible for hyper-IgM type 3.

CLINICAL MANIFESTATIONS

Recurrent bacterial infections of the sinopulmonary tract usually begin in the first or second year of life. Stomatitis and mouth ulcers may occur in association with the neutropenia. *P. jirovecii* has been reported in patients with X-linked hyper-IgM. Other opportunistic pathogens include cytomegalovirus, *Cryptococcus,* and mycobacteria. Patients are susceptible to opportunistic organisms and have a high incidence of autoimmune diseases such as thrombocytopenia, hemolytic anemia, neutropenia, nephritis, and arthritis. Diarrhea is a frequent finding, occurring in more than 50% of patients, often as a result of cryptosporidiosis. Hepatitis B and hepatitis C viral infections produce chronic hepatitis in these patients. Unlike patients with XLA, these patients have marked hypertrophy of the lymphoid tissues, including the tonsils, lymph nodes, and spleen. However, the lymph nodes are poorly organized, with an absence of germinal centers. Proliferation of IgM-producing plasma cells, with extensive invasion of the gastrointestinal tract and liver, may occur by the second decade of life. Patients also have an increased risk of malignant diseases, especially lymphomas. An increased incidence of liver and biliary tumors is a unique feature of X-linked hyper-IgM.

DIAGNOSIS

Serum levels of IgM are often markedly increased and may exceed 1000 mg/dL; however, early in life the serum level of IgM may be normal. Patients can produce IgM antibody, but the secondary IgG response is usually markedly diminished or absent. Surface immunoglobulin–positive lymphocytes in the peripheral blood are primarily positive for IgM; IgA- and IgG-bearing lymphocytes are decreased or absent. T-lymphocyte numbers and mitogen responses are normal. Patients with X-linked hyper-IgM type 1 lack CD40L on activated T cells as a result of mutations in the gene for CD40L. Patients with hyper-IgM type 3 lack the receptor for CD40 ligand (CD40) on B cells and antigen-presenting cells.

TREATMENT Rx

Supportive care, prophylactic antibiotics for *P. jirovecii,* and recognition and treatment of other opportunistic infections are important. Parenteral nutrition may be necessary for patients with severe gastrointestinal disturbances. Treatment consists of IVIG replacement therapy. The commonly associated autoimmune neutropenia responds well to treatment with IVIG and granulocyte colony-stimulating factor. Bone marrow transplantation has been used to treat patients with this disease.

OTHER FORMS OF HYPER–IMMUNOGLOBULIN M PHENOTYPES

Other patients with a hyper-IgM phenotype have been described with normal CD40L and CD40 expression; these patients may possess mutations in the activation-induced cytidine deaminase (type 2) gene *(AICDA)* or the uracil DNA glycosylase (type 5) gene *(UNG)*. These patients differ from those with the X-linked form by exhibiting marked lymph node hyperplasia, enlarged germinal centers with highly proliferating B cells, and the absence of T-cell defects or opportunistic infections.

Another rare form of X-linked hyper-IgM syndrome (sometimes called NEMO syndrome) is associated with ectodermal dysplasia characterized by the absence or hypoplasia of hair, teeth, and sweat glands and by the presence of immunodeficiency. These patients exhibit increased susceptibility to bacterial infections, including atypical mycobacteria, encapsulated bacteria, and herpes viral infections. Most patients have low serum levels of IgG, variable levels of IgM and IgA, and poor antibody production; NK cell function is also defective. This disorder is related to mutations in the gene that encodes the nuclear factor-κB (NF-κB) essential modulator (NEMO or IKKγ), which is required for activation of the transcription factor NF-κB. Treatment consists of IVIG and mycobacterial prophylaxis.

DISEASES OF IMMUNE DYSREGULATION AND IMMUNODEFICIENCY

DEFINITION

The majority of autoimmune diseases have a complex, multifactorial, polygenic cause in which environmental triggers play an important role in their pathogenesis. A separate group of immune disorders affects patients with monogenic defects that impact processes of immune tolerance. These immune deficiencies include autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy (APECED); immunodysregulation with polyendocrinopathy, enteropathy, and X-linked inheritance syndrome (IPEX); and autoimmune lymphoproliferative syndrome (ALPS).

PATHOBIOLOGY

APECED is an autosomal recessive disorder with a higher frequency in individuals of Finnish, Sardinian, and Iranian Jewish origin. This disorder is caused by mutations in the gene encoding the autoimmune regulator protein (AIRE), a transcription factor that is important in controlling the ectopic expression of self-antigens in the thymus. Mutations in the *AIRE* gene lead to a breakdown in central tolerance and the development of multiorgan autoimmune diseases. IPEX is an X-linked disorder that involves mutations in the *FOXP3* gene, which is important in peripheral tolerance and the function of T-regulatory cells. ALPS is a disorder of programmed cell death, with several different gene mutations leading to defective Fas-mediated lymphocyte apoptosis (Table 258-4).

CLINICAL MANIFESTATIONS

Chronic mucocutaneous candidiasis, hypoparathyroidism, and adrenocortical failure are the classic triad of findings in APECED, with only two of the three required to make the diagnosis. Associated autoimmune disorders include insulin-dependent diabetes mellitus, thyroiditis, premature ovarian failure, hepatitis, and hypergonadotropic hypogonadism. IPEX patients typically present during the first few months of life, most commonly with diabetes mellitus, intractable diarrhea, and failure to thrive. Eczema, hemolytic anemia, thyroiditis, and serious infections are also classic features of the syndrome. Patients with ALPS may present with splenomegaly and lymphadenopathy (Chapter 171), as well as with various autoimmune manifestations, including hemolytic anemia, thrombocytopenia, and neutropenia.

DIAGNOSIS

There are no specific diagnostic tests for APECED; if the disease is suspected based on the clinical presentation, establishing the diagnosis depends on sequencing the *AIRE* gene. For IPEX, evaluating T cells for *FOXP3* expression is helpful. In ALPS, flow cytometry for the presence of double-negative T cells (CD4 and CD8 negative), along with the clinical presentation, is useful to screen for the disorder.

TABLE 258-4 IMMUNE DISORDERS WITH ABNORMALITIES IN IMMUNE REGULATION

Autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy (APECED): mutations in autoimmune regulator gene (*AIRE*)
Immune dysregulation, polyendocrinopathy, enteropathy, X-linked disorder (IPEX): mutations in *FOXP3* gene
Autoimmune lymphoproliferative syndrome (ALPS)
ALPS type Ia: mutations in Fas (*TNFRSF6*)
ALPS type Im: somatic mutation in the gene encoding Fas
ALPS type Ib: mutations in Fas ligand (*TNGSF6*)
ALPS type II: mutation in caspase 10 (*CASP10*)
ALPS type III: unknown mutation
ALPS type IV: mutation in *NRAS*

TREATMENT

Rx

Therapy for APECED is directed at the autoimmune processes and the candidiasis. In IPEX, immunosuppression with calcineurin inhibitors is the most frequent approach. Bone marrow transplantation early in the disease can arrest the progression of diabetes. In ALPS, thrombocytopenia secondary to hypersplenism may respond to splenectomy, although the autoimmune cytopenias may require immunosuppressive therapy. Pneumococcal infections are frequent, and prophylactic antibiotics may be helpful. The increased risk of lymphoma in ALPS patients and family members requires careful vigilance.

COMMON VARIABLE IMMUNODEFICIENCY

DEFINITION

CVID comprises a heterogeneous group of disorders involving both B-cell and T-cell immune dysfunction in which the predominant manifestation is hypogammaglobulinemia. CVID is characterized by recurrent bacterial infections, decreased serum immunoglobulin levels (at least two immunoglobulin isotypes more than 2 standard deviations lower than normal for age), and abnormal specific antibody responses. These patients may present in early childhood, during adolescence, or as young adults. In most patients, the onset of symptoms occurs in the second or third decade of life. In a large study, the average age at onset of symptoms was 25 years, and the average age at diagnosis was 28 years.

EPIDEMIOLOGY

The estimated incidence of CVID ranges from 1 in 10,000 to 1 in 50,000. These figures may underestimate the true numbers of CVID patients because of the late onset of symptoms and underdiagnosis of this immunodeficiency disorder.

PATHOBIOLOGY

The number of immune deviations described in patients with CVID underscores the heterogeneous nature of the immune defects in this syndrome. A homozygous deletion in the gene encoding ICOS, a T-cell costimulatory molecule of the CD28 family that enhances the activation of T cells and is important in T-cell–B-cell interactions, was found in two German families of CVID patients. The clinical phenotype of ICOS deficiency is similar to that of other patients with CVID. Other genetic mutations associated with CVID include the CD19 receptor TACI (*TNFRSF13B*, a receptor for the B-cell growth factor cytokines BAFF and APRIL), the BAFF receptor (*TNFRSF13C*), and *MSH5*.

Family members of patients with CVID exhibit an unusually high incidence of IgA deficiency, autoimmune diseases, autoantibodies, and malignant disease. An inheritance pattern of autosomal dominance with variable penetrance has been suggested.

CLINICAL MANIFESTATIONS

The most frequent presenting infections in adults with CVID involve the respiratory tract, including recurrent otitis media, chronic sinusitis, and recurrent pneumonia, often resulting in bronchiectasis. The bacterial pathogens are similar to those described in XLA. The gastrointestinal tract is affected in approximately half the patients with CVID; patients often present with malabsorption or chronic diarrhea. These symptoms can be related to numerous underlying abnormalities, including lactose intolerance, protein-losing enteropathy, superimposed infection of the small bowel with bacteria such as *Campylobacter* or *Yersinia* or the parasite *G. lamblia,* or infection of the large bowel with normal flora (small bowel bacterial overgrowth syndrome). Atrophic gastritis with achlorhydria may lead to pernicious anemia.

Approximately 5 to 10% of patients with CVID present with noncaseating granulomatous lesions that infiltrate the liver, lymph nodes, skin, and, more commonly, lung. These lesions are often confused with sarcoidosis (Chapter 95). Chronic gastrointestinal disease is often associated with nodular lymphoid hyperplasia, characterized by hypertrophy of the Peyer's patches in the small bowel and diffuse lymphoid infiltration. Hypertrophy of other lymphoid tissues, including the peripheral lymph nodes, the spleen, and occasionally the liver, is also seen. Rarely, hepatosplenomegaly may be severe enough to result in secondary neutropenia or thrombocytopenia. The pathogenesis of this process is not known but may be related to increased production of tumor necrosis factor-α. Patients with granulomatous-lymphocytic interstitial lung disease have a worse prognosis, often developing a restrictive pulmonary pattern with a low-normal diffusing lung capacity for carbon monoxide and diminished T-cell function. High-resolution computed tomography of the chest is helpful in identifying these patients, who require higher replacement doses of IVIG and sometimes treatment with corticosteroids.

Autoimmune disorders occur frequently in CVID (20 to 25% of patients), including rheumatic diseases, hematologic disorders, neurologic diseases, chronic active hepatitis, and endocrinopathies. The incidence of malignant disease is increased (11 to 13%) in patients with CVID during the fifth and sixth decades of life. Most of these malignant diseases involve the gastrointestinal tract and the lymphoid tissues (e.g., non-Hodgkin's lymphoma).

DIAGNOSIS

The serum immunoglobulin levels are markedly diminished in patients with CVID; however, a large variability is seen in the degree of hypogammaglobulinemia. Specific antibodies are usually lacking, and isohemagglutinin titers are generally diminished. The proportions of circulating B cells in the peripheral blood are usually normal, but a subset of patients may lack circulating B lymphocytes. T-cell function can be quite variable, being normal in half of patients. The other half of patients with CVID may exhibit depressed T-cell function, with absent delayed hypersensitivity skin reactivity to recall antigens, low numbers of circulating peripheral blood $CD4^+$ T cells, often a decrease in the CD4/CD8 ratio, and depressed in vitro responses to mitogens and specific antigens. Other recent laboratory findings associated with CVID include the lack of isotype-switched memory B cells (e.g., $CD27^+$, IgM^-, IgD^- B cells).

TREATMENT

Rx

Patients with CVID are treated with doses of IVIG ranging from 400 to 600 mg/kg every 4 weeks. Generally, this regimen should achieve a trough serum IgG level higher than 500 mg/dL. Patients who continue to experience recurrent infections or who develop bronchiectasis should be treated with higher doses of IVIG to achieve higher trough levels (e.g., >750 mg/dL).

PROGNOSIS

The prognosis is generally good for patients with CVID whose illness is diagnosed early and who undergo replacement IVIG therapy. The reported mortality rate over a 25-year period was 24%, mostly because of lymphoma (18%) and chronic pulmonary disease (11%). The mean age at the time of death was 45.5 years in women and 40 years in men. The patients who died were more likely to have lower levels of IgG at the time of diagnosis and poorer T-cell proliferative responses to phytohemagglutinin. Twenty-year survival after the diagnosis of CVID was 64% for men and 67% for women, compared with 92 to 94% for the general population. With early diagnosis and replacement IVIG therapy, survival is much improved.

Immunodeficiency with Thymoma

Immunodeficiency with thymoma (Good's syndrome) is a disorder of adults. It typically presents between the ages of 40 and 70 years with recurrent sinopulmonary infections. Affected individuals have adult-onset hypogammaglobulinemia, which may affect all major immunoglobulin isotypes. During the initial investigation of hypogammaglobulinemia, a thymoma (Chapter 99) may be detected as a mediastinal mass on the chest radiograph. Occasionally, the thymoma predates the hypogammaglobulinemia. Thymic tumors are predominantly of the spindle cell type and are usually benign. The clinical symptoms are similar to those found in patients with CVID. In contrast to CVID, however, frequently associated disorders include aregenerative (pure red cell) anemia, agranulocytosis, and myasthenia gravis. These conditions may improve after thymectomy, but the immunodeficiency may persist; $CD4^+$ T-cell lymphopenia and a decreased $CD4^+/CD8^+$ ratio are commonly seen. Infections associated with T-cell abnormalities can be seen in these patients, including mucocutaneous candidiasis, cytomegalovirus infection, herpes zoster, and *P. jirovecii* pneumonia.

IMMUNOGLOBULIN A DEFICIENCY

DEFINITION

IgA deficiency is defined as a serum IgA concentration lower than 7 mg/dL, with normal serum levels of IgM and IgG. It is one of the most common

B-cell immunodeficiencies, with an approximate incidence of 1 in 400 to 2000 individuals in the general population.

PATHOBIOLOGY

The genetic defect responsible for IgA deficiency is not known. IgA deficiency shares with CVID the inheritance of a restricted major histocompatibility complex extended haplotype. Although the pathogenesis of IgA deficiency is still unknown, it may share a common origin with CVID because these two disorders have many immune aspects in common. In fact, some patients with IgA deficiency have mutations in *TACI,* similar to the defects described in patients with CVID. IgA deficiency may occur in association with the administration of drugs such as phenytoin, sulfasalazine, hydroxychloroquine, and D-penicillamine. IgA deficiency has also been described in association with partial deletion of the long arm of chromosome 18 (18q syndrome) or with a ring chromosome 18.

CLINICAL MANIFESTATIONS

Many individuals with selective IgA deficiency do not have symptoms. The variability in clinical expression may be related to two factors. First, the IgA-deficient patients who are relatively asymptomatic appear to have a compensatory increase in secretory monomeric IgM in their saliva, upper respiratory tract secretions, and gastrointestinal fluids. Second, the association of IgG2/IgG4 or IgG4 subclass deficiencies with IgA deficiency may predispose IgA-deficient patients to more severe and recurrent sinopulmonary infections.

Symptoms of IgA deficiency include sinopulmonary infections and involvement of the gastrointestinal tract with giardiasis, nodular lymphoid hyperplasia, ulcerative colitis, Crohn's disease, or a sprue-like disease. An increased frequency of autoimmune disorders has also been associated with IgA deficiency, including arthritis, a lupus-like illness, endocrinopathies, chronic active hepatitis, and hematologic disorders. IgA-deficient patients are at risk for the development of anti-IgA antibodies on receipt of blood products. Caution must be exercised in the administration of IVIG for the treatment of IgG subclass deficiency in IgA-deficient patients because most of these preparations contain small amounts of IgA. However, this risk does not appear to be significant in patients with partial IgA deficiency.

DIAGNOSIS

Despite very low serum levels of IgA, the peripheral blood B cells of IgA-deficient patients coexpress IgA, IgM, and IgD, an immature phenotype. However, the lymphoid tissues are deficient in IgA-producing plasma cells. Studies of T-cell function have been normal in most patients with selective IgA deficiency.

TREATMENT

Rx

No specific treatment for IgA deficiency exists. Prophylactic antibiotics may be helpful in patients with recurrent sinopulmonary tract infections. Patients with chronic lung disease should receive conventional therapy to prevent the development of bronchiectasis (Chapter 90). IVIG is not indicated in patients with isolated IgA deficiency. Other supportive treatments are aimed at associated diseases. Patients should be transfused only with washed red cells to avoid sensitization to the IgA in blood products.

PROGNOSIS

The prognosis is good in most cases. Respiratory infections and autoimmune disease are more common in IgA-deficient patients. A few patients with IgA deficiency presenting in childhood may recover spontaneously; other patients may develop CVID.

IMMUNOGLOBULIN G SUBCLASS DEFICIENCIES AND SELECTIVE ANTIBODY DEFICIENCY

DEFINITION

Considerable controversy exists over the biologic significance of IgG subclasses and the clinical significance of an isolated IgG subclass level outside of the normal range. Because healthy individuals without recurrent infections may have abnormally low serum IgG subclass concentrations, immunologists have questioned whether IgG subclass deficiency represents a true immunodeficiency disease. Deficiency in an IgG subclass is defined as a serum IgG subclass concentration more than 2 standard deviations lower than the normal mean for age. The age at which each of the IgG subclasses reaches adult levels varies. In adults, IgG3 deficiencies are most common, whereas in children, IgG2 deficiencies are most prevalent. IgG subclass deficiency may be seen in conjunction with other primary immunodeficiency disorders such as ataxia-telangiectasia and IgA deficiency. IgG subclass deficiency occurs in approximately 18% of IgA-deficient patients. An IgG subclass deficiency may occur as an isolated immune defect, or two or more IgG subclass deficiencies may coexist (e.g., IgG2 and IgG4 deficiency).

Patients with *selective antibody deficiency* exhibit low responses to immunization with polysaccharides such as *H. influenzae* type b (Hib) capsular antigen or to the pneumococcal polysaccharide antigens, but they have normal serum immunoglobulin isotypes and IgG subclass concentrations. However, these patients respond normally to immunization with Hib-conjugate vaccine, in that the antibody response to the vaccine falls principally within the IgG1 subclass instead of the IgG2 subclass.

CLINICAL MANIFESTATIONS

The most frequent clinical problems associated with IgG subclass deficiency and selective antibody deficiency are recurrent infections of the upper and lower respiratory tracts. Pathogens are generally limited to encapsulated bacteria and respiratory viruses. Because IgG2 is important in the response to polysaccharide antigens, patients with IgG2 deficiency may have increased infections with *H. influenzae* or *S. pneumoniae.* Patients may be unable to produce specific antibodies after immunization with purified polysaccharide antigens (e.g., Pneumovax). Some patients with IgG2 subclass deficiency may be asymptomatic. In part, this may result from a shifting of the antibody response to another IgG subclass or immunoglobulin isotype to compensate for the IgG2 deficiency. IgG3 deficiency, more common in adults, has been associated with recurrent upper and lower respiratory tract infections and may occur in combination with IgG1 deficiency. Several studies have suggested that IgG3 is especially important in the primary response to viral respiratory agents. IgG3 is also the predominant antibody response in *Moraxella catarrhalis,* an organism frequently isolated from patients with chronic sinusitis. IgG4 deficiency occurs in the general population at a rate of approximately 10 to 15%. The clinical significance of IgG4 deficiency is not known.

DIAGNOSIS

Serum immunoglobulin concentrations should be measured by quantitative techniques (nephelometry). Levels in children must be compared with laboratory normals for age. Immunoelectrophoresis is semiquantitative and should not be used to evaluate patients with suspected antibody deficiency. Immunoelectrophoresis should be used only to examine serum for paraproteins such as those found in Waldenström's macroglobulinemia or multiple myeloma. IgG subclass quantification may be helpful, although controversy exists over the utility of these measurements. A careful history and physical examination, and the measurement of functional or specific antibodies, are important in determining the clinical relevance of an IgG subclass deficiency.

Patients may have normal levels of total serum immunoglobulins and normal IgG subclasses yet may fail to make specific antibodies to bacterial or common viral pathogens. Therefore, the assessment of specific antibody formation following vaccine administration is an important part of the laboratory evaluation in patients with suspected B-cell deficiency. Usually, specific antibody titers are obtained at baseline and at 4 weeks after immunization to assess the specific antibody response. Isohemagglutinins are naturally occurring IgM antibodies to the ABO blood group substances. Responses to protein antigens generally fall in the IgG1 subclass, whereas the immune response to the polysaccharide antigens resides in the IgG2 subclass. The antibody responses to conjugate vaccines for Hib and pneumococcal polysaccharides occur primarily in the IgG1 rather than IgG2 subclass. Therefore, these conjugate vaccines may not be helpful in the functional evaluation of an IgG2 subclass deficiency or a selective polysaccharide antibody deficiency. Because recurrent upper respiratory tract infections are common in these patients, one can test the serum for the presence of antibodies to common respiratory agents such as influenza A and B, mycoplasma, respiratory syncytial virus, adenovirus, and the parainfluenza viruses.

TREATMENT

Rx

Replacement IVIG should be considered *only* if patients demonstrate poor antibody responses to vaccine immunization such as Pneumovax. Often, prophylactic antibiotics are useful in this group of patients, at least during the winter months.

ALLERGIC RHINITIS AND SINUSITIS

LARRY BORISH

DEFINITION

Allergic rhinitis (AR) refers to the nasal and ocular symptoms that occur as a result of an inflammatory hypersensitivity reaction to aeroallergens deposited on the nasal mucosa and conjunctiva.

EPIDEMIOLOGY

AR, the most common chronic disease in the United States, affects between 10 and 30% of adults and up to 40% of children. Each year, nearly 80 million people in the United States experience 7 or more days of nasal or ocular symptoms as a result of AR. Although it is not a severe disorder, the socioeconomic costs of AR are substantial. AR is one of the chief reasons for visiting a primary care physician; it adversely affects work productivity and school performance, and it limits socialization. The impact of AR also reflects its association with a variety of comorbid conditions, including asthma (Chapter 87), acute and chronic sinusitis, nasal polyposis, secretory otitis media, and sleep disorders. Adequately addressing AR requires a thorough understanding of its pathophysiology, its relation to these comorbid conditions, and the effects of various therapeutic options on AR and its associated comorbidities.

PATHOBIOLOGY

Airborne Allergens

Allergic respiratory diseases result from a hypersensitivity immune reaction to airborne allergens. These include the pollens and molds that are responsible for seasonal AR (SAR) and the indoor allergens, such as dust mites and animal proteins, that are responsible for perennial AR (PAR) (Table 259-1).

In any area, the specific pollens that are likely to cause symptoms can be predicted from the number of days a pollen is airborne in large numbers. All these pollens use a windborne mechanism to achieve fertilization. Insect-borne pollens, specifically those produced by flowers, are not significantly airborne and therefore are not inhaled in sufficient concentrations to generate immune responses. In the United States, grass pollens (May to June) and ragweed (mid-August to October) are the most important causes of SAR. Tree pollens vary locally but typically start in late February and continue through April. The major trees implicated in allergy include birch in the North, oak in the mid-Atlantic region, live oak in the South, and mountain cedar in the Southwest. In addition to pollens, outdoor molds, particularly *Alternaria* and *Cladosporium,* can produce symptoms. These molds have variable seasons, depending on the weather; high levels of airborne fungi may be common at any time between March and October. In recent years, climate change has influenced both the length and the region of pollen seasons.

PAR may occur year-round, but the term is applied to any rhinitis that does not have a clearly defined seasonal association. The most common causes include (1) indoor fungi, which are related to periods of high indoor humidity; (2) animal danders, particularly cats, but rodents (mice, rats, guinea pigs, ferrets, hamsters), rabbits, dogs, and birds may also be significant; (3) dust mites of the genus *Dermatophagoides,* which grow in bedding and pillows and are semiseasonal, with maximal levels from August to December; and (4) other insects (the best studied is the cockroach, but gypsy moths, crickets, ladybugs, spiders, and beetles may be locally important). Dust mites and cats produce the most important indoor allergens. Dust mites grow well only with a relative humidity higher than 50%. Dust mite allergy is probably relevant in all areas with more than 6 humid months in the year.

Immunoglobulin E, Mast Cell, and Basophil Activation

The traditional view is that AR is caused by the triggering of mast cell degranulation resulting from the cross-linking of surface-bound immunoglobulin

TABLE 259-1 ALLERGENS CAUSING ALLERGIC RHINITIS

COMMON NAME	SEASON
SEASONAL ALLERGENS

(Ig) E molecules by the aeroallergen. As with all antibody-mediated immune responses, the initial exposure to the antigen results in B-lymphocyte secretion of low-affinity IgM antibodies. Subsequent exposure to the allergen in genetically predisposed subjects leads to a secondary immune response characterized by the isotype switch to IgE. The resulting release of IgE antibodies into the circulation does not cause allergic symptoms; only after these IgE antibodies bind to their high-affinity receptors on basophils and mast cells do symptoms develop with subsequent allergen exposure. It takes the cross-linking of approximately 300 IgE receptors and cells to stimulate degranulation; therefore, it often requires several allergy seasons before sufficient numbers of allergen-specific IgE molecules are present on the mast cell surface to drive degranulation. This means that the development of symptomatic AR is a protracted process, generally requiring at least three or four exposures. As a result, SAR is generally not observed in children until they are approximately 4 years of age. Similarly, in adults, symptomatic responses to local allergens may not develop until approximately 4 years after moving to a region. PAR, however, can develop much faster.

Within minutes of allergen exposure, IgE-sensitized mast cells degranulate and release preformed and newly synthesized mediators, including histamine, proteases (tryptase and chymase), cysteinyl leukotrienes, prostaglandins, and cytokines. Some of these mediators produce the characteristic early-phase symptoms of AR—namely, sneezing, pruritus, rhinorrhea, and, to some extent, congestion. Other mediators stimulate infiltration of the nasal mucosa with inflammatory cells, including basophils, eosinophils, neutrophils, additional mast cells, and mononuclear cells. This infiltration of inflammatory cells and their subsequent release of a secondary wave of mediators sustain the inflammatory reaction and produce the late-phase response of AR. This slowly developing inflammatory response is characterized primarily by nasal congestion. The inflammation that develops over the course of an allergy season is associated with an approximately 10-fold increase in the number of mast cells present in nasal epithelial and submucosal tissue. This reflects the migration of preexisting mast cells into the epithelium and the differentiation and influx of newly synthesized mast cells under the influence of cytokine growth factors. During the course of chronic allergen stimulation, these mast cells also display increased *priming*, which reflects increases in the number of IgE receptors and surface-bound IgE, as well as enhancement of signal transduction pathways. As a result, as the allergen season progresses, less and less allergen is required to trigger mast cell degranulation.

Antigen-Presenting Cell and Helper T-Lymphocyte Activation

In addition to their interaction with mast cells, allergens behave like any other foreign antigen and are processed and presented by antigen-presenting cells to helper T (T_H) lymphocytes. Activation of these antigen-presenting cells, including mononuclear phagocytic cells, B lymphocytes, and especially dendritic cells, is an important source of cytokines, especially those associated with innate immunity such as interleukin (IL)-1, IL-6, and tumor necrosis factor-α (TNF-α). With the development of allergic inflammation, there is an increased presence of B cells expressing allergen-specific surface immunoglobulin and dendritic cells expressing surface-bound IgE. These antibodies can function as receptors that "capture" allergen and increase these cells' effectiveness in antigen processing. The newly activated T lymphocytes tend to resemble T_H2 cells, characterized by the production of IL-4, IL-5, IL-9, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF). These cytokines are also major components of the inflammatory response in AR and contribute to the increased production, recruitment, and activation of eosinophils, mast cells, and basophils. A milieu rich in IL-4 and IL-13 drives the IgE isotype switch and contributes to the further production of allergen-specific IgE.

As a result of these inflammatory processes, over the course of allergen exposure, rhinitis evolves and becomes more dependent on mediators associated with the infiltration of eosinophils, basophils, neutrophils, mononuclear cells, and T_H lymphocytes, as well as the increasingly primed mast cells. The symptoms of acute rhinitis, such as sneezing, itching, and rhinorrhea, largely reflect vasoactive mediator release, especially histamine. As SAR or PAR persists, however, these infiltrating cells continue to produce cytokines and other inflammatory mediators, leading to the mucous hypersecretion, tissue edema, goblet cell hyperplasia, and tissue damage that become the primary sources of allergy patients' symptoms. Because the role of histamine diminishes as AR progresses (discussed later), antihistamines become less effective.

Eosinophils represent an important component of the inflammation that develops in AR. Eosinophils release a wide variety of pro-inflammatory mediators, including cysteinyl leukotrienes (leukotrienes C4, D4, and E4), eosinophil cationic protein, eosinophil peroxidase, major basic protein, IL-3, IL-5, GM-CSF, and platelet-activating factor. Eosinophil-derived mediators are major components of the chronic allergic response and produce many of the symptoms of AR, especially nasal congestion. The natural history of AR is for symptoms to worsen inexorably over several weeks in the presence of ongoing allergen exposure. Symptoms often do not peak until well after the peak in pollen counts, and then they persist after pollen counts have declined. These observations reflect the time frame of the onset of nasal inflammation and tissue damage. The influx of eosinophils into the nasal mucosa correlates with the development and progression of symptoms. In summary, the natural history of AR represents an evolution from an acute, primarily mast cell–mediated process that is responsive to antihistamines to a chronic inflammatory process that is primarily eosinophil mediated and is much less responsive to antihistamines.

CLINICAL MANIFESTATIONS

The diagnosis of AR is based on a history of sneezing, which is often paroxysmal; rhinorrhea with clear, watery secretions; nasal congestion; and itching in the nares and palate. These symptoms are generally associated with allergic conjunctivitis manifested by ocular itching, lacrimation, and conjunctival injection. Severe conjunctivitis is less common in PAR than in SAR. The best explanation for this difference is that pollen grains affect the eyes when they are blown into them. Indoor allergens are less likely to be blown into the eyes because the air is relatively still. Indoor aeroallergens are drawn into the nose by breathing.

What is less well appreciated is that AR is a systemic disease associated with circulating activated T lymphocytes and mononuclear phagocytic cells. The activation of these cells is demonstrated by their production of cytokines associated with innate immunity, such as IL-1, TNF-α, and IL-6. These cytokines are responsible for the lethargy, fatigue, arthralgias, myalgias, and cognitive impairment that frequently accompany AR. These systemic symptoms, which are often the chief complaints of allergy sufferers, contribute to a diminished quality of life and are often severe enough to make normal activities difficult, including work or school. Although fever is not a feature of AR, it is intriguing that the lay terminology for this condition is *hay fever*, a designation reflecting the pronounced flu-like nature of this disease.

DIAGNOSIS

AR is primarily a clinical diagnosis based on symptoms and exposure history. It is a complex genetic disorder, and affected patients generally give a positive family history. Vasoactive mediators induce glandular secretions and vascular leakage, along with engorgement of capacitance nasal venous sinusoids. Physical examination therefore reveals the nasal mucosa to be cyanotic and swollen, with clear secretions. Nasal smears (Hansel stains) of nasal secretions are seldom required, but when performed, they typically reveal eosinophils.

The diagnosis of AR is confirmed by the demonstration of specific IgE antibodies reactive to the relevant allergen through either positive allergy skin tests or IgE immunoassays. Identification of the specific triggering allergen is essential for the institution of appropriate environmental controls. Prick skin testing is safe, specific, and rapid, and it is the diagnostic test of choice for identifying relevant allergens. A positive intradermal test in the presence of a negative prick skin test is often a false-positive result. Intradermal testing is therefore rarely indicated and is associated with potentially life-threatening systemic reactions. If prick skin testing is not available or if the test cannot be performed (e.g., in patients with eczema or dermatographism or in those using antihistamines or antipsychotic agents), IgE immunoassays are an appropriate alternative. As with prick skin tests, positive IgE immunoassays correlate with symptoms caused by natural exposure, establish the diagnosis of AR, and can form the basis for environmental therapy; these assays should therefore be used extensively by primary care physicians who manage patients with AR. However, a negative IgE immunoassay with a strong clinical suspicion suggests the need for referral.

Differential Diagnosis

Other causes of rhinitis are shown in Table 259-2, and the approach to patients with sneezing and rhinorrhea is illustrated in Figure 259-1.

Viral rhinitis may be difficult to distinguish from SAR. Viral rhinitis is not associated with the release of mast cell mediators. The main mediators present in nasal secretions from patients with the common cold are kinins; histamine, leukotrienes, and prostaglandins are less prevalent. The presence of these different mediators is in keeping with the observation that pruritus, paroxysmal sneezing, and clear secretions help distinguish SAR from viral rhinitis, along with the distinct recurrent, seasonal nature of SAR. Viral rhinitis produces thicker, purulent secretions, with neutrophils present on the nasal smear. Conjunctival symptoms are less pronounced, and on physical examination, the nasal mucosa is erythematous and swollen.

Hormonal influences that may produce chronic nasal congestion and rhinorrhea include hypothyroidism, birth control pill use, pregnancy, and menopause. Abuse of topical nasal decongestants (e.g., oxymetazoline), with chronic reflex vasodilation, has historically been the most common cause of rhinitis medicamentosa; however, cocaine abuse is another frequent cause of this condition. Chronic unilateral nasal blockage suggests an anatomic defect, typically a deviated or fractured septum, but such blockage can also result from polyps, tumors, and foreign bodies. This history necessitates computed tomography (CT) of the nose and sinuses and rhinoscopy. Nasal septum deviation hardly ever causes bilateral nasal congestion, and surgical therapy has little role in the treatment of rhinitis that is producing symptomatic congestion.

An abnormal neurogenic response to irritants (e.g., cold air, pollutants, cigarette smoke, strong odors, alcohol, foods) is the predominant feature of vasomotor rhinitis. This disorder is characterized by nasal autonomic nerve dysfunction. Patients with vasomotor rhinitis typically have chronic nasal congestion and posterior pharyngeal drainage, but they lack the paroxysmal sneezing, rhinorrhea, pruritus, conjunctivitis, and systemic complaints typical of patients with AR. In addition, eosinophils are absent in nasal mucus. Topical antihistamines (nasal azelastine, olopatadine) are often effective in vasomotor rhinitis. Patients with this condition also respond to therapy with topical corticosteroids or atropine (nasal ipratropium).

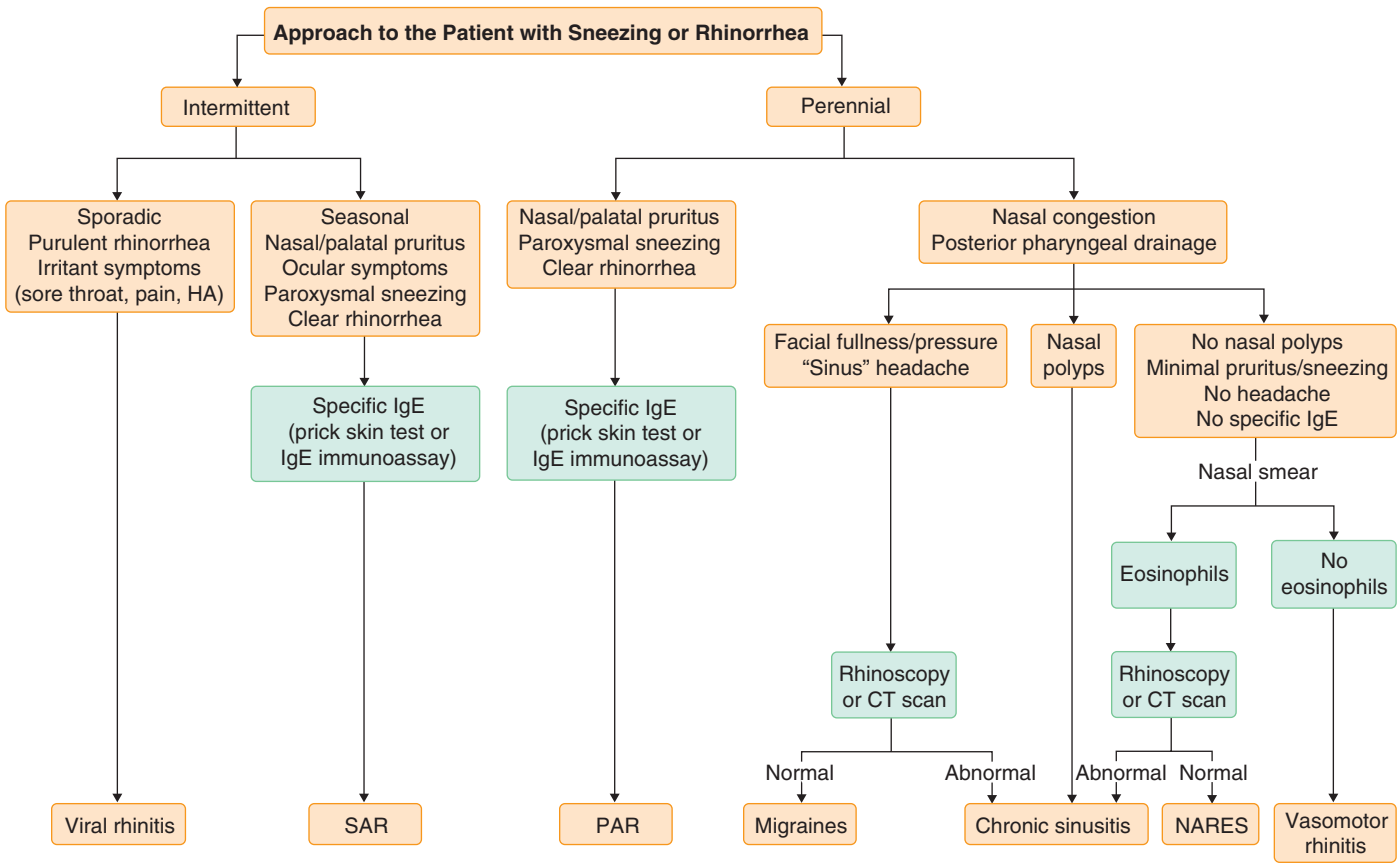

FIGURE 259-1. Approach to the patient with rhinitis symptoms. CT = computed tomography; HA = headache; IgE = immunoglobulin E; NARES = nonallergic rhinitis with eosinophilia syndrome; PAR = perennial allergic rhinitis; SAR = seasonal allergic rhinitis.

Chronic sinusitis with or without nasal polyposis can produce a spectrum of symptoms, including rhinorrhea, mucopurulent posterior pharyngeal drainage, and nasal congestion, that can be mistaken for PAR. However, chronic sinusitis, particularly when it is eosinophilic (discussed later), is often asymptomatic, and a reduced or absent sense of smell may be the only complaint. In contrast to acute sinusitis, headaches are an unusual manifestation of either perennial rhinitis (allergic or nonallergic) or chronic sinusitis, and virtually all patients who complain of "sinus headaches" suffer from atypical migraines or other headache syndromes. Atypical migraines routinely produce headaches that occur in a bilateral distribution involving the maxillary or ophthalmic branches of the trigeminal nerve; this distribution, especially when combined with vasomotor symptoms such as nasal congestion, rhinorrhea, and conjunctival injection, often leads to their misdiagnosis as chronic sinusitis or rhinitis. Because of this overlap in symptoms among chronic sinusitis, perennial rhinitis, and atypical migraines, objective evaluation with either CT or rhinoscopy is usually required to establish the diagnosis of chronic sinusitis.

Atrophic rhinitis is characterized by atrophy of the nasal epithelium and is associated with complaints of nasal congestion and a perceived bad odor. It is observed in elderly patients, but the most common cause is devascularization secondary to nasal surgery or trauma.

Finally, a nonallergic nasal disease characterized by prominent eosinophilic inflammation has been described and termed *non-AR with eosinophilia syndrome* (NARES). On further analysis, many of these patients prove to have chronic sinusitis and nasal polyps. Patients with NARES present with symptoms similar to those of vasomotor rhinitis. NARES is diagnosed by performing a nasal smear (Hansel stain) for eosinophils; however, a CT scan or rhinoscopy is required to rule out chronic sinusitis or nasal polyposis because these conditions may be minimally symptomatic. In contrast to vasomotor rhinitis, NARES is more responsive to intranasal cromolyn and intranasal corticosteroids.

SYSTEMIC MANIFESTATIONS

Allergic inflammation associated with AR can lead to obstruction of the sinus ostia and is an important cause of acute (bacterial) sinusitis. More important is the association between AR and chronic sinusitis. Chronic sinusitis represents many disease processes, including those caused by chronic bacterial infections, cystic fibrosis, immotile cilia syndrome, immune deficiencies, nonspecific inflammation (Fig. 259-2A), hypersensitivity to colonized fungi (allergic fungal sinusitis), aspirin-exacerbated respiratory disease (Samter's triad), and a disorder termed *chronic hyperplastic eosinophilic sinusitis* (CHES) (Table 259-3). In the absence of immunodeficiency or cystic fibrosis, infection is a very unusual cause of chronic sinusitis. Approximately half of all patients with chronic sinusitis have CHES, and this discussion focuses on the underlying allergic mechanisms.

CHES, which generally occurs in association with nasal polyposis, is an inflammatory disorder characterized by the accumulation of eosinophils, fibroblasts, goblet cells, and T_H2-like lymphocytes. The prominent accumulation of eosinophils, however, is the diagnostic feature of this condition (Fig. 259-2B). The inflamed tissue expresses cytokines responsible for eosinophil hematopoiesis (IL-5), survival (IL-3, IL-5, and GM-CSF), recruitment (CCL11 [eotaxin]), and activation (CCL11, CCL5 [RANTES], IL-3, IL-4, IL-5, GM-CSF, and TNF-α). Sensitivity to allergens increases the risk of developing CHES, and more than 50% of individuals with AR have abnormal sinus radiographs. Allergens are unable to gain access to the sinus cavities in healthy subjects (they are not inhaled into the sinuses with breathing, and diffusion is not efficient), and they are even less likely to do so in the presence of occlusion of the sinus openings, which is characteristic of sinusitis. Nevertheless, nasal allergen challenges in sensitive individuals produce radiographic changes and eosinophilic infiltration within the sinuses, and worsening of CHES can be demonstrated during seasonal exacerbations of AR.

The link between AR and sinusitis is thought to involve a systemic inflammatory process (Fig. 259-3). AR is not just a localized inflammatory disorder of the nasal mucosa; it is associated with systemic inflammation. Consequently, it is often seen with other inflammatory conditions such as asthma (Chapter 87), secretory otitis media, and CHES. For example, in patients with SAR who also have asthma, nasal allergen provocation, performed so that the allergen does not gain access to the lungs, leads to increased adhesion molecule expression, eosinophil infiltration, and bronchial hyperreactivity. As illustrated in Figure 259-3, in sensitized subjects, allergen exposure activates immune cells, including T_H lymphocytes, dendritic cells, mononuclear cells, mast cells, and others, both within the nares and in nasal-associated lymphatic tissues. These cells also include locally produced eosinophil precursors. Some of these T_H cells migrate to the bone marrow, where they stimulate the marrow to produce inflammatory cells, including basophils, eosinophils, and mast cell precursors. Thus, allergen challenges increase the bone marrow concentrations of both cytokines and eosinophil and basophil progenitor cells. Ultimately, these newly generated inflammatory cells enter the circulatory system and are selectively recruited to the sinuses in CHES (and to the lungs in asthma). This selective recruitment of inflammatory cells into the sinuses occurs only in individuals with preexisting CHES in whom specific adhesion molecules, such as vascular cell adhesion molecule-1

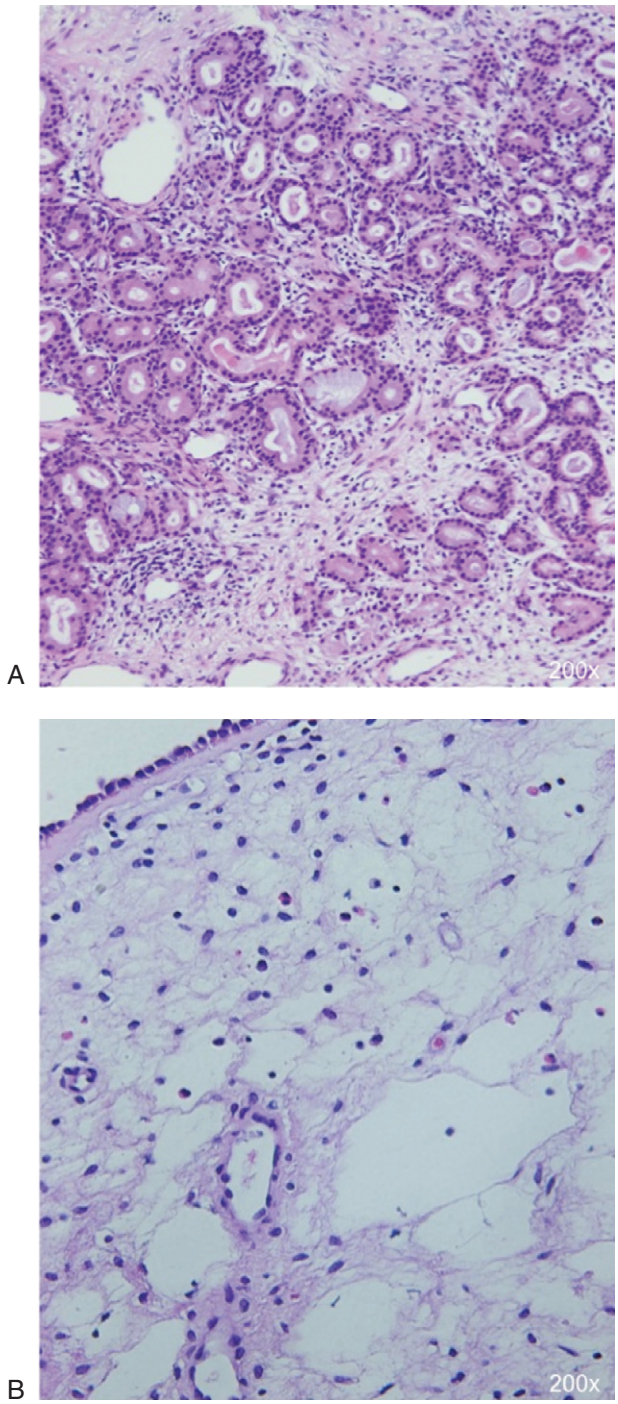

FIGURE 259-2. Immunohistochemical analysis of nasal polyp biopsies. A, Chronic inflammatory sinusitis displays prominent glandular hypertrophy, collagen bundles, and scattered mononuclear infiltrates. **B,** Chronic hyperplastic eosinophilic sinusitis demonstrates edematous tissue, basement membrane thickening, and prominent eosinophilia (original magnification × 200). (From Payne S, Early SB, Huyett P, et al. Histology and cytochemical profile of nasal polyposis: evidence for distinct eosinophilic and non-eosinophilic diseases distinguished by edema, collagen content, and growth factor expression. In press.)

TABLE 259-3 HETEROGENEITY OF CHRONIC SINUSITIS

PHENOTYPE	CHARACTERISTIC
Infectious	Very unusual as a cause of chronic sinusitis Occurs in association with cystic fibrosis, immune deficiency
Inflammatory	Reflects remodeling secondary to frequent, recurrent acute sinusitis Develops secondary to anatomic obstruction of the sinus ostia; often responds to surgical correction Pathology demonstrates dense collagen fibrils and glandular hypertrophy and a chronic mononuclear infiltrate, with or without neutrophils Bacterial biofilms contribute to presence and severity Often associated with nasal polyps
Hyperplastic eosinophilic	Prominent eosinophilic infiltrate with systemic eosinophilia Pathology demonstrates edema, sub-basement thickening Frequent association with allergies and asthma Usually associated with nasal polyps
Allergic fungal	Often unilateral; presents as expansive infiltrate on CT scan Associated with elevated total IgE and specific IgE to colonizing fungi
Aspirin-exacerbated respiratory disease (Samter's triad)	Intense eosinophilic infiltrate Usually associated with nasal polyps and asthma Exacerbations of upper and lower respiratory disease (asthma) after ingestion of aspirin and nonselective COX1 inhibitors

COX1 = cyclooxygenase 1; CT = computed tomography; IgE = immunoglobulin E.

(VCAM-1), and chemoattractants, such as CCL11 (eotaxin), are already present. Persons without CHES do not have these addressins in their sinuses and thus do not have the machinery in place to recruit inflammatory cells in response to AR. This model explains the absence of CHES in approximately half of AR sufferers, but it does not explain the event that initiates CHES. Similar systemic mechanisms could produce an interaction between AR and secretory otitis media or asthma. It is not known whether treating AR can lessen the severity of CHES, but the observation that nasal-directed therapies can attenuate bronchial inflammation and symptoms of asthma suggests that such a linkage is plausible.

PREVENTION

Avoidance and Environmental Control

When feasible, avoidance or elimination of the source of the allergen is the treatment of choice for patients with AR. Avoidance studies in AR are limited, and the amount of allergen reduction needed to alleviate symptoms is unknown. Avoidance studies in asthma (Chapter 87) provide compelling evidence of a beneficial effect on bronchial hyperreactivity, symptom severity, and need for β-agonist rescue therapy.

Dust mite avoidance involves four principles: (1) remove reservoirs for mite growth (i.e., use allergen-impermeable mattress and pillow covers and remove fitted carpets), (2) keep the relative humidity lower than 50%, (3) wash bedding in hot water (130° F) to kill mites, and (4) wear a simple mask when dust is being disturbed. Many of the measures suggested for mites are also helpful for fungi, especially dehumidification. Windows, shower curtains, and indoor plants are important sites for fungal growth and can be treated with mild fungicides (dilute household bleach).

In some houses, and particularly urban apartment blocks, large numbers of cockroaches are present, and IgE sensitivity is common. Although it may be difficult to kill cockroaches in an apartment, it is usually possible to keep a house clear of cockroaches by using chemical sprays and traps. Care must be taken when using chemical sprays because they be an irritant to asthmatic patients.

Air-conditioning with closed windows is useful for reducing seasonal allergens, and the dehumidification provided by air-conditioning also mitigates the mite and indoor mold load.

Pets, especially cats, are the most preventable source of allergic diseases. Animal dander accumulates in houses over a prolonged period and takes many months to eliminate after the pet is removed. Although it is difficult to persuade patients to get rid of their animals, it may be possible to move the pet outside into the garage or to restrict the pet's access to certain parts of the house. Dogs kept outside and allowed into the house only occasionally do not appear to be an important cause of symptoms. Cat allergy is a much more serious problem because a single cat can deposit a huge concentration of allergen. Cat owners, in turn, deposit sufficient concentrations of allergen in classrooms and work environments to induce symptoms in their allergic colleagues. The dominant rodent allergen is a urinary protein, and rodents, like cats, can deposit large quantities of allergen in a house.

EVIDENCE-BASED TREATMENTS Rx

Although avoidance interventions can reduce allergen levels, they often fail to produce clinically significant improvement.[1,2] As a result, pharmacotherapy is frequently required.

Antihistamines

Antihistamines are the oldest drugs used to treat AR and are considered first-line therapy. Antihistamines compete with histamine for the H_1-receptor sites that contribute to sneezing, itching, rhinorrhea, and conjunctivitis. Oral antihistamines ameliorate these symptoms of AR but generally do not improve nasal congestion. They also inhibit mast cell activation as manifested by diminished histamine, cysteinyl leukotrienes, and mast cell tryptase secretion. First-generation antihistamines cross the blood-brain barrier and have significant sedative and anticholinergic effects. In addition to causing sleepiness, they interfere with school, work, driving, or use of machinery. Whereas only 10 to 15% of treated patients complain of sedation, virtually all subjects demonstrate decreased motor skills, diminished driving ability, and reduced cognition when they are given first-generation antihistamines (e.g., chlorpheniramine, diphenhydramine, clemastine). Therefore, use of these drugs is no longer recommended. Second-generation antihistamines have a longer duration of action, do not cross the blood-brain barrier, and are nonsedating. These agents include fexofenadine, descarboxyloratadine, and loratadine. Although less sedating than their parent compound hydroxyzine, cetirizine and levocetirizine may occasionally produce sedation. The intranasal antihistamines azelastine and olopatadine do not have a significantly more rapid onset of action than currently available oral antihistamines, but they do have decongestant efficacy and are useful in nonallergic forms of rhinitis. No studies have convincingly demonstrated the superiority of one oral antihistamine over another.

As discussed earlier, the role of histamine diminishes over the course of an allergy season or with PAR, making antihistamines less effective. Antihistamines are quite effective for acute allergic reactions that are mediated prominently by mast cell–derived histamine; as such, they are most beneficial in patients with intermittent allergen exposures, such as occasional outdoor exposure during pollen season. In patients with continuous allergen exposures, however, such as PAR caused by indoor allergens or after several days of continuous exposure to seasonal allergens, these drugs often prove to be little better than placebo.[3,4]

Decongestants

Decongestants such as pseudoephedrine treat nasal stuffiness but are mild stimulants. These drugs are usually used in combination with antihistamines to control the full spectrum of AR symptoms. Antihistamines and decongestants alone generally do not provide satisfactory relief in patients with moderate to severe AR.

Leukotriene Modifiers

Leukotriene modifiers (zileuton, zafirlukast, montelukast) have confirmed efficacy in AR comparable to that of antihistamines.[3,4] This efficacy reflects the presence and importance of these pro-inflammatory vasoactive mediators in AR. Zafirlukast significantly reduces sneezing, rhinorrhea, and—in contrast to antihistamines—nasal congestion in patients with SAR. Similarly, montelukast significantly improves nasal and ocular symptoms as well as quality of life in patients with SAR and PAR.[3] No studies have been performed to determine whether, in contrast to antihistamines, leukotriene modifiers have additive effects when combined with intranasal corticosteroids in patients with refractory AR.

Nasal Cromolyn

Nasal cromolyn stabilizes mast cells and mediates additional anti-inflammatory activities toward macrophages and T lymphocytes. Although not as effective as intranasal corticosteroids, cromolyn provides relief in patients with mild to moderate symptoms,[4] and it may be effective in combination with corticosteroids in the treatment of refractory symptoms. The

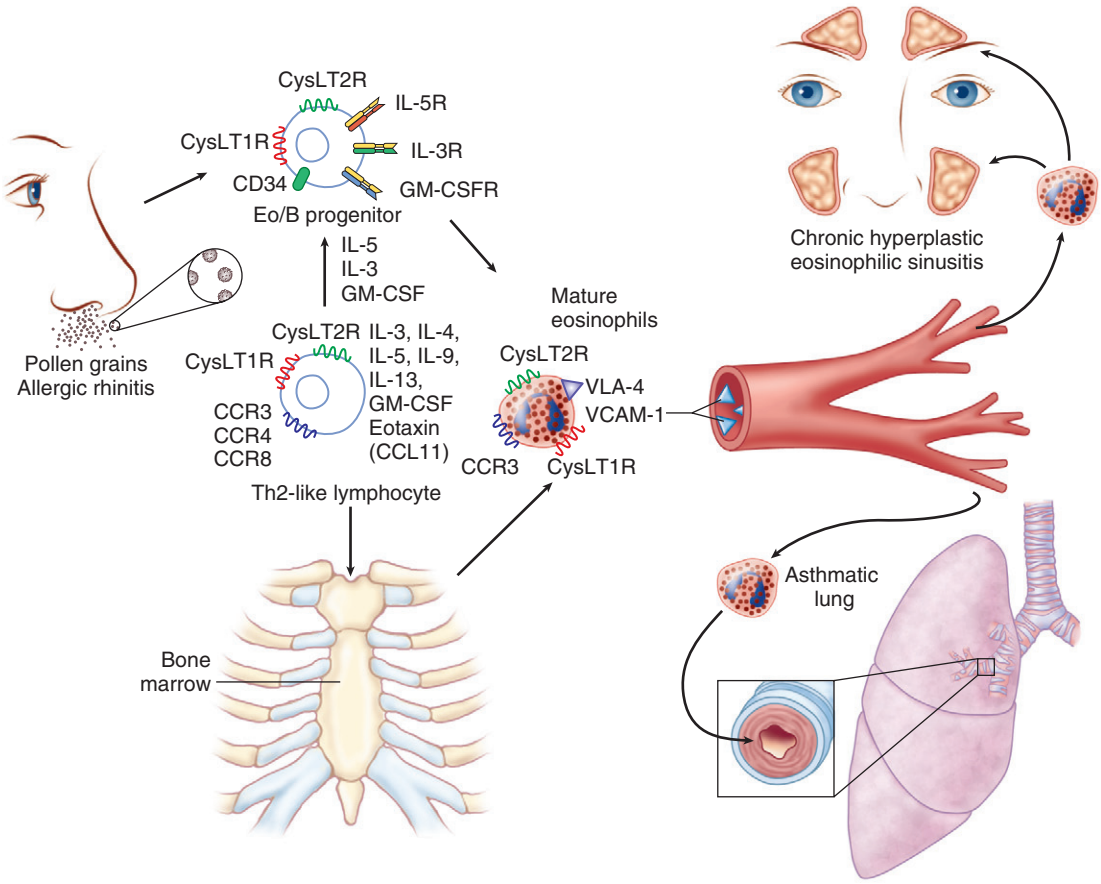

FIGURE 259-3. In sensitized subjects, allergen exposure activates immune cells, including helper T (Th) lymphocytes, dendritic cells, mononuclear phagocytic cells, mast cells, and others, both within the nares and in nasal-associated lymphatic tissues. These cells may also include locally produced $CD34^+$ interleukin-5 receptor-positive ($IL\text{-}5R^+$) eosinophil/basophil (Eo/B) progenitors. These newly activated Th lymphocytes have the phenotype of Th2-like cells, characterized by their production of IL-3, IL-4, IL-5, IL-9, IL-13, CCL11 (eotaxin), and granulocyte-monocyte colony-stimulating factor (GM-CSF). Some of these T_H cells migrate to the bone marrow, where they stimulate the marrow to produce inflammatory cells, including basophils, mast cells, and—most important—eosinophils. Ultimately, these newly generated inflammatory cells enter the circulatory system and are selectively recruited back to the nose as well as to the sinuses (and lungs), thus exacerbating inflammation. This selective recruitment of inflammatory cells into the sinuses and lungs occurs only in individuals with preexisting chronic hyperplastic eosinophilic sinusitis and asthma in whom specific adhesion molecules, such as vascular cell adhesion molecule-1 (VCAM-1), and chemoattractants, such as CCL11, already exist. VLA-4 = α4B1 integrin; very late antigen-4. (From Borish L. Allergic rhinitis: systemic inflammation and implications for management. *J Allergy Clin Immunol*. 2003;112:1021-1032.)

value of cromolyn is mitigated by the need for frequent doses (four times/day), a lack of efficacy in approximately 30 to 40% of recipients, and the superior efficacy of intranasal corticosteroids in controlled studies. Cromolyn (one to two sprays in each nostril every 3 to 4 hours) may be especially useful preventatively (e.g., immediately before cat exposure or before the start of the allergen season). Unlike antihistamines, cromolyn controls nasal congestion. Ocular cromolyn has been especially useful in the treatment of allergic conjunctivitis. No significant side effects are associated with its use.

Intranasal Corticosteroids

Intranasal corticosteroids (fluticasone [Flonase, Veramyst], triamcinolone [Nasacort], flunisolide [Nasarel], budesonide [Rhinocort], mometasone [Nasonex], and ciclesonide [Omnaris]) are the most effective AR treatments and are considered the treatments of choice for patients with moderate to severe SAR or PAR.[4,5] Comparative studies of antihistamines and intranasal corticosteroids consistently favor the corticosteroids and show insignificant additive effects when antihistamines are combined with optimal topical corticosteroids.[4,6] In well-performed placebo-controlled studies, intranasal corticosteroids provided a 50 to 90% reduction in symptoms (compared with 20 to 30% for antihistamines). In contrast to antihistamines, topical corticosteroids reduce nasal congestion in addition to relieving itching, rhinorrhea, sneezing, and allergic conjunctivitis. Few studies have directly addressed the influence of corticosteroids on the systemic effects of AR—including missed work and school, poor productivity, reduced cognition, and fatigue—which are often the dominant complaints of patients with AR; however, intranasal corticosteroids significantly improve quality of life, reflecting relief from these complaints. Corticosteroid therapy must be given for up to 1 week before it is fully effective, so ideally, it should be started before exposure or the start of the allergy season. However, intranasal corticosteroids produce some clinical improvement in less than 24 hours and possibly as quickly as 6 to 8 hours. Although efficacy is greatest with continuous administration, as-needed intranasal corticosteroids have proved efficacious.

Topical corticosteroid therapy does not inhibit IgE synthesis or mast cell degranulation, traditionally considered the two determinants for the development of AR. However, corticosteroids do inhibit T-lymphocyte proliferation, chemokine and cytokine production, recruitment of eosinophils and basophils, mucous secretion, vascular permeability, and mast cell proliferation. Intranasal corticosteroid use is therefore associated with diminished nasal eosinophilia, mast cell numbers, and cytokine expression. The efficacy of intranasal corticosteroids emphasizes the importance of these nonhistamine mechanisms to the pathophysiology of AR.

Several intranasal corticosteroid preparations are currently available and differ according to dose, approval age, and propellant (Table 259-4). No studies have demonstrated superior efficacy for any of the nasal corticosteroid preparations. Clinical experience with asthma (Chapter 87) suggests that patients refractory to one intranasal corticosteroid may be switched to a higher-potency corticosteroid; however, the best evidence is that all these agents are comparably valuable when patients are willing to comply with their use. Choices should be based primarily on patient preference.

There is no convincing evidence of clinically significant systemic absorption or the production of systemic side effects from intranasal corticosteroids. Given these drugs' hydrophobicity, local metabolism, and lack of absorption from lung tissue, systemic absorption from the nasal passages is unlikely. Intranasal corticosteroids, even at greater than recommended doses, do not significantly suppress serum or urinary cortisol levels or adrenocorticotropic hormone stimulation tests. Studies have reported a small but statistically significant effect on short-term growth velocity in children with PAR but no impact on ultimate adult height. Nasal corticosteroids cause minimal topical side effects, including local irritation, dryness, and epistaxis. Adverse side effects may differ based on the drug's formulation; aqueous formulations usually produce fewer adverse reactions than aerosols. Nasal biopsy studies do not demonstrate nasal atrophy. Nasal perforation has been reported, but primarily in the setting of underlying devascularization (previous trauma, surgery, or cocaine abuse).

TABLE 259-4 INTRANASAL CORTICOSTEROIDS*

GENERIC NAME	DOSE (PER ACTUATION)	MINIMUM APPROVED AGE	USUAL DOSING
Flunisolide	25 µg	6 yr	Twice daily
Triamcinolone	55 µg	6 yr	Once daily
Budesonide	32 µg	6 yr	Twice daily
Fluticasone	50 µg	4 yr	Once daily
Mometasone	50 µg	12 yr	Once daily
Ciclesonide	50 µg	6 yr	Once daily

*Intranasal corticosteroids are generally administered at 2 sprays per nostril.

Immunotherapy

The clinical efficacy of immunotherapy for AR caused by grass, ragweed, many other pollens, cat and dog dander, and dust mites has been categorically established in innumerable well-designed, controlled studies. Immunotherapy decreases the severity of AR, reduces the need for pharmacotherapy, and significantly improves quality of life. In patients with severe AR and conjunctivitis poorly controlled by antihistamines and intranasal corticosteroids, immunotherapy can reduce allergen sensitivity by more than 10-fold, as well as significantly decreasing total symptoms and reducing total antiallergic drug usage.[7,8] The efficacy of immunotherapy has also been convincingly established in allergen-exacerbated (extrinsic) asthma (Chapter 87), with studies showing decreased symptoms and less need for β-agonist rescue therapy. Efficacy depends on delivery of the correct antigen, regular injections for 3 to 5 years, and administration of an adequate dose of the allergen (10 to 15 µg), a dose significantly higher than those used historically.

Immunotherapy is indicated primarily in patients with refractory rhinitis or in those experiencing unacceptable side effects from standard medications. Because intranasal corticosteroids are not universally effective and do not provide complete relief in all patients, consideration of immunotherapy is necessary. In addition, despite the excellent safety profile of intranasal corticosteroids, many patients are reluctant to use them. Patients should normally go through at least one full pollen season before considering immunotherapy. Immunotherapy is the only treatment that produces long-term immune modulation. Both avoidance and pharmacotherapy are effective only if they are sustained. The effects of immunotherapy, in contrast, persist for many years after a 3- to 5-year course of treatment has been discontinued, and they could be lifelong.[9] A 5-year course of immunotherapy also has cost advantages over lifelong pharmacotherapy. Many patients are attracted to immunotherapy by this potential for long-term immune modulation, remission of symptoms, and ability to discontinue daily pharmacotherapy.

Immunotherapy is associated with a small risk of fatal anaphylaxis (about 3 fatalities/year in the United States, out of 2 million people receiving this form of treatment). Because of this risk, immunotherapy must be administered only in a facility where resuscitation equipment and trained personnel are available. Asthmatic patients are uniquely at risk for fatal anaphylaxis, so immunotherapy should be recommended with caution in these patients.

Summary

Many patients have multiple antigen sensitivities, and specific immunotherapy at effective doses may not be practical. Furthermore, immunotherapy has poor efficacy for many antigens, such as molds. These issues have led to a search for new immune-based therapies capable of attenuating allergic inflammation. Many experimental approaches being developed for asthma, including various anticytokine therapies, may have efficacy for AR.

In general, however, currently available therapies provide adequate relief for virtually all AR sufferers. The persistence of nasal symptoms in the face of adequate AR-directed pharmacotherapies should suggest the diagnosis of an alternative form of rhinitis (see Fig. 259-1) or the presence of sinusitis or atypical migraines. Given the high frequency of AR in the population (and the even higher prevalence of allergic sensitization), treatment becomes particularly challenging when a patient presents with nonallergic nasal symptoms and either concomitant AR or evidence of allergic sensitization (IgE) in the absence of AR.

260 URTICARIA AND ANGIOEDEMA

STEPHEN C. DRESKIN

URTICARIA

Urticaria (hives) consists of pruritic, edematous, erythematous, blanching papules that are round or oval in shape; have pale, raised centers (wheals); are several millimeters to a few centimeters in size; and are transient, lasting minutes to days (Fig. 260-1). Angioedema appears as a brawny, nonpitting edema, typically without well-defined margins and without erythema. Angioedema can be accompanied by a sense of burning, pressure, or aching but not pruritus; it is distinguished from other edematous states by its frequent involvement of the lips, tongue, eyelids, hands, feet, or genitalia and its rare occurrence in dependent areas of the body. Episodes (daily or almost daily symptoms) of recurrent hives and/or angioedema over a period of less than 6 weeks are considered acute, and those lasting longer are said to be chronic. Patients typically present with urticaria alone or urticaria with angioedema. Rarely, patients present with angioedema alone. The terms *urticaria* and *urticaria/angioedema* are used interchangeably here to refer to illnesses characterized by urticaria and/or angioedema in which mast cells are activated.

EPIDEMIOLOGY

Urticaria/angioedema occurs in 15 to 25% of individuals at some time during their lives and can affect both genders and all races. Acute urticaria is more common in young adults and children. Chronic urticaria is more common in adults, affecting women (75% of cases) more often than men.

PATHOBIOLOGY

Mast cells, the primary effector cells in urticaria/angioedema, are found in high numbers throughout the body, particularly within the subcutaneous tissue. After activation of mast cells there is a rapid (<10 minutes) release of histamine, leukotriene C_4 (LTC_4), and prostaglandin D_2 (PGD_2), leading to vasodilation, subcutaneous and intradermal leakage of plasma from postcapillary venules, and pruritus. In addition, there is the delayed (4 to 8 hours) production and secretion of inflammatory cytokines such as tumor necrosis factor-α (TNF-α), interleukin (IL)-4, and IL-5, leading to an inflammatory infiltrate and perpetuation of longer-lived lesions. Angioedema is formed by a similar extravasation of fluid, not superficially in the skin but in deeper dermal and subdermal sites.

Lesions of acute urticaria typically show subcutaneous edema with widened dermal papillae, swollen collagen fibers, and rare inflammatory cells. Most episodes of acute urticaria/angioedema are caused by immediate hypersensitivity reactions to drugs or foods or result from inflammatory

FIGURE 260-1. Extensive urticaria. Many presentations are more subtle. (From Roitt I, Brostoff J, Male D, eds. *Immunology*, 6th ed. London: Mosby; 2001: figure 21-2.)

processes initiated by viral illnesses. The most common drugs that cause acute urticaria/angioedema are penicillins, sulfonamides, muscle relaxants, diuretics, and nonsteroidal anti-inflammatory drugs (NSAIDs), although any drug acting as a hapten can generate an allergic response. The predominant allergenic foods are milk, eggs, and peanuts for children and peanuts, tree nuts, fish, and shellfish for adults, although sensitization can occur to many other foods as well. These allergens cross-link immunoglobulin (Ig) E bound to the high-affinity receptor for IgE (FcεRI), leading to activation of mast cells. Some drugs (e.g., opioids, vancomycin, NSAIDs) and radiocontrast dye can activate mast cells by an IgE-independent (pseudoallergic) mechanism. Ingestion of fish contaminated with bacteria that produce histamine leads to hives as part of a toxic reaction to the histamine (scombroid food poisoning).

Lesions of chronic urticaria are characterized by similar edematous findings, with the addition of a dense perivascular inflammatory infiltrate consisting of $CD4^-$ and $CD8^+$ T lymphocytes, eosinophils, basophils, and neutrophils. A minority of patients exhibit urticarial vasculitis, with lesions characterized by vascular destruction with leukocytoclasis.

The largest subgroup of chronic urticaria/angioedema is idiopathic urticaria, accounting for approximately 80% of cases. These patients have symptoms in the absence of a specific physical trigger, allergen exposure, or coexistent disease. Half the patients with idiopathic urticaria have evidence of autoimmunity based on the presence of IgG antibodies that can cross-link FcεRI and/or antithyroid antibodies. Some experts consider these patients to have a separate entity called *autoimmune urticaria,* whereas others consider these patients to have idiopathic urticaria with evidence of autoimmunity.

Physical stimuli activate mast cells by unknown mechanisms and account for about 20% of cases of chronic urticaria. The most common of the physical urticarias is dermographism (also called dermatographism), in which wheals can be "written on the skin" by simple stroking or scratching. Cholinergic urticaria is often included as a physical urticaria, although the trigger leading to mast cell activation is related to cholinergic stimuli occurring after exposure to heat or after exercise. Other physical stimuli can cause urticaria, including cold, solar radiation, pressure, vibration, and water. Cold-induced urticaria is rarely caused by cryoglobulins.

In approximately 5% of patients with chronic urticaria/angioedema, symptoms appear to be caused by ingestants (e.g., foods, medications, dietary supplements), contactants (e.g., soaps, detergents, cosmetics, hair or nail products, latex), concomitant infections, hormonal changes, or systemic illnesses. A food must be consumed regularly to cause chronic urticaria. Wheat is occasionally found to be a trigger. Multicellular parasites (e.g., those causing strongyloidiasis or filariasis) elicit strong IgE responses and are important causes of chronic urticaria in endemic areas. Rare patients report that their urticaria occurs only during menses or is worsened by menses. Some of these patients have immediate hypersensitivity to progesterone (positive skin tests), and others may be reacting to NSAIDs taken for uterine cramping. Chronic urticaria/angioedema can be associated with flares of rheumatic conditions, other autoimmune conditions (including Hashimoto's thyroiditis), or neoplastic conditions. Occult neoplasia is exceedingly unlikely to be the cause of chronic urticaria.

CLINICAL MANIFESTATIONS

Patients often report that the first sensation of urticaria is poorly localized pruritus that quickly develops into the typical lesions of urticaria. The intensity of the pruritus varies from a minor inconvenience to an unbearable sensation that can lead to self-inflicted abrasion of the skin. Groups of hives often appear together over a short period, and episodes of hives can come in waves starting several times a day. Patients with cholinergic urticaria usually have a distinctive clinical presentation of diffuse urticarial lesions measuring a few millimeters in diameter on exertion sufficient to cause sweating. The pruritus is particularly intense, and all the symptoms are generally limited to the skin. A self-rated quality-of-life survey of patients with chronic urticaria revealed dramatic impairment in terms of loss of sleep, fatigue, and emotional discomfort. Angioedema can originate near a wheal or independently in other parts of the body. Symptoms vary from minor discomfort to an intense sense of pressure and may lead to other symptoms, such as severe shortness of breath if there is compromise of the airway.

DIAGNOSIS

The first episode of acute urticaria/angioedema may occur in the absence of an identifiable stimulus. If hives occur 5 to 30 minutes after ingestion of a drug or a food, the patient often can identify the association. If a physician is consulted, the best approach is to take a careful history, with attention to ingestants and intercurrent illnesses. Unnecessary drugs and food supplements should be discontinued, and any recently added medication should be changed to a structurally different agent. Most often no causative agent is identified, and the hives are treated symptomatically (see the later discussion) for days or weeks before they resolve spontaneously.

Differential Diagnosis

The differential diagnosis of chronic urticaria/angioedema includes the subgroups of urticaria discussed earlier: idiopathic, autoimmune, physical, ingestant-mediated, and associated with a variety of systemic illnesses. Other conditions that can be confused with chronic urticaria/angioedema include diffuse pruritus complicated by dermographism, flushing disorders, urticarial vasculitis, urticaria pigmentosa, systemic mastocytosis, exercise-induced anaphylaxis, exercise-induced food-associated anaphylaxis, idiopathic anaphylaxis, hereditary angioedema, acquired angioedema, and angioedema associated with angiotensin-converting enzyme (ACE) inhibitors (Table 260-1).

Approximately 95% of patients with urticaria/angioedema are not reacting to an ingestant and do not have another illness that is causing their hives. However, it is sometimes difficult for patients (and some physicians) to accept this fact, prompting an extensive, invasive, expensive, and unnecessary investigation. The best "test" to identify patients with a specific underlying cause (i.e., physical trigger, autoimmune condition, allergen, or systemic disease) is a careful and detailed history and physical examination by a specialist knowledgeable in urticarial disease.

A good place to begin is by excluding possible physical triggers. Specific tests are available to establish the diagnosis of most physical urticarias, including scratching the skin and exposing the skin to heat, ice, vibration, pressure, ultraviolet radiation, or water. Acquired cold urticaria must be distinguished from the familial cold autoinflammatory syndrome, which is characterized by a cold-induced papular rash (not urticaria) and is now classified in the family of hereditary periodic fever syndromes. Solar urticaria must be distinguished from other types of light sensitivity, including metabolic abnormalities (e.g., erythrogenic porphyria) and photosensitivity due to drugs.

Even though foods and drugs are infrequent causes of chronic urticaria, many patients focus on ingestants and are not satisfied until these causes are ruled out. As in the evaluation of acute urticaria, the patient must discontinue all food supplements and medications that are not absolutely necessary and, if possible, change essential medications to structurally unrelated compounds. The patient then keeps a food diary to identify suspect foods that

can be eliminated. Some allergists use skin tests with foods to identify "suspects." For highly motivated patients, 2 weeks of a severely restricted diet, often based on lamb and rice, is recommended. Antihistamines and other medications used to control the urticaria must be discontinued. If the urticaria resolves, it is critical to reintroduce foods in a controlled fashion to identify the specific food causing the urticaria and to reinstate a healthy diet.

Chronic infections, including sinus infection, dental abscess, *Helicobacter pylori* gastric infection, cholecystitis, onychomycosis, and tinea pedis, have been associated with urticaria. Case reports indicate the resolution of urticaria after treatment of these infections, although rigorous proof of an association is lacking. The natural history of chronic urticaria probably accounts for coincidental spontaneous improvement after treatment of these conditions, at least in some cases.

Laboratory evaluation in a patient with typical urticaria should always include a complete blood count with differential, basic metabolic panel, liver enzymes, and urinalysis. Specialists are not in full agreement regarding the necessity of additional laboratory testing. Levels of thyroid-stimulating hormone and antithyroid antibodies may be measured in otherwise euthyroid-appearing patients to screen for occult hypothyroidism and for antithyroid autoantibodies. Skin tests for immediate hypersensitivity to foods may be ordered for patients with a suggestive history. Some specialists order no screening tests at all. As in vitro tests for anti-FcεRI autoantibodies become more widely available, it is likely that many specialists will perform this test. A positive test for anti-FcεRI autoantibodies is useful, because this reassures the patient that the urticaria is being driven by an internal process and is not caused by an ingestant or occult illness. Also, this finding helps direct the physician toward immunomodulatory therapies. Other tests should be ordered only as a result of positive findings in the history and physical examination.

Although not routinely indicated in every case of chronic urticaria, a skin biopsy can provide useful information. The most common indication for this procedure is to rule out urticarial vasculitis when the hives are more painful than pruritic, last longer than 24 hours, or leave discolored skin. The presence of vascular destruction, fibrinoid necrosis, and immune complex deposition on microscopic examination (including immunofluorescence) should lead to a consideration of the specific causes of urticarial vasculitis (e.g., systemic lupus erythematosus) and the rapid initiation of more aggressive treatment.

Primary mast cell disorders rarely manifest as chronic urticaria (Chapter 263). Systemic mastocytosis is a very rare condition resulting in increased numbers of atypical mast cells in the bone marrow, skin, and other organs. Levels of tryptase (an enzyme specific for mast cells) are usually elevated in the serum. This condition is frequently accompanied by episodic flushing, urticaria pigmentosa, prominent gastrointestinal symptoms, neuropsychiatric symptoms, and/or recurrent anaphylaxis. Urticaria pigmentosa is characterized by distinctive pigmented cutaneous lesions containing nests of mast cells and is not easily confused with urticaria/angioedema.

Hereditary angioedema, acquired angioedema, and angioedema associated with ACE inhibitors are discussed later in this chapter. Briefly, these syndromes are characterized by episodic swelling without urticaria and are best identified by a careful history, physical examination, and focused laboratory evaluation.

TREATMENT Rx

Acute urticaria is usually self-limited and responds well to histamine 1 (H_1)-type antihistamines. Antihistamines work better if they are taken prophylactically rather than after histamine has been released and is bound to the receptor. Patients often self-medicate with or are prescribed diphenhydramine (25 to 50 mg every 6 hours) and hydroxyzine (25 to 50 mg every 6 hours), but they may experience significant sedation. Second-generation antihistamines such as cetirizine (10 mg nightly at bedtime), fexofenadine (180 mg/day), and loratadine (10 mg/day) are much better tolerated and can be effective, although doses two to three times the standard doses are sometimes necessary. Occasionally, a brief course of corticosteroids is warranted to control severe symptoms. Epinephrine (0.3 mL of 1:1000 intramuscularly) quickly (but transiently) reverses the signs and symptoms of urticaria and angioedema. Patients who have experienced potentially life-threatening angioedema or anaphylaxis should have ready access to epinephrine and be knowledgeable about its indications, administration, and brief duration of action. β-Blockers not only can aggravate urticaria but also can interfere with the action of epinephrine. NSAIDs and codeine can lead to IgE-independent mast cell activation. These medications should be discontinued if it is clinically safe to do so.

H_1 antihistamines are the cornerstone of therapy for chronic urticaria/angioedema but are frequently inadequate to control symptoms. Certain H_1 antihistamines have been proposed as "preferred" for particular subtypes of chronic urticaria, such as hydroxyzine (25 to 50 mg three to four times daily) for cholinergic urticaria or cyproheptadine (2 to 4 mg every 6 hours) for cold-induced urticaria. Some have advocated using multiple H_1 antihistamines, changing or "rotating" agents, or using them in dosages well above those approved by U.S. Food and Drug Administration (FDA) labeling procedures.

Approximately 15% of histamine receptors in the skin are of the H_2 subtype; therefore, the addition of an H_2 antihistamine, such as ranitidine (150 mg twice daily) or famotidine (20 mg twice daily), is a logical adjunct to H_1 antihistamine therapy, providing additional clinical benefit. The tricyclic antidepressant doxepin (10 to 100 mg nightly at bedtime) has highly potent H_1 and H_2 antihistamine activity, with an H_1-receptor affinity almost 800 times that of diphenhydramine and an H_2-receptor affinity 6 times that of cimetidine, but its use can be limited by significant sedation.

Symptoms often persist despite the use of maximal or supramaximal doses of antihistamines. This is not surprising, considering the number of vasoactive and pruritogenic mediators released by mast cells, of which histamine is only one. Antileukotriene medications, such as montelukast (10 mg/day) or zafirlukast (20 mg twice daily) can be added to antihistamines, with some success. Especially severe symptoms may require systemic corticosteroids (prednisone 10 to 60 mg/day) to achieve symptomatic control, but concerns about side effects limit their usefulness.

Refractory symptoms have been treated with a wide variety of other medications. Some of these medications (adrenergic agents, calcium-channel blockers) are thought to decrease the ability of mast cells to release mediators. Others drugs are anti-inflammatory (hydroxychloroquine, sulfasalazine, dapsone, colchicine), immunomodulatory (cyclosporine, tacrolimus, mycophenolate), or antimetabolic (azathioprine, cyclophosphamide, methotrexate). Other treatments of refractory autoimmune chronic urticaria include intravenous immunoglobulin, plasmapheresis, and omalizumab (anti-IgE).

Evidence-Based Treatments

Multiple randomized, placebo-controlled studies of chronic urticaria/angioedema have shown the efficacy of both sedating and nonsedating

antihistamines. If sedating antihistamines must be used, doxepin is more effective than diphenhydramine, but it must be titrated carefully to avoid significant sedation. Prednisone is generally accepted as a mainstay of therapy in difficult cases but has not been formally studied. Cyclosporine (4 mg/kg/day) was shown to be effective in a randomized, placebo-controlled, parallel study of 30 patients with autoimmune urticaria.■ LTC_4 receptor antagonists (montelukast, zafirlukast) do not provide any incremental benefit when added to an antihistamine. Although well described in case studies and used by experts, sulfasalazine, hydroxychloroquine, dapsone, colchicine, methotrexate, azathioprine, intravenous gamma globulin, and omalizumab have not been formally studied.

PREVENTION

It is essential to encourage patients with chronic urticaria to accept the chronicity of their illness and to focus on achieving reasonable symptomatic control with effective treatments that cause the fewest side effects. Many patients with physical urticaria can learn to avoid or minimize triggers. The few patients whose chronic urticaria is a feature of systemic illness may find relief if the underlying condition is appropriately treated. An excellent example is that chronic urticaria in patients with clinically apparent thyroid disease often resolves once the thyroid disease is treated. For many patients, other factors that exacerbate their specific symptoms can be identified, including stress or anxiety, hormonal fluctuations, aspirin and other NSAIDs, and agents that cause cutaneous vasodilation (e.g., alcohol, hot baths or showers, exercise, heated waterbeds). Psychosocial stress is a commonly reported trigger of worsening symptoms. A plausible biochemical mechanism may include increased release of cutaneous neuropeptides known to lower the threshold for mast cell degranulation.

PROGNOSIS

The prognosis for most patients with chronic urticaria/angioedema is excellent. Spontaneous resolution occurs within 12 months in 50% of patients and within 5 years in an additional 20%. However, 10 to 20% of patients, particularly those with physical or autoimmune urticaria, continue to have symptoms for as long as 20 years. Patients who had one episode of chronic urticaria that lasted for months or years and then resolved may experience one or more similar recurrences later in life.

FUTURE DIRECTIONS

The current trend in the treatment of urticaria/angioedema is to use multiple antihistamines and other agents that block the actions of the mediators produced by mast cells. In the near future, it is likely that patients will be treated earlier with anti-inflammatory and immunomodulatory drugs. Some agents under development for asthma and rhinitis may be useful for the treatment of urticaria/angioedema, including 5-lipoxygenase inhibitors, PGD receptor antagonists, and more potent nonsedating antihistamines. Agents that decrease the sensitivity of mast cells to degranulation, such as phosphodiesterase 4 inhibitors and syk kinase inhibitors, may also find a role in the treatment of this condition. In spite of the fact that chronic urticaria/angioedema is not thought to be an IgE-mediated disease, omalizumab, a humanized antibody to IgE, appears to have therapeutic activity. This may be due to unexpected effects of IgE on mast cell activation. This finding could have a significant impact on future therapies.

HEREDITARY ANGIOEDEMA AND RELATED DISEASES

DEFINITION

Hereditary angioedema (HAE) and related illnesses are characterized by recurrent attacks of angioedema mediated by vasoactive peptides such as bradykinin.

EPIDEMIOLOGY

HAE affects approximately 1 in 50,000 people. It is an autosomal dominant disease and therefore affects 50% of offspring of both genders. Frequently, a history of several generations with this disease is obtained, but new mutations do occur, and a negative family history is not uncommon. Acquired angioedema (AAE) is rarer, affecting older persons who often have paraproteinemia or malignancies such as lymphoma. Angioedema associated with ACE inhibitors occurs in 0.1 to 0.2% of treated patients.

PATHOBIOLOGY

HAE and AAE are caused by either low levels or abnormal function of a regulatory protein in the plasma, C1 inhibitor (C1 INH deficiency), which exerts control of the complement, fibrinolytic, and kinin-generating pathways. Because there is one normal gene, levels of C1 INH are detectable but are not sufficient to control the generation of kinins. The C1 esterase enzyme, when activated, cleaves two complement products, C4 and C2; without proper inhibition, this leads to low levels of circulating C4 and C2. C1 INH is also a critical modulator of the bradykinin pathway, and decreased C1 INH function leads to increased levels of bradykinin. Increased generation of bradykinin, not mediators from mast cells or activation of complement, leads to capillary leakage and angioedema.

In HAE type I (85% of patients), the abnormal gene does not produce C1 INH. In HAE type II (15%), an antigenically detectable C1 INH protein is produced, but it is not functional. In HAE type III (very rare), C1 INH is present and functional, but there is a yet-to-be-defined abnormality in the generation of vasoactive compounds. In AAE, unknown factors activate C1 and deplete the C1 INH activity in plasma, or there is an autoantibody to C1 INH that interferes with its function. ACE inhibitor–associated angioedema is due to unintended inhibition of the enzyme that inactivates bradykinin; the complement pathway is unaffected.

CLINICAL MANIFESTATIONS

Children with HAE can have attacks shortly after birth, but these tend to be mild. For most patients, the severity of the attacks worsens at puberty, with episodes of swelling that can affect any external body surface, including the genitalia. Mucosal surfaces are also affected, and patients can have life-threatening swelling of the uvula and posterior pharynx, leading to asphyxiation. Swelling of the submucosa of the gastrointestinal tract can cause symptoms of an "acute abdomen," leading to unnecessary exploratory laparotomy. About half of patients report that trauma, particularly trauma associated with local pressure, precipitates an attack, and about half note an increased frequency of attacks during times of emotional stress. Attacks in patients with AAE are clinically similar to those in patients with HAE. In patients taking ACE inhibitors, angioedema may manifests as severe swelling or simply as a chronic cough beginning days to months after ACE inhibitor therapy is initiated.

DIAGNOSIS

The best tests to support the diagnosis of HAE or AAE are measurements of C1 INH levels, C1 INH function, and C4 levels, particularly during an attack. The distinguishing features of AAE are onset later in life and the presence of a malignancy or paraproteinemia. However, in addition to having low levels of C2 and C4, patients with AAE can have profound depressions in the level of C1, a protein that is commonly normal in HAE. Patients with ACE inhibitor–associated angioedema can present within hours after initiation of therapy or after many months. The angioedema seen in urticaria/angioedema is distinctive, in that it is usually associated with urticaria and is pruritic, responding to antihistamines, steroids, and epinephrine.

TREATMENT Rx

Acute Attacks of HAE

C1 INH concentrate (20 units/kg intravenously) is the treatment of choice for acute attacks.■ Another new agent, ecallantide, an inhibitor of the bradykinin B_2 receptor, is also approved for treatment of acute attacks (30 mg SC).■ If C1 INH concentrate or ecallantide is not available, treatment of angioedema of the airway should include racemic epinephrine (1:1000) delivered in the airway by nebulization and by intramuscular injections (0.2 to 0.3 mL of 1:1000 at intervals of 20 to 30 minutes). The addition of antihistamine for sedation may be helpful. Treating physicians must be prepared to perform nasotracheal intubation, preferably in the operating room under conditions in which tracheostomy can be performed if needed. Acute attacks can be terminated by administering 2 units of fresh-frozen plasma (FFP) to supply the missing C1 INH, but in rare instances, patients may become more edematous, presumably reflecting the increased availability of substrates for the generation of kinins. Therefore, although FFP can be useful for treating non–life-threatening acute attacks, it is not recommended for life-threatening laryngeal edema. At this time, C1 INH concentrate and ecallantide are the recommended treatments for acute abdominal or facial attacks.

Long-Term Treatment of HAE

Attenuated androgens, such as danazol (100 to 200 mg up to twice daily), increase the production of C1 INH and lead to a marked amelioration of symptoms in patients with HAE. Masculinizing side effects are usually mild but can be problematic. C1 INH concentrate (1000 units IV every 3 to 4 days) is approved for long-term treatment but is very expensive.

Prophylaxis

Patients should be treated prophylactically before dental work or other procedures that involve trauma to tissue. Those treated with attenuated androgens, antifibrinolytic agents, FFP (2 units intravenously), or C1 INH concentrate (500 units subcutaneously) have fewer attacks.

Acquired Angioedema

Treatment of AAE is similar to that for HAE, but definitive treatment requires amelioration of the underlying disease. Treatment of angioedema associated with the use of an ACE inhibitor includes antihistamines, epinephrine, or both, as appropriate, and discontinuation of the ACE inhibitor. The direct renin inhibitor aliskiren is also associated with a significant risk of angioedema. Rare patients develop angioedema when taking angiotension receptor blockers. An approach to the evaluation and treatment of patients with urticaria and angioedema is summarized in Figure 260-2.

Evidence-Based Treatments

Current therapy for HAE in the United States is directed toward prophylactic treatment, including attenuated androgens, antifibrinolytics, and FFP. C1 INH concentrate and danazol were shown in a double-blind, placebo-controlled trial to significantly reduce the number of acute attacks; they are also used for prophylaxis. In a study of 193 episodes of laryngeal edema treated with C1 INH concentrate, 192 responded within 60 minutes, and the remaining 1 case responded at 4 hours.

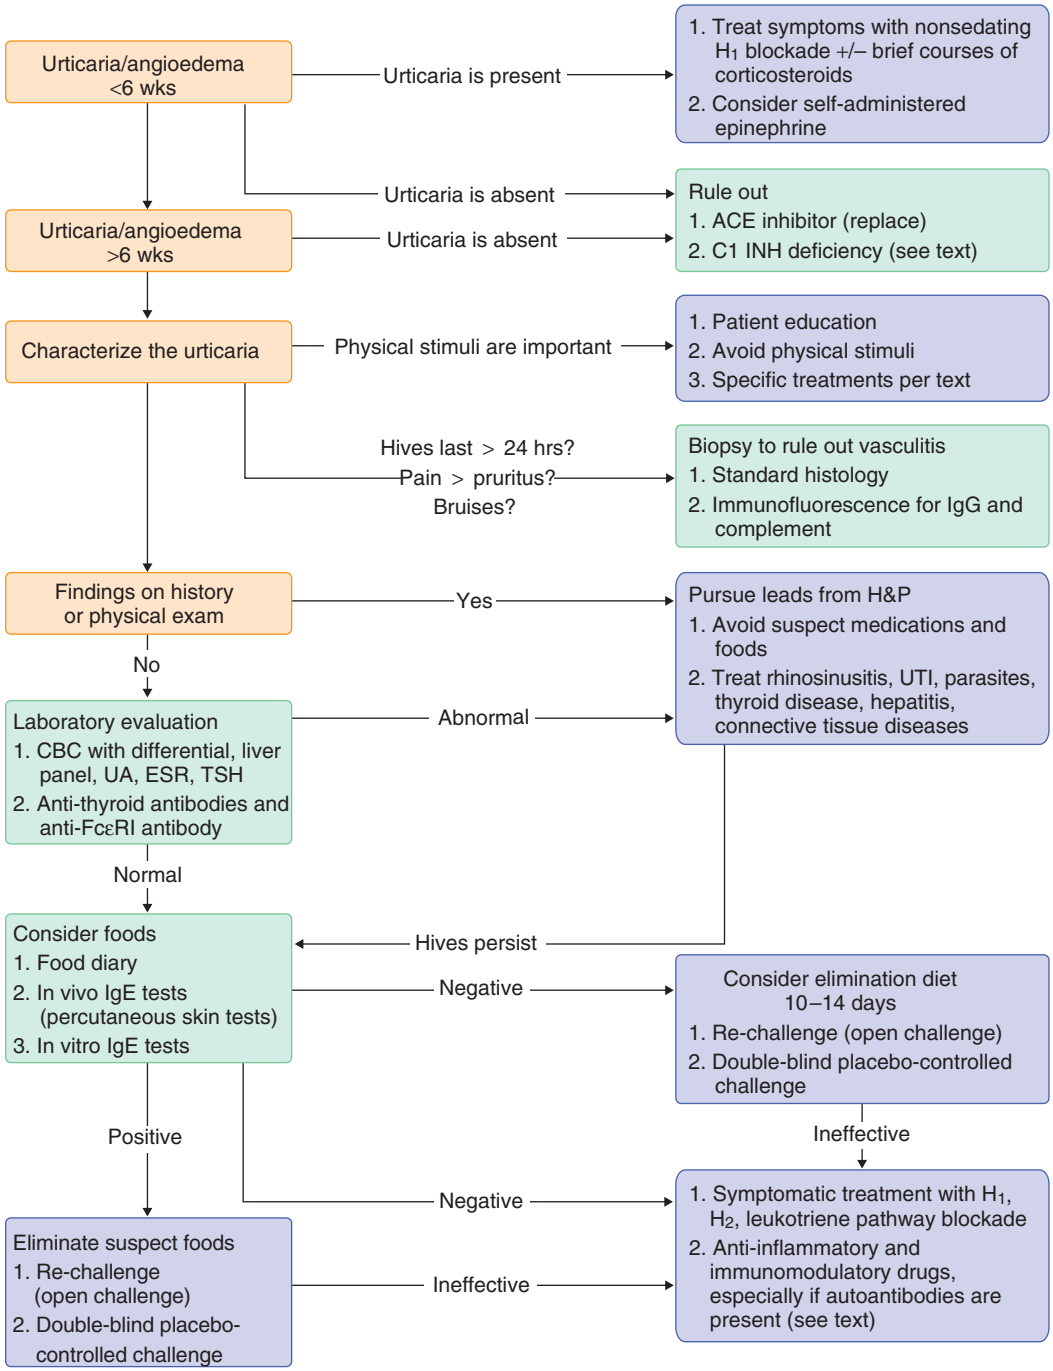

FIGURE 260-2. Evaluation and treatment of urticaria/angioedema. Treatment of urticaria with or without angioedema (AE) is similar. Treatment of AE without urticaria depends on the cause. If the AE is caused by an angiotensin-converting enzyme (ACE) inhibitor, discontinuation of the medication is required. Treatment of AE caused by a deficiency or dysfunction of C1 inhibitor (C1 INH) is discussed in the text. Idiopathic AE often responds to treatments described for urticaria/angioedema. CBC = complete blood count; ESR = erythrocyte sedimentation rate; FcεRI = high-affinity receptor for IgE; H & P = history and physical examination; H_1 = histamine 1; H_2 = histamine 2; IgE = immunoglobulin E; IgG = immunoglobulin G; TSH = thyroid-stimulating hormone; UA = urinalysis; UTI = urinary tract infection.

PROGNOSIS

The long-term outlook for patients with HAE is largely dependent on the phenotype of the illness (frequency of laryngeal attacks), the patient's access to C1 INH concentrate, and how well the patient tolerates attenuated androgens. For most patients, life expectancy should be normal. AAE usually resolves with treatment of the underlying condition, but the ultimate prognosis depends on the nature of that illness. Angioedema associated with the use of an ACE inhibitor resolves after the medication is removed.

FUTURE DIRECTIONS

For the treatment of HAE and related disorders, there is a strong effort to have C1 INH concentrate approved for use in the United States. New therapies are also being developed, including kallikrein inhibitors, bradykinin receptor antagonists, and recombinant C1 INH.

SYSTEMIC ANAPHYLAXIS, FOOD ALLERGY, AND INSECT STING ALLERGY

LAWRENCE B. SCHWARTZ

DEFINITION

Systemic anaphylaxis, a form of immediate hypersensitivity, arises when mast cells and possibly basophils are provoked to secrete mediators with potent vasoactive and smooth muscle contractile activities that evoke a systemic response. Although mast cells in any organ system may be involved, depending on the distribution of the instigating stimulus, the principal targets are the cardiovascular, cutaneous, respiratory, and gastrointestinal systems, sites where mast cells are most abundant. Systemic anaphylaxis can occur when these cells are activated by an allergen that binds immunoglobulin (Ig) E, resulting in classic immediate hypersensitivity, or when they are activated by alternative pathways.

EPIDEMIOLOGY

Assessments of the annual incidence of systemic anaphylaxis and the prevalence of those at risk for it are compromised by imprecise diagnostic measures. Data analyzed retrospectively in Rochester, Minnesota, indicate that the incidence of systemic anaphylaxis has increased from about 48 per 100,000 person years in 1990 to about 60 in 2000. In the United States, approximately 1500 to 2000 deaths occur each year from systemic anaphylaxis. Nonfatal cases are much more common, estimated to occur at an incidence of between 10 and 100 cases per 100,000 person years. Further analyses suggest that between 3 million and 43 million people (1 to 15% of the U.S. population) may be at risk for such reactions. Drug reactions (Chapter 262) account for many of these cases. β-Lactam antibiotics and radiocontrast media provoke most such events, but the list of offending agents is lengthy and ever-increasing. During general anesthesia, systemic anaphylactic reactions occur with a frequency of about 1 in 3500, and muscle relaxants, latex, and induction drugs are the three classes of agents most commonly implicated.

Anaphylaxis to foods and insect stings each account for about 100 deaths per year. Most fatal anaphylactic reactions to injected venom proteins begin within 30 minutes after the sting. Most fatal food and insect sting reactions and many drug reactions are preceded by an immediate mild hypersensitivity reaction to the same allergen. Recognition that these earlier events are important risk factors for future fatal anaphylaxis should lead to the implementation of an action plan to prevent and deal with such reactions.

Food allergy is found in about 6% of children younger than 3 years and in half that percentage of adults; these individuals are at risk for food-induced anaphylaxis. Most children lose their allergic sensitivities to cow's milk, egg, wheat, or soy by 5 years of age, whereas sensitivities to peanuts, tree nuts, or seafood are typically long-lasting. About 20% of children lose peanut sensitivity by school age, but a small portion of them regain peanut sensitivity later in life, particularly if they continued to avoid this food.

Latex provokes anaphylaxis in a small but significant group of individuals, particularly patients who have undergone multiple surgical procedures early in life, such as those with spina bifida or congenital urinary tract disorders, and those with frequent exposure later in life, such as medical personnel. Estimates of the prevalence of latex hypersensitivity range from 1 to 6% in the general population and about 10% among regularly exposed health care workers. Over a 5-year period, the Food and Drug Administration (FDA) collected approximately 1100 reports of latex-induced anaphylaxis, including 15 deaths. The elimination of powder latex gloves and the use of nonlatex gloves have diminished the prevalence of this problem. Contact hypersensitivity is diagnosed by patch testing, and immediate hypersensitivity is diagnosed by latex-specific IgE tests performed in vitro. Latex allergen skin test reagents have not yet received FDA approval.

PATHOBIOLOGY

Etiology

The mediators produced by activated mast cells and basophils initiate many of the signs and symptoms of anaphylaxis. These cells constitutively express the high-affinity receptor for IgE, FcεRI, on their cell surfaces. Consequently, these cells are always armed by the antigen-specific IgE being produced by sensitive individuals and respond to antigens that aggregate IgE-FcεRI complexes on their cell surfaces. Therapeutic interventions aim to prevent the activation of these cells and to block the production or actions of their mediators. Cells other than mast cells and basophils also undoubtedly participate in systemic anaphylaxis, particularly those expressing FcεRI. Eosinophils, monocytes, antigen-presenting cells, and epithelial cells may be induced to express this receptor and thereby affect the intensity, duration, or character of anaphylactic reactions.

Most IgE-dependent mast cell activation events occur at local sites and result in local disease. For example, allergic conjunctivitis, allergic rhinitis, or allergic asthma typically occurs when allergen lands on the corresponding mucosal surface of a sensitive individual and diffuses into the tissue where mast cells reside. Systemic anaphylaxis presumably requires the allergen (or nonallergen agonist) to be distributed systemically to activate mast cells at remote sites. This is most likely to occur when allergen is administered parenterally; it is less likely after oral ingestion, inhalation, or cutaneous or ocular topical contact. Activation of mast cells in perivascular locations should have the greatest effect on systemic vascular responses. Although mediators released at one tissue site could, in theory, spill into the circulation and affect remote sites, most vasoactive mediators are rapidly metabolized. Accordingly, intravenous penicillin is more likely than oral penicillin to elicit a severe anaphylactic reaction. However, the precise distribution of mast cells activated during anaphylactic reactions is undetermined.

Allergens

The most common allergens causing systemic anaphylactic reactions include drugs, insect venoms, foods, radiocontrast media, allergen immunotherapy injections, and latex (Table 261-1). Most allergens are typically proteins or glycoproteins that serve as complete antigens, capable of eliciting immediate hypersensitivity reactions in a sensitized subject without further processing. The protease activity of some allergens may facilitate their penetration at

TABLE 261-1 CAUSES OF SYSTEMIC ANAPHYLAXIS

IgE-MEDIATED (ANAPHYLAXIS)	NON-IgE-MEDIATED (ANAPHYLACTOID)
Insect stings	Aspirin
Foods	Radiocontrast media
Drugs	Exercise
Latex	Narcotics/vancomycin
Allergen extracts	Autoimmune
	Idiopathic

mucosal sites. Others have lipid binding domains that may increase their antigenic potency. Anaphylactic reactions to a humanized monoclonal antibody, cetuximab, have occurred owing to IgE recognizing a nonhuman carbohydrate moiety made by the animal cells expressing the antibody. In contrast to complete antigens, most drugs act as haptens. They become covalently linked to self-proteins in the circulation, in tissues, or on cells, emerging as multivalent allergens. Multivalency is important for immediate hypersensitivity because the cross-linking of at least two IgE molecules on the surface of cells aggregates FcεRI molecules, which then transmit an activating signal into the cell. Monovalent antigens fail to elicit mediator release because they bind IgE molecules without cross-linking them.

An allergen exposure must lead to sensitization before an immediate hypersensitivity reaction can occur. This process, which takes 1 to 2 weeks, involves antigen processing by antigen-presenting cells, which then present peptide antigens to T_H2 cells (helper T lymphocytes), which in turn select, nurture, and instruct allergen-specific B cells to switch from the production of IgM or IgG to IgE. This involves the production of interleukin (IL)-4 or IL-13 by T_H2 cells and the binding of T_H2 CD40 ligand to B-cell CD40. Consequently, anaphylaxis does not occur on first exposure to an allergen (sensitization phase) but may occur after subsequent exposures.

Most cases of food-induced anaphylaxis in children occur in response to eggs, peanuts, cow's milk, wheat, or soy, whereas peanuts, tree nuts, and seafood account for most reactions in adults. Reactions to seeds such as sesame seem to be growing in importance, and a variety of different foods have proved to be important allergens in specific individuals. Some individuals have the oral allergy syndrome, in which allergic reactions result from food contact but rarely progress to systemic reactions. Many of these reactions are associated with cross-reactivities between food and pollen allergens, such as melon with ragweed pollen and peach or apple with birch pollen. Also, the food epitopes associated with this syndrome are typically conformational (rather than linear) and are therefore more easily destroyed by heating (cooking) and by protease degradation and acid denaturation in the stomach and intestines.

Food allergy–associated, exercise-dependent anaphylaxis occurs when a sensitive subject exercises within several hours after eating a food to which he or she is sensitive, but not when the food is eaten without exercise. Shrimp and wheat are most commonly implicated. Exercise appears to increase intestinal permeability to food antigens, which then enter the systemic circulation. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) can act similarly to exercise. Avoiding the implicated food for at least 4 to 6 hours before exercising is recommended.

The Hymenoptera families primarily responsible for anaphylactic reactions are the Apidae (honeybees and bumblebees), Vespidae (hornets, yellow jackets, and paper wasps), and Formicidae (fire ants). Major allergens of honeybees include phospholipase A_2 (Api m 1), hyaluronidase (Api m 2), and melitin (Api m 4). Bumblebee venom proteins exhibit immunologic cross-reactivity with those of the honeybee, even though melitin is lacking. Vespid venoms cross-react among themselves and include a protein called antigen 5, phospholipase, and hyaluronidase; the latter allergen cross-reacts with bee hyaluronidase. Fire ant venom toxicity is caused principally by various alkaloids, which are not allergenic. Immediate hypersensitivity reactions to fire ant venom target a phospholipase that cross-reacts with the comparable vespid enzyme and various other proteins that are unique antigens. Allergens in fire ant venom cross-react with those in scorpion venom. A person may exhibit an anaphylactic reaction on first exposure to an insect's sting if he or she was previously sensitized to cross-reactive venom from a different insect. In contrast to stinging insects, allergens from biting insects of the Diptera order (mosquitoes, gnats, midges, true flies) are salivary in origin and do not cross-react with Hymenoptera venom allergens. Anaphylaxis to these salivary proteins appears to be uncommon, but precise epidemiologic data are problematic because people are often unaware of mosquito bites, and high-quality commercial diagnostic reagents are not yet available.

Latex allergens are derived from the rubber tree *Hevea brasiliensis*. Irritant dermatitis is the most frequent contact reaction and does not involve acquired immunity. Contact hypersensitivity, which results from cell-mediated immunity to haptenic chemicals added to latex during processing, produces a poison ivy–like local reaction that may appear the day after a sensitive subject is exposed. In contrast, immediate hypersensitivity occurs when IgE is made against proteins naturally found in this plant-derived product. Cutaneous (elastic materials), mucosal or intravascular (catheters), oral (balloon), and inhaled (powdered latex gloves) routes of exposure have been well documented and generally elicit signs and symptoms within minutes of exposure. IgE-mediated cross-reactivities between latex proteins and allergens in certain fresh foods such as banana, chestnut, avocado, kiwi, peach, bell pepper, and tomato have been reported and may necessitate avoidance of these foods.

Non-IgE-Dependent Agonists

Most non-IgE-dependent foreign agents do not require antigen processing and can elicit a mast cell activation response on first exposure. These include radiocontrast dyes, narcotics such as codeine and morphine, and vancomycin (see Table 261-1). The dose and rate of administration and individual variations in sensitivity determine severity. For radiocontrast dyes, media of low ionic strength are less likely than those of high ionic strength to elicit a systemic reaction. Vancomycin produces a mast cell activation event known as "red man syndrome," typically involving urticaria without cardiovascular compromise; this can usually be avoided by reducing the rate of administration of the antibiotic.

Endogenous mast cell activators include neuropeptides such as substance P, neurokinin A, calcitonin gene-related peptide, and the complement anaphylatoxins C3a and C5a. Whether mast cell activation of sufficient magnitude to cause systemic anaphylaxis can result from endogenous secretion or generation of these peptides by themselves is unproved.

Aspirin hypersensitivity typically manifests as either a respiratory or a cardiovascular reaction, although overlap is sometimes observed. Respiratory reactions include bronchospasm, nasal congestion, and rhinorrhea and may extend beyond the respiratory tract to include abdominal cramping, watery diarrhea, and urticaria. Cardiovascular reactions that are clinically identical to allergen-induced systemic anaphylaxis and shock can also occur. In most cases, such reactions appear to be pharmacologically (not IgE) mediated, and in sensitive subjects they can occur in response to any of the cyclooxygenase 1 (COX1) inhibitors (Chapter 36). Although COX inhibitors may shunt arachidonic acid metabolism to the lipoxygenase pathway, a mechanism to explain mast cell activation has not yet emerged. COX2-selective inhibitors appear to be relatively safe in aspirin-intolerant asthmatics, but they may still cause cardiovascular reactions in those who present with this manifestation. Less commonly, sensitivity occurs to only one of the drugs in this class and is caused by IgE against an associated unique chemical moiety on that particular drug.

Physical stimuli may precipitate systemic anaphylaxis in certain individuals. Episodes can occur in response to exercise, heat, solar radiation, vibration, pressure, or cold. Exercise-dependent anaphylaxis is sometimes associated with the ingestion of any food, regardless of whether sensitivity to the food can be documented; it occurs within several hours of ingestion and may be avoided by delaying exercise until several hours after eating.

Autoimmunity and Activating Kit Mutations

Some patients experience spontaneous bouts of anaphylaxis without an obvious stimulus. Those with systemic mastocytosis are particularly prone to systemic anaphylaxis, perhaps because they have too many mast cells and because those mast cells harbor an activating mutation of Kit tyrosine kinase that primes their activation status. A related disorder, mast cell activation syndrome, occurs in patients with clonal mast cell disease, reflected by these same Kit mutations, who have recurrent bouts of anaphylaxis but do not meet the diagnostic criteria for systemic mastocytosis.

Some cases of chronic urticaria are known to be associated with IgG and IgM antibodies against FcεRI or IgE. In such cases, complement activation leading to the generation of complement anaphylatoxins at the surface of mast cells has been postulated to synergize with FcεRI-mediated activation. These reactions may occur preferentially in the skin because the

anaphylatoxin receptors are expressed on the type of mast cell predominant in the skin but not on the type predominant in the lung. An analogous, albeit speculative, autoimmune process might activate mast cells localized in blood vessel walls, resulting in anaphylaxis.

Autoimmune progesterone-mediated anaphylaxis, which tends to occur just before menses, is uncommon but well documented and may respond to oral conjugated estrogens.

Pathophysiology

Mast cells participate in both acquired and innate forms of immunity. They develop in peripheral tissues from bone marrow progenitors (Chapter 159), primarily under the influence of stem cell factor, the ligand for the tyrosine kinase receptor called Kit. Armed with allergen-specific IgE, mast cells are activated by multivalent allergens that cross-link IgE and aggregate FcεRI molecules on the cell surface. This may be important in the defense against certain parasites that elicit a strong IgE response. Experiments performed in rodents suggest that mast cells can also be directly activated by certain bacterial products, leading to the secretion of mediators that recruit neutrophils. This innate immune response may restrain bacterial dissemination until a more potent acquired immune response develops. Activation of mast cells by endogenous peptides such as substance P or calcitonin gene-related peptide may influence basic biologic processes such as wound healing and angiogenesis. Whether human mast cells have a critical, nonredundant role in these biologic and immunologic processes remains controversial. However, their central role in immediate hypersensitivity is clear.

Mediators released by mast cells include preformed mediators stored in secretory granules, newly generated products of arachidonic acid, and an array of cytokines and chemokines. Histamine, formed from histidine by histidine decarboxylase, is the sole biogenic amine stored in all granules of human mast cells and basophils. Histamine released by mast cells or basophils diffuses freely and interacts with H_1, H_2, H_3, and H_4 receptors. H_1 receptors are found on endothelial cells, smooth muscle cells, and sensory nerves; when stimulated, they lead to bronchial and gastrointestinal smooth muscle contraction, vascular smooth muscle relaxation, increased permeability of postcapillary venules, coronary artery vasoconstriction, and pruritus—signs and symptoms often associated with systemic anaphylaxis. In the central nervous system (CNS), blockade of H_1 receptors appears to cause drowsiness. H_2 receptors reside on gastric parietal cells and at lower levels on inflammatory cells, bronchial epithelium, and endothelium and in the CNS. An H_2-receptor-mediated increase in acid production in the stomach, albeit transient, may occur during systemic anaphylaxis, but it is more likely to become clinically significant if histamine levels are chronically elevated, as observed in patients with systemic mastocytosis. H_3 receptors are found primarily on cells in the CNS. H_4 receptors are found on hematopoietic cells such as mast cells, basophils, eosinophils, and lymphocytes and may modulate certain aspects of inflammation, such as eosinophil recruitment, as well as pruritus. Histamine, after its secretion from mast cells and basophils, is rapidly metabolized to inactive methyl histamine and indole acetic acid.

Prostaglandin D_2 (PGD_2) is the principal COX-catalyzed product of arachidonic acid secreted by activated mast cells, but it is not made by basophils. It binds to the G protein–coupled receptors CRTH2 and DP. Both COX1 and COX2 are involved in PGD_2 production by mast cells. Consequently, a bipotent COX inhibitor might be better than a selective one at blocking PGD_2-mediated responses during anaphylaxis, which may include hypotension, bronchospasm, and inhibition of platelet aggregation.

Leukotriene (LT) C_4 is released by both mast cells and basophils after its formation from arachidonic acid and glutathione; its formation is sequentially catalyzed first by 5-lipoxygenase and 5-lipoxygenase-activating protein and then by LTC synthase. Conversion to LTD_4 and LTE_4, which are also bioactive, occurs in the extracellular space. These sulfidopeptide leukotrienes bind to the G protein–coupled receptors cysteinyl leukotriene 1 ($CysLT_1$), on bronchial smooth muscle, epithelial and endothelial cells, and leukocytes, and $CysLT_2$, on vascular smooth muscle, endothelial and epithelial cells, leukocytes, and heart muscle. Sulfidopeptide leukotrienes cause bronchoconstriction, mucus secretion, eosinophil recruitment, vasopermeability, diminished cardiac contractility, vasoconstriction of coronary and peripheral arteries, and vasodilation of venules. Antagonists of $CysLT_1$ (montelukast, zafirlukast) but not of $CysLT_2$, as well as a 5-lipoxygenase inhibitor (zileuton), are currently available for patients.

Platelet-activating factor (PAF) is generated from 2-lyso-glycero-3-phosphorylcholine when an acetyl group is placed on the sn-2 carbon of glycerol by acetyltransferase. PAF activates platelets, but it is also a potent vasoactive mediator that enhances vasodilation and vasopermeability and a smooth muscle constrictor that is capable of inducing bronchospasm. PAF is generated by both mast cells and basophils, as well as by other cell types. Elevated levels of PAF and low levels of circulating PAF acetylhydrolase, which converts PAF back to inactive lyso-PAF by removing the sn-2 acetyl moiety, have been associated with more severe food-induced systemic anaphylaxis.

Sphingosine-1-phosphate (S1P) is generated from sphingosine by sphingosine kinase in activated mast cells as well as in other cell types, and it may affect the vascular response during systemic anaphylaxis.

Mast cells are also the sole or principal source of heparin proteoglycan and certain proteases. All express β-tryptase, and a subset also expresses chymase, mast cell carboxypeptidase, and cathepsin G (like neutrophils and monocytes). Mast cells that express only tryptase are called MC_T cells; those that also express the other proteases are called MC_{TC} cells. Mature tryptase is stored in the secretory granules of all mast cells and is released during the degranulation of activated cells; levels in serum serve as a clinical marker of mast cell activation. In contrast, precursor forms of tryptase (protryptase) are spontaneously secreted by mast cells at rest; levels in serum serve as a clinical marker of the total body burden of mast cells and of anaphylactic risk in allergen-sensitized subjects. MC_{TC} cells express CD88 and therefore are activated by C5a generated during complement activation. Basophils are relatively deficient in these proteases, but they also express CD88.

Cytokines (tumor necrosis factor-α [TNF-α]; IL-4, -5, -6, -8, -13, and -16; granulocyte-macrophage colony-stimulating factor [GM-CSF]; basic fibroblast growth factor [bFGF]; vascular endothelial growth factor [VEGF]) and chemokines (IL-8, monocyte chemotactic protein-1, monocyte inflammatory protein-1α) represent another dimension of the mediators released by mast cells and basophils. Although these mediators are not selectively produced by mast cells and basophils, their vasoactive and inflammatory potential can affect the severity and duration of anaphylaxis. As selective antagonists of the relevant cytokines and chemokines become available and are tested for therapeutic benefits, the roles of these mediators in the pathogenesis of anaphylaxis will be better understood.

DIAGNOSIS

Systemic anaphylaxis can be diagnosed clinically by consensus criteria outlined in Figure 261-1. The acute onset of cutaneous signs of immediate hypersensitivity, along with either hypotension or respiratory compromise in the apparent absence of allergen exposure; the rapid onset of hypersensitivity signs involving at least two organs from among the cutaneous, gastrointestinal, respiratory, and cardiovascular systems after exposure to a likely allergen; or the rapid onset of hypotension after exposure to a known allergen can be used to diagnose systemic anaphylaxis. This can sometimes be precisely confirmed in the laboratory by demonstrating antigen-specific IgE (sensitization) and an acute serum level of total (mature plus pro-) tryptase (mast cell activation) that is greater than a baseline level obtained at least 24 hours after all signs and symptoms have resolved. Skin testing or in vitro measurements of antigen-specific IgE should be delayed for at least 2 weeks after the precipitating event to prevent false-negative results. Insect venom allergies have also been assessed by experimental sting challenges, but these are not recommended for routine evaluation. For food allergies, larger wheal-and-flare responses to prick skin tests and higher IgE titers to specific allergens are associated with more severe reactions. Oral food challenges are performed under certain circumstances, taking care to minimize the risk of systemic anaphylaxis. These food-allergic reactions involve IgE sensitization and IgE-dependent mechanisms and should be distinguished from a variety of other types of adverse food reactions, including lactose intolerance due to a deficiency in lactase, food-induced enterocolitis in infants (in reaction to cow's milk, soy, or grains), and celiac disease associated with the ingestion of gluten in wheat and other grains.

An increased level of total tryptase in serum, which peaks 15 to 60 minutes after the onset of anaphylaxis and then declines, with a half-life of about 2 hours (normal levels being undetectable), indicates that mast cell activation has occurred. The magnitude of mast cell activation is a primary determinant of clinical severity. Although an increased serum total tryptase level during putative systemic anaphylaxis may be useful for distinguishing anaphylaxis from other conditions in the differential diagnosis, elevations do not occur in some cases of anaphylaxis, particularly after food ingestion. This observation raises questions of whether there are anaphylactic pathways that bypass mast cells, perhaps involving basophil activation. Plasma histamine, because it is rapidly metabolized, is not as practical as serum or plasma mature tryptase for detecting anaphylaxis. Urinary histamine or methylhistamine levels

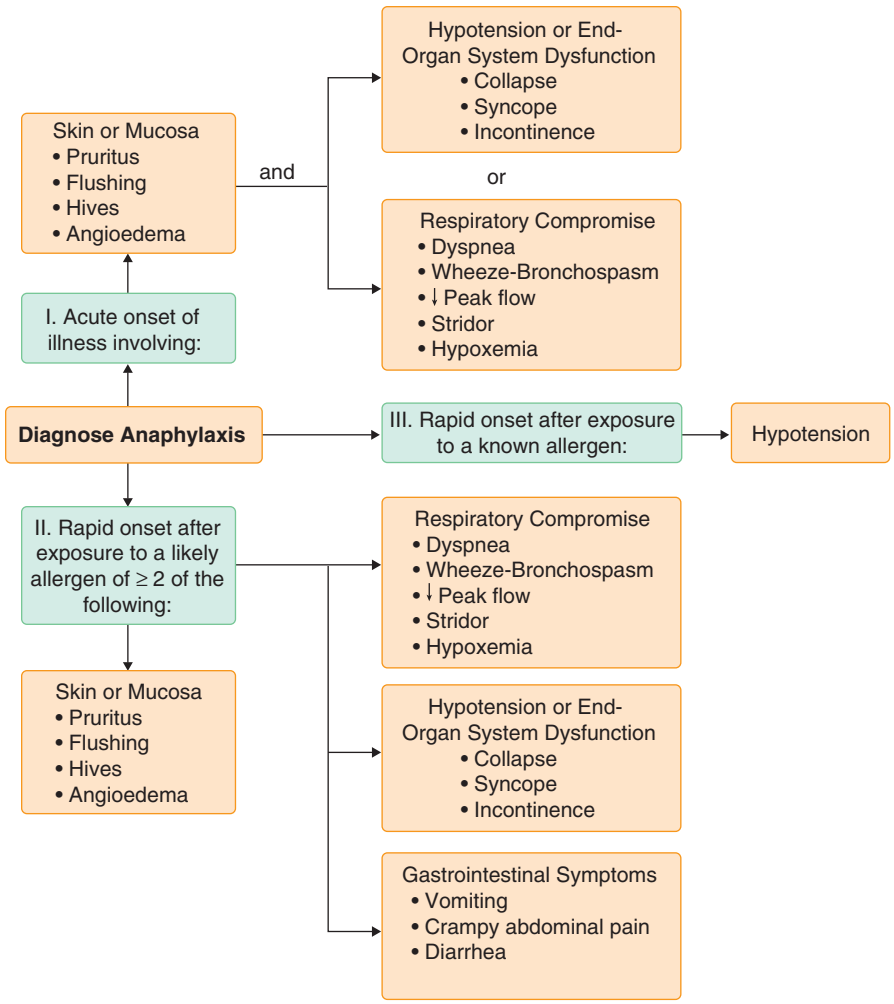

FIGURE 261-1. Clinical diagnosis of systemic anaphylaxis. Acute onset of systemic anaphylaxis in the apparent absence of allergen exposure means that the signs and symptoms develop over minutes to several hours, while rapid onset after exposure to a likely or known allergen means that these signs and symptoms begin to occur within minutes to several hours after that exposure. (Based on Sampson HA, Munoz-Furlong A, Campbell RL, et al. Second symposium on the definition and management of anaphylaxis: summary report—Second National Institute of Allergy and Infectious Disease/Food Allergy and Anaphylaxis Network symposium. *J Allergy Clin Immunol.* 2006;117:391-397).

also may reflect overall levels of released histamine, but they are affected by ingested histamine-containing foods, histamine-producing mucosal bacteria, and variability in histamine metabolism. PGD_2 is also rapidly metabolized and is made by several cell types, including mast cells, and urinary metabolites of this mediator are elevated during anaphylaxis.

Elevated baseline levels of serum total tryptase also appear to be a risk factor for increasing severity of insect venom–mediated systemic anaphylaxis. Future studies will determine whether baseline serum tryptase levels should guide therapy for venom-sensitive subjects as well as for those with other allergic sensitivities. Other risk factors for severe systemic anaphylaxis include a prior allergic event to that allergen and high blood pressure, particularly if the latter is being treated with nonspecific β-blockers or angiotensin-converting enzyme (ACE) inhibitors.

Low serum levels of PAF acetylhydrolase, which metabolizes PAF, and of ACE, which metabolizes bradykinin, have been associated with more severe food-induced systemic anaphylaxis. Whether slow metabolism of PAF and bradykinin might allow these mediators to play a role in such reactions, and whether mediator-specific therapies would be clinically useful in such reactions, remains to be determined.

Differential Diagnosis

Anaphylaxis should be distinguished from a variety of disorders with overlapping presentations. Vasovagal syncope (Chapter 62) causes diaphoresis, nausea, hypotension, and bradycardia, but without urticaria. Flushing disorders may be benign and unrelated to anaphylaxis, or they could be a manifestation of pathologic conditions such as the carcinoid syndrome (Chapter 240), which is typically not associated with urticaria and profound hypotension, or pheochromocytoma (Chapter 235), which causes episodic hypertension. Precise detection of these latter conditions involves the determination of serum levels of serotonin and urinary levels of 5-hydroxyindole acetic acid, catecholamines, and vanillylmandelic acid. Panic attacks and vocal cord dysfunction can be a challenge to distinguish from anaphylaxis, especially by history alone, but they must be considered. Acute attacks of hereditary and acquired angioedema caused by C1 esterase inhibitor deficiency (Chapter 260) are not associated with pruritic urticaria and persist longer than anaphylaxis. Shock due to complement activation by contaminated hemodialysis tubing or to activation of the contact system by an oversulfated chondroitin sulfate contaminant in heparin preparations, presumably leading to the production of bradykinin, has occurred without involving mast cell activation. Scombroidosis occurs 5 to 90 minutes after the ingestion of histamine in poorly stored fish and manifests with flushing, palpitations, headache, and gastrointestinal symptoms. The condition lasts several hours, with both duration and severity dependent on the amount of histamine ingested; it usually responds to H_1-receptor and H_2-receptor antihistamines but occasionally requires epinephrine and intravenous fluids. Acute serum sickness, various cell activation syndromes, endotoxin-mediated septic shock, and superantigen-mediated toxic shock syndromes manifest with fever, which is not characteristic of anaphylaxis by itself. Also, hypoglycemia, seizure, and primary pulmonary or cardiac events should be considered.

The systemic capillary leak syndrome is a rare condition that may present with shock and mimic anaphylaxis or sepsis (Chapter 108). Patients may report preceding fatigue, weakness, and myalgias before presenting with shock and massive edema, accompanied by hemoconcentration and hypoalbuminemia owing to reversible plasma extravasation. About 80% of patients have an underlying monoclonal gammopathy of undetermined significance (Chapter 193), but the role of paraproteins in precipitating the syndrome is unknown. The syndrome is distinguished from anaphylaxis by the presence of hypoalbuminemia and the absence of allergic signs or symptoms; it is distinguished from hereditary angioedema by the presence of severe hypotension. The syndrome typically responds to intravenous vasopressors and fluid replacement, but unlike anaphylaxis, it may be resistant to even high doses of vasopressors. When the syndrome resolves, usually rapidly, the re-entry of plasma into the systemic circulation can cause pulmonary edema. Other acute complications include compartment syndromes, acute tubular

necrosis, rhabdomyolysis, and venous and arterial thrombosis. Most patients survive the acute attack, but recurrences are common and can be prevented or reduced by the administration of terbutaline (20 to 25 mg/day in divided doses, as tolerated) and theophylline (400 to 1600 mg/day to achieve a peak serum concentration between 55.5 and 111 µmol/L).

In some cases, systemic anaphylaxis occurs together with another disorder. For example, severe hypotension or its treatment with epinephrine may precipitate an acute myocardial infarction.

Systemic mastocytosis is an important condition to consider in the setting of anaphylaxis. In adults, a somatic activating mutation in the gene for Kit in mast cell progenitors results in mast cell hyperreactivity and an excessive body burden of mast cells. The disease may regress spontaneously in children, but regression is uncommon in adults. Patients with an elevated baseline level of tryptase, one of the diagnostic criteria for systemic mastocytosis, are at increased risk for anaphylaxis, and anaphylaxis may be a presenting manifestation of an underlying clonal mast cell disorder such as the mast cell activation syndrome or systemic mastocytosis. For example, anaphylaxis in response to an insect sting, particularly in the absence of venom-specific IgE (due to direct mast cell agonists), should raise the possibility of such disorders. Diagnostic criteria for systemic mastocytosis and the mast cell activation syndrome are discussed in detail in Chapter 263.

TREATMENT

Rx

Fatal outcomes in anaphylaxis are principally the result of either airway constriction or hypotension. Accordingly, the acute treatment of systemic anaphylaxis requires that airway patency, blood pressure, and cardiac status be addressed (Fig. 261-2). Intubation, tracheostomy, volume expanders, and vasopressors may be needed. Patients exhibiting any signs or symptoms of hypotension should immediately assume the Trendelenburg position, which may prevent progression to anaphylactic shock or what has been called in postmortem examinations the "empty ventricle syndrome," because almost all hypotensive anaphylactic deaths are preceded by syncope occurring in a sitting or upright posture. Epinephrine injected intramuscularly into the thigh (0.2 to 0.5 mg for adults and 0.01 mg/kg [up to 0.3 mg] for children, repeated every 5 to 30 minutes, as indicated) is the most critical drug to administer; the earlier during the course of an anaphylactic event it is administered, the better. Alternatively, intravenous administration of a solution of epinephrine (1 mg/100 mL solution starting at 30 to 100 mL/hour and titrated to the lowest effective rate of infusion) can be considered. Epinephrine relaxes bronchial smooth muscle and improves vasomotor tone and vasopermeability, thereby counteracting bronchospasm, hypotension, and tissue edema. However, the benefits of epinephrine need to be weighed against its disadvantages in elderly subjects and in those with cerebrovascular or coronary artery disease, hypertension, diabetes, hyperthyroidism, cardiomyopathy, or narrow-angle glaucoma, in whom adverse events such as myocardial infarction, stroke, or pulmonary edema can be precipitated. Also, patients taking a β-blocker may be resistant to epinephrine; in such cases, glucagon (1 mg IV, or 1 to 5 mg/hour IV) or vasopressin (5 to 40 IU IV) may be used. Oxygen should be administered by nasal cannula. Inhaled bronchodilators can relieve bronchospasm. Parenteral administration of H_1-receptor (diphenhydramine 1 to 2 mg/kg, up to 50 mg) and H_2-receptor (ranitidine 300 mg IV over 5 minutes) antihistamines may prevent the progression of some signs and symptoms, particularly urticaria and pruritus, but it is not likely to reverse hypotension or tissue edema. Prednisone (40 mg PO) or Solu-Medrol (40 mg IV) may reduce the risk of a protracted reaction or the late phase of biphasic anaphylaxis, but it is unlikely to be of benefit acutely.

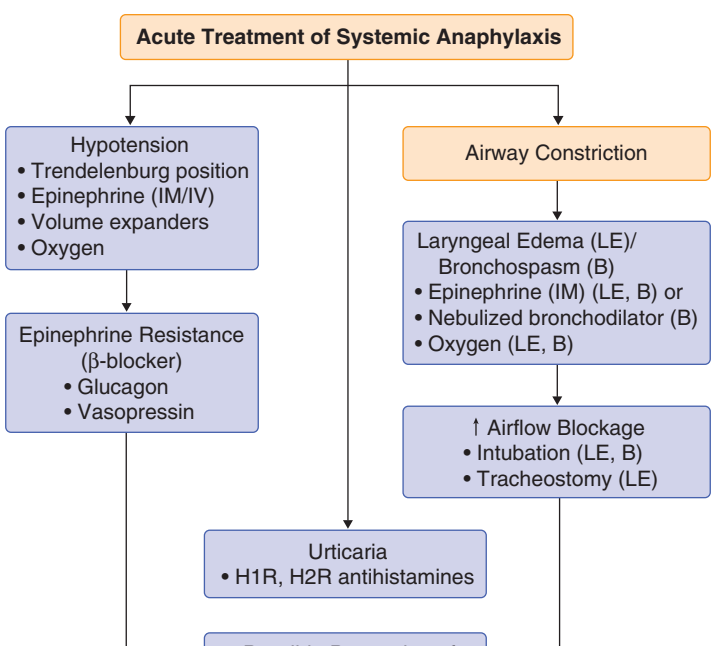

FIGURE 261-2. Acute treatment of systemic anaphylaxis. H1R = histamine-1 receptor; H2R = histamine-2 receptor.

PREVENTION

Patients who have experienced an anaphylactic reaction are at greatest risk for another episode. Such individuals should wear a Medic-Alert bracelet and be instructed in the use of epinephrine (e.g., EpiPen), which they should carry. Avoidance of nonspecific β-blockers and ACE inhibitors is recommended because either may worsen the severity of an anaphylactic episode, and β-blockers clearly interfere with β-agonist treatment. In subjects with recurrent anaphylaxis, prophylactic use of H_1- and H_2-receptor antihistamines is beneficial. A leukotriene antagonist and COX inhibitor would theoretically provide additional benefit, but this has not been well studied. Finally, cyclosporine (3 to 5 mg/kg/day) might be considered in difficult cases of recurrent anaphylaxis because of its ability to inhibit mast cell activation in vitro and in vivo in chronic urticaria. Glucocorticosteroids do not inhibit mast cell activation in vitro or immediate skin test responses to allergens in vivo, but they may be beneficial in selected patients with recurrent anaphylaxis.

Specific anaphylactic syndromes have unique considerations. Anti-IgE therapy in peanut-allergic subjects can increase the threshold of sensitivity from the equivalent of half a peanut to almost nine peanuts. Insect venom sensitivity can be selectively treated by venom immunotherapy, which dramatically decreases the risk of anaphylaxis in response to future stings. Reactions to radiocontrast media can be prevented or attenuated by prior administration of prednisone and H_1- and H_2-receptor antihistamines. Patients who are hypersensitive to penicillin should avoid β-lactam antibiotics in general but can be desensitized if an antibiotic in this class is critically needed (e.g., penicillin for neurosyphilis). However, desensitization is temporary; once the drug has cleared, sensitivity is likely to return. Progesterone-induced anaphylaxis may respond to the luteinizing hormone–releasing hormone analogue leuprolide acetate (Lupron), oophorectomy, or conjugated estrogens. Patients with systemic mastocytosis, in addition to instituting prophylactic pharmacologic measures, should avoid using direct mast cell agonists such as codeine, morphine, and vancomycin. Aspirin-intolerant subjects can be desensitized, but they must continue to ingest a daily dose of aspirin to maintain their desensitization status. Food- and latex-sensitive subjects must practice avoidance of the provocative agent, although preliminary data on anti-IgE neutralization therapy and oral immunotherapy indicate that these measures might provide some protection against small inadvertent food allergen exposures. Future research should yield therapies that produce more effective and long-lasting clinical tolerance.

FUTURE DIRECTIONS

Ongoing research will provide more precise diagnostic tools for delineating different pathways of anaphylaxis, indicating which cell types and biochemical pathways are involved, and thereby dictating appropriate treatments. Predictors for anaphylactic risk will be better understood. Consequently, interventions that reduce anaphylactic risk (including better desensitization regimens) and that more effectively reverse the signs and symptoms of this potentially fatal disorder will be developed.

DRUG ALLERGY

LESLIE C. GRAMMER

DEFINITION

Adverse drug reactions (ADRs) are recognized as an important public health problem, in that they may be life-threatening. An ADR is defined by the World Health Organization (WHO) as an unintended, noxious response to a drug that occurs at a dose usually prescribed for human patients. The classic pharmacologic definition of ADRs by Rawlins and Thompson separates these into two major types: type A reactions, which are predictable and dose dependent, and type B reactions, which are unpredictable and not dose dependent. Type B reactions account for 10 to 25% of all ADRs and include drug allergy. The WHO Nomenclature Review Committee defines *drug allergy* as a hypersensitivity reaction for which a definite immunologic mechanism, either a B-cell– (antibody) or a T-cell–mediated process, is documented. Most published epidemiologic studies refer to ADRs in general and not to drug allergy specifically because the demonstration of drug-specific B-cell– or T-cell–mediated mechanisms is often quite difficult, and the immunologic culprit may be a drug metabolite.

EPIDEMIOLOGY

Drug allergy is responsible for significant mortality, morbidity, and socioeconomic costs that are probably underestimated. Current data must be evaluated carefully, because they involve different populations, different definitions of ADRs and drug allergy, and different methodologies, especially in terms of data analysis. The Boston Collaborative Drug Surveillance Program collected information on all ADRs in 4031 hospitalized patients during a period of 6 months. An incidence of 6.1% was reported, of which 42% were severe; 1% of the severe reactions resulted in the patient's death. Using an automatic detection system in a Salt Lake City hospital, Claussen and coinvestigators identified 731 ADRs among 36,653 hospitalized patients. Of note, only 12.3% of these were reported by physicians in the hospital. In a meta-analysis of 33 U.S. prospective studies from 1966 to 1996, Lazarou reported that 15% of hospitalized patients experienced ADRs and that the frequency of drug-related hospital admissions varied from 3 to 6%. Most other subsequent studies reported similar data. Epidemiologic information on drug allergy in nonhospitalized people and in the general population is even more limited and is confined mainly to studies of antibiotics.

Risk Factors

Some risk factors have been identified for the development of drug allergy. Certain drugs more commonly cause adverse reactions, and some drugs lead to more severe reactions (Table 262-1). The dosage and route of administration of a drug can also be risk factors; intermittent, repeated administrations of a drug can be more sensitizing than uninterrupted therapy. Drug allergy is more common in women, the elderly, and patients with AIDS. Some ethnic groups appear to be more prone to certain ADRs. White Americans are at a higher risk for hypersensitivity reactions to abacavir than other ethnic groups. In a study of drug allergy caused by angiotensin-converting enzyme (ACE) inhibitors, the vulnerable population was African American.

TABLE 262-1 DRUGS FREQUENTLY IMPLICATED IN ALLERGIC DRUG REACTIONS

Allopurinol
Amiodarone
Anesthetic agents (muscle relaxants, thiopental)
Antiarrhythmic drugs (procainamide, quinidine)
Antibiotics (β-lactams, sulfas, nitrofurans)
Anticonvulsants (hydantoin, phenobarbital, carbamazepine)
Antihypertensive agents (angiotensin-converting enzyme inhibitors)
Antipsychotic tranquilizers
Antisera (antitoxins, monoclonal antibodies)
Antituberculous drugs (isoniazid, rifampicin)
Aspirin and nonsteroidal anti-inflammatory drugs
Chemotherapy agents (cisplatin, doxorubicin, taxanes)
Enzymes (L-asparaginase, streptokinase, chymopapain)
Heavy metals (gold salts)
Monoclonal antibodies (anti–tumor necrosis factor, anti-CD20, epidermal growth factor receptor inhibitors)
Radiocontrast media
Recombinant proteins (insulin, other hormones)
Vaccines (egg-based, gelatin)

In the United States, approximately 10% of individuals who seek health care have a history of penicillin allergy. However, if tested with an appropriate panel of skin tests, less than 10% of those individuals would be deemed to have a penicillin allergy. Individuals with a positive history and negative skin tests tolerate penicillin-type antibiotics at the same rate as the general population with a negative history; in addition, there is a very low rate of resensitization.

PATHOBIOLOGY

Hypersensitivity reactions to drugs can be classified according to the type of immunologic reaction. An immunologic response to any antigen may be diverse, and the resulting reaction complex: drugs are no exception. Drugs that are more frequent perpetrators of significant allergy are listed in Table 262-1.

Most pharmacologic agents are simple structures with molecular weights of less than 1000 D. Alone, they are unable to induce hypersensitivity-type immunologic responses. However, most of these agents have the ability to covalently bind to proteins and form hapten-carrier complexes, with the low-molecular-weight agent acting as the hapten and the protein being the carrier. Hapten-carrier complexes can induce immunologic responses, with most responses being directed at the hapten.

A well-known example of such an agent is penicillin. Benzylpenicillin has a molecular weight of approximately 300 D and is metabolized into a penicilloyl hapten moiety. The penicilloyl moiety, which constitutes about 95% of all penicillin metabolites, is referred to as the major determinant because it is the major metabolite in terms of quantity. It has been conjugated to poly-D-lysine to form penicilloyl-polylysine, which is now commercially available as Pre-Pen (Alk-Abello, Round Rock, TX) for skin testing. The other 5% of penicillin metabolites are referred to as the minor determinants. Although they are minor in quantity, these determinants actually cause most of the immediate-type anaphylactic reactions, whereas the major determinant is associated with later and less severe reactions. Minor determinant reagents have never been commercially available in the United States. Penicillin skin testing is not widely used by U.S. physicians; annually, only 40,000 doses of the major determinant are sold. The potential market for a complete set of penicillin skin test reagents is estimated to be approximately 30 million tests in the United States alone.

In contrast to simple low-molecular-weight drugs, therapeutic agents that are proteins with molecular weights exceeding 5000 D can be recognized by the human immune system and can result in sensitization and hypersensitivity reactions on subsequent exposure. Because these proteins are complete antigens, they can be used as skin testing reagents or as antigens or allergens in in vitro assays. Included among therapeutic protein reagents that reportedly cause hypersensitivity are antithymocyte globulin (rabbit or equine), chymopapain, streptokinase, latex, and vaccines such as tetanus toxoid, influenza, yellow fever, pertussis, rubella, and MMR (measles, mumps, rubella). Unexpectedly, a variety of human recombinant proteins, including insulin and fully humanized monoclonal antibodies, can cause hypersensitivity reactions. In addition to hypersensitivity reactions, biologics such as monoclonal

antibodies can cause other immunologic reactions (Chapter 35). One such reaction is the cytokine release syndrome, in which high cytokine levels result in systemic symptoms, including fever, arthralgia, and capillary leak; interleukin-2 is the original biologic agent in which this was described. Immune imbalance is another immunologic reaction, exemplified by anti–tumor necrosis factor therapy that results in immune dysregulation consisting of increased susceptibility to infection or autoimmunity.

CLINICAL MANIFESTATIONS

The clinical manifestations of drug allergy often include a dermatologic component (Chapter 448). It is estimated that 80 to 90% of drug allergies result in one of the following cutaneous manifestations: exanthematous or morbilliform eruption; urticaria, angioedema, or both; contact dermatitis; fixed drug eruption; erythema multiforme–like eruption; or photosensitivity. There are, however, organ-specific drug hypersensitivity reactions that do not include cutaneous manifestations (Table 262-2).

DIAGNOSIS

The diagnosis of drug allergy may be quite simple if a patient has recently started therapy with a single agent known to cause hypersensitivity, such as a β-lactam antibiotic. In contrast, in a hospitalized patient in whom multiple drugs have been started and stopped, identifying the offending drug may be difficult, requiring a complete and exhaustive history along with a physical examination. It also requires compatible clinical manifestations and temporal relationships. In vitro tests are rarely useful clinically. In vivo testing, such as cutaneous tests and provocative test dosing, may be indicated in some situations.

TABLE 262-2 ORGAN-SPECIFIC REACTIONS AND IMPLICATED DRUGS

REACTION	IMPLICATED DRUG
PULMONARY MANIFESTATIONS	
Pulmonary infiltrates with eosinophilia	Nitrofurantoin
Pneumonitis and fibrosis	Bleomycin, amiodarone
Noncardiogenic pulmonary edema	Hydrochlorothiazide, cocaine, heroin, methadone
AUTOIMMUNE MANIFESTATIONS	
Drug-induced lupus	Hydralazine, procainamide
DRUG-INDUCED IMMUNE CYTOPENIAS	
Thrombocytopenia	Quinidine, gold salts, sulfonamides, heparin
Hemolytic anemia	Penicillin, methyldopa
Agranulocytosis	Sulfonamides, propylthiouracil, quinidine, procainamide, phenytoin
HEPATIC MANIFESTATIONS	Aminosalicylic acid, dapsone
Cholestasis	Phenothiazines, erythromycin
Hepatocellular damage	Halothane, isoniazid, phenytoin
Mixed pattern	Phenytoin, sulfonamides
RENAL MANIFESTATIONS	
Nephrotic syndrome	Gold salts, captopril, NSAIDs, penicillamine
Acute interstitial nephritis	β-Lactam antibiotics, NSAIDs, sulfonamides
LYMPHOID SYSTEM MANIFESTATIONS	
Pseudolymphoma	Phenytoin
Infectious mononucleosis–like syndrome	Aminosalicylic acid, dapsone
CARDIAC MANIFESTATIONS	Sulfonamides, β-lactam antibiotics
NEUROLOGIC MANIFESTATIONS	
Peripheral neuritis	Colchicine, nitrofurantoin, sulfonamides

NSAIDs = nonsteroidal anti-inflammatory drugs.

Differential Diagnosis

To distinguish drug allergy from other ADRs, several criteria are helpful. Allergic reactions occur in a tiny fraction of individuals who receive the drug, and they cannot be predicted. The observed clinical effects do not resemble known pharmacologic actions of the drug. In the absence of prior exposure to the drug, allergic or hypersensitivity symptoms rarely appear before 1 week of continuous therapy. In general, drugs used with no reactions for several months or longer are rarely responsible.

Drug allergy often resembles other allergic or hypersensitivity reactions, such as anaphylaxis, urticaria, and serum sickness–like illness. Although most drug reactions include cutaneous manifestations, some involve only other organ systems—for example, pulmonary infiltrates with eosinophilia, hepatitis, and acute interstitial nephritis. A list of drugs that cause organ-specific reactions is provided in Table 262-2. Drug-specific antibodies or T-cell receptors or T lymphocytes have been identified that react with the suspected drugs or relevant drug metabolites. As with ADRs in general, the reaction often subsides after the drug is discontinued. However, a hypersensitivity reaction may persist because of the formation of drug metabolites, which act as haptens and bind to carrier proteins such as human serum albumin.

TREATMENT

Evidence-Based Treatments

There is a paucity of evidence-based information regarding drug allergy. One study, evaluating the evidence related to premedication before the administration of antivenom snakebite toxins, concluded that routine prophylactic adrenaline for polyvalent antivenom, known to have high adverse event rates, seems sensible, based on one clinical trial.■ Antihistamines have no obvious benefit in preventing acute reactions from antivenoms. A second study, evaluating treatment for toxic epidermal necrolysis, concluded that there are no randomized controlled trials of the most commonly used therapies (i.e., systemic steroids, cyclosporin A, intravenous immunoglobulins).

There are published clinical guidelines for the management of infusion-related hypersensitivity reactions caused by the administration of chemotherapeutic or biologic therapy. These guidelines were developed as part of a performance improvement initiative and resulted in a standardized approach to the management and reporting of ADRs.

PREVENTION

Although the outcome of allergic drug reactions is generally favorable, prevention is the obvious goal. The physician should prescribe medications only if they are clinically appropriate and, if possible, should avoid drugs that are known to produce significant hypersensitivity reactions (see Table 262-1). Before starting a medication, the patient should be asked about prior ADRs to the medication or to other pharmacologically related medications. If appropriate, oral administration is probably preferable to parenteral administration; anaphylaxis is less likely, as is sensitization. Protocols for skin testing to foreign antisera and for management of medication hypersensitivity reactions (e.g., premedication, test dosing, desensitization) are available in Suggested Readings. Therapeutic guidelines regarding treatment of the most important and common allergic drug reactions are also reviewed in those references. A general algorithm is provided in Figure 262-1.

The risk of an anaphylactic reaction to a drug such as penicillin is a function of the history of onset, severity, and proximity (Table 262-3). If an individual experienced an immediate-type reaction that was rapid in onset, involved life-threatening symptoms or signs, and occurred relatively recently, that individual is at high risk for a severe anaphylactic reaction on subsequent exposure.

Even with a negative Pre-Pen skin test, a patient could have reactivity against minor determinants;, therefore, the approach to a patient who needs a β-lactam antibiotic depends on the risk as listed in Table 262-3. Risks and benefits should be thoroughly discussed and documented. In a high-risk individual, cautious test dosing can be performed. If a reaction occurs, desensitization can be considered if the clinical risks and benefits so warrant. In the case of HIV/AIDS patients with a previous history of mild hypersensitivity to cotrimoxazole, evidence-based rechallenge protocols are available.■

PROGNOSIS

Most drug allergies involve cutaneous eruptions that are self-limited and resolve shortly after the offending agent has been discontinued. However,

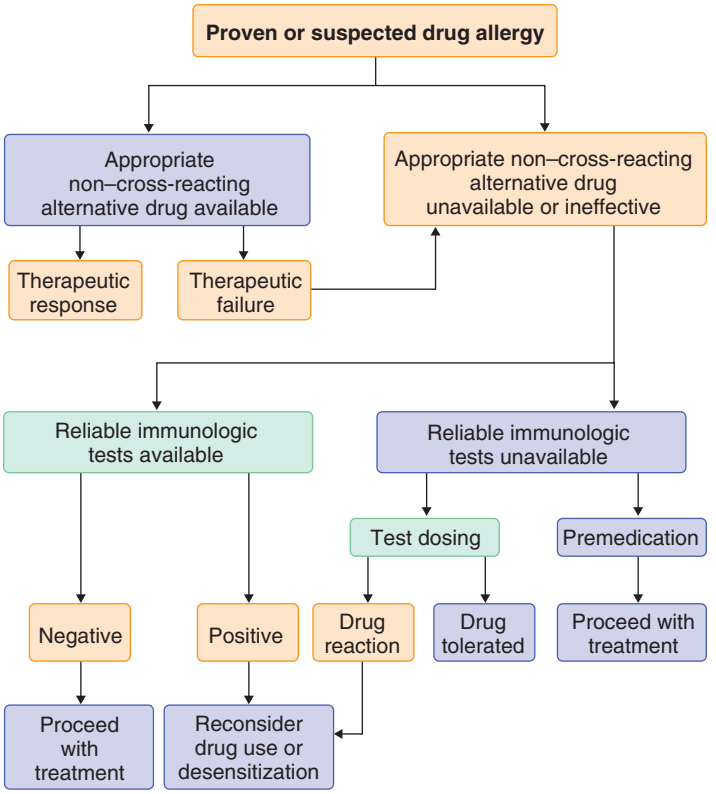

FIGURE 262-1. Guidelines for the treatment of patients with a history of drug allergy. In patients with a suspected or known drug allergy, the first choice is to use an appropriate non–cross-reacting drug. If such a drug is not available, or if the patient does not respond to it, further evaluation is based on the availability of a reliable immunologic test to detect drug hypersensitivity.

TABLE 262-3 RISK OF ANAPHYLACTIC REACTION TO PENICILLIN OR OTHER PHARMACOTHERAPEUTIC AGENT

FACTOR	LOW RISK	HIGH RISK
Onset of previous reaction	>24 hr	<30 min
Signs and symptoms of previous reaction	Morbilliform eruption Urticaria alone	Life-threatening symptoms: hypotension, upper airway angioedema, bronchospasm
Time elapsed since previous reaction	>20 yr	<1 yr

severe, life-threatening reactions occur in approximately 1 in every 1000 hospitalized patients. In 1998, the death rate for hospitalized Medicare patients was 20% higher in those who experienced an ADR. The proportion of ADRs that were allergic reactions was not determined in this study, but it can be estimated at about one fourth. The incidence of adverse cutaneous reactions to drugs is higher in women than in men. There is also an increased incidence of ADRs in the elderly.

One of the most severe reactions associated with drug allergy is anaphylactic shock. It is usually immunoglobulin E (IgE) mediated, but it may occur with non-IgE-mediated reactions to drugs such as nonsteroidal anti-inflammatory drugs or radiocontrast media. It is estimated that approximately 1500 people die annually in the United States owing to anaphylaxis from medications. In the United Kingdom, drugs are the leading cause of anaphylactic fatalities (88 of 202 fatalities in 2001).

Anaphylaxis is not the major cause of mortality due to allergic drug reactions, however. Erythema multiforme major, also known as Stevens-Johnson syndrome, has a mortality rate of about 5%, and toxic epidermal necrolysis has a mortality rate of about 30%, mostly due to sepsis. The estimated incidence of Stevens-Johnson syndrome or toxic epidermal necrolysis is approximately five cases per million.

FUTURE DIRECTIONS

Pharmacogenomics will be an important method of identifying those individuals at risk for a significant allergic reaction to a given drug. Human leukocyte antigen (HLA) genotyping can reportedly identify individuals who are at increased risk for drug hypersensitivity. For example, individuals with HLA-B*5701 are at greater risk for a drug hypersensitivity reaction to abacavir, an HIV transcriptase inhibitor. Severe cutaneous adverse reactions to allopurinol are highly associated with the genetic marker HLA-B*5801. In patients of Asian ancestry, HLA-B*1508 is highly associated with development of Stevens-Johnson syndrome if carbamazepine is prescribed. Why this genetic variant is not a risk factor in patients of African or European ancestry is unclear. Other avenues by which susceptible individuals may be identified include polymorphisms in genes for immune recognition molecules, drug-metabolizing enzymes, and macromolecular adduct repair systems.

MASTOCYTOSIS

CEM AKIN

DEFINITION

Mastocytosis is a heterogeneous group of disorders characterized by pathologic accumulation of mast cells in tissues such as skin and bone marrow. According to the classification of the World Health Organization (WHO), based on clinical presentation and pathologic findings, there are seven distinct categories of mastocytosis (Table 263-1). The term *cutaneous mastocytosis* describes skin disease alone without any evidence of internal organ involvement, whereas the term *systemic mastocytosis* describes the disorder when it involves internal organs (most commonly the bone marrow) with or without skin disease.

EPIDEMIOLOGY

Mastocytosis can be diagnosed at any age. Pediatric-onset and adult-onset forms are distinguished based on the age of the patient at initial diagnosis. These forms display differences in their clinical course, molecular pathology, and prognosis. The most common clinical scenario leading to diagnosis in the pediatric population is a child presenting with skin lesions of cutaneous mastocytosis within the first year of life. Patients with a later onset of skin lesions are more likely to have systemic mastocytosis, as are most patients with adult-onset mastocytosis. The disease has been diagnosed in all ethnic populations. Pediatric-onset mastocytosis appears to be diagnosed more

TABLE 263-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF MASTOCYTOSIS

FIGURE 263-1. Urticaria pigmentosa.

commonly in males (approximately 60%). Estimates of the prevalence of patients with cutaneous mastocytosis range from 1 in 500 to 1 in 8000 patients presenting in dermatology clinics. The prevalence of systemic mastocytosis is more difficult to estimate because the diagnosis requires biopsy of an involved tissue and a high degree of clinical suspicion. Systemic mastocytosis is likely to be underdiagnosed, considering the fact that there are neither physical examination findings nor routine hematologic or chemistry laboratory abnormalities specifically associated with the disease. Consequently, it is not unusual to encounter several years' delay after the onset of symptoms in many patients before a diagnosis of mastocytosis is reached. The disease is sporadic, although rare cases of familial occurrence have been described.

PATHOBIOLOGY

Pathogenesis

The pathogenesis of mastocytosis involves the accumulation of mast cells in tissues, with mediators released by activated mast cells. The primary reason for the increased mast cell numbers in tissues appears to be defective apoptosis rather than uncontrolled proliferation. It is unusual to see increased mitotic activity in biopsy specimens from patients with mastocytosis, and, in most patients, the disease follows an indolent course. Tissue microenvironment and altered chemotaxis may also contribute to the final level of tissue mast cell burden.

Genetics

Mast cells are derived from hematopoietic progenitors. Systemic mastocytosis is associated with somatic gain-of-function point mutations in the *KIT* (formerly *c-kit*) gene of the mast cell progenitor, leading to a clonal neoplastic expansion of mast cells. *KIT* encodes a transmembrane receptor (Kit), whose intracellular portion functions as a tyrosine kinase enzyme. The extracellular portion of Kit binds the cytokine stem cell factor (SCF or Kit ligand). The interaction between SCF and Kit provides the single most important growth and differentiation stimulus for mast cells from their progenitors. Under physiologic conditions, homodimeric SCF binds and cross-links two Kit receptor molecules, which leads to autophosphorylation of the tyrosine amino acids of the intracellular portion of the Kit molecule. Phosphorylated tyrosine residues in turn act as docking sites for downstream adaptor and signal transduction molecules that regulate the differentiation, proliferation, chemotaxis, and functional activation of mast cells.

Most of the mutations reported in systemic mastocytosis involve codon 816 in *KIT,* resulting in the replacement of an aspartic acid by a valine residue (D816V) in the Kit protein. D816 is a critical residue involved in the kinase activity of Kit. Substitution of the wild-type aspartic acid residue in this location by another amino acid results in constitutive activation and autophosphorylation of the receptor molecule without the need for cross-linking by its ligand, SCF. The D816V mutation has been shown in lesional mast cells from the skin and bone marrow tissue of patients with mastocytosis, as well as from other hematopoietic lineages in patients with extensive disease. This aspect of the pathobiology of systemic mastocytosis is similar to the multilineage involvement observed in myeloproliferative disorders (Chapter 169). The sensitivity of detecting the mutation is much higher when a lesional tissue such as bone marrow or skin is analyzed compared with peripheral blood. Other pathogenetic factors, some yet to be determined, appear to be responsible for the final disease phenotype because the presence of the D816V *KIT* mutation alone does not explain the remarkable heterogeneity in the clinical presentation and prognosis of the disease.

Symptomatology

The symptomatology of mastocytosis is primarily manifested by the release of mast cell mediators and rarely by a destructive infiltration of mast cells into tissues. Mast cell activation results in the release of various preformed mediators stored in mast cell granules, de novo synthesis of sulfidopeptide leukotrienes such as LTC_4 and prostaglandins (mostly PGD_2) from membrane lipids, and cytokine synthesis. Preformed mediators stored in mast cell granules include histamine; proteases such as tryptase, chymase, and carboxypeptidase A; and proteoglycans such as heparin and chondroitin sulfate. Vasoactive mediators such as histamine, LTC_4, and PGD_2 at local or distant tissues cause vasodilation, which may lead to flushing, tachycardia, hypotension, presyncope, and syncope. Histamine also causes pruritus and stimulates gastric acid hypersecretion from parietal cells. Mast cells are rich sources of cytokines. Elevated serum levels of tumor necrosis factor-α (TNF-α) and interleukin-6 (IL-6) have been found in patients with mastocytosis and may contribute to the pathophysiology of fatigue and accelerated osteoporosis observed in some patients. Rare aggressive categories of mastocytosis may be associated with an extensive destructive infiltration of mast cells into tissues such as the gastrointestinal tract, which may result in malabsorption, and the liver, which may cause portal fibrosis with associated portal hypertension.

Mast cell activation and mediator release may occur after triggers such as temperature changes (e.g., hot showers); exercise; ingestion of alcohol or spicy foods; emotional stress; insect stings; exposure to certain drugs such as opioid analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), or muscle relaxants; and sometimes spontaneously without an obvious trigger. The prevalence of atopic disease in patients with mastocytosis is similar to that in the general population, and the serum immunoglobulin E (IgE) level is often found to be low. However, patients with anaphylactic sensitivity to hymenoptera venoms appear to have a disproportionately high incidence of mastocytosis.

Clinical Manifestations

Mastocytosis is a disease with protean clinical manifestations. Although in some patients the only complaint is the cosmetic appearance of urticaria pigmentosa lesions, others suffer from frequent episodes of vascular instability or have life-threatening hematologic disease. In general, patients with mastocytosis belong to one of two broad categories, according to the site of tissue involvement: those with cutaneous disease alone, or those with systemic disease with or without skin involvement. Cutaneous mastocytosis (i.e., disease limited to the skin in the absence of internal organ involvement) is commonly diagnosed in children within the first year of life, whereas systemic mastocytosis is mostly diagnosed in adults by a bone marrow biopsy and aspirate.

Cutaneous Manifestations

Skin lesions of urticaria pigmentosa are the most common presentation of cutaneous mastocytosis (Fig. 263-1). They are also present in 50 to 90% of patients with systemic mastocytosis, depending on the disease category. Remarkably different in appearance from urticaria or hives, lesions of urticaria pigmentosa are fixed, tan- to salmon-colored, maculopapular lesions

varying in size from a few millimeters to a few centimeters. They are most prominently observed on the trunk and extremities and tend to spare the face and the sun-exposed areas of the skin, although facial involvement may be seen in children. Blistering of the lesions may occur in children in the first 3 years of life. The lesions are generally not pruritic at rest but may urticate after exposure to a number of triggers (see Pathobiology). Many patients note that the skin lesions become more prominent after exposure to heat or after physical irritation such as rubbing. The lesions may be found concentrated in skin areas that are prone to irritation, such as the axillae and groin.

Uncommon presentations of cutaneous mastocytosis include mastocytomas, diffuse cutaneous mastocytosis, and telangiectasia macularis eruptiva perstans (TMEP). Mastocytomas are benign and generally solitary mast cell tumors, although they have been known to precede urticaria pigmentosa lesions in some cases. They occur almost exclusively in children, and physical irritation of the lesion may result in generalized flushing and other symptoms of mast cell mediator release. Diffuse cutaneous mastocytosis (DCM) is another form of skin involvement seen exclusively in children. It is characterized by diffuse thickening of the skin and appendages with a peau d'orange appearance without individual urticaria pigmentosa lesions. TMEP is a rare form of cutaneous mastocytosis characterized by the presence of diffuse telangiectatic macules. Because TMEP lesions are generally seen in the presence of urticaria pigmentosa, there is debate about whether TMEP represents a distinct form of cutaneous mastocytosis.

Patients with cutaneous mastocytosis may manifest systemic symptoms such as abdominal pain, diarrhea, and flushing.

Systemic Manifestations

Symptoms caused by mast cell degranulation may be experienced as brief, recurrent, and self-limited episodes with multiorgan manifestations or as chronic complaints over a prolonged time course. A typical mast cell degranulation episode may variably involve flushing, conjunctival hyperemia, nausea, vomiting, abdominal cramping, diarrhea, tachycardia, and lightheadedness. Hypotension may develop, and the episode may progress to full loss of consciousness in some patients. Therefore, mastocytosis should be ruled out in all patients with recurrent anaphylaxis before a diagnosis of idiopathic anaphylaxis can be made. Tryptase, a protease stored in mast cell granules, may be elevated above the patient's baseline level in the serum or plasma if measured within 3 hours after the onset of the episode in patients with suspected mast cell degranulation or anaphylaxis, regardless of the cause. Angioedema, hives, and wheezing are uncommon in mastocytosis, in contrast to idiopathic anaphylaxis. Flushing usually involves the face and upper chest area. A consistent trigger can be identified in only a small number of patients (see Pathobiology). The episodes usually last 30 minutes to a few hours. Hypotensive episodes can be life-threatening, particularly in the presence of comorbidities such as cardiac or pulmonary disease.

Gastrointestinal Symptoms

Gastrointestinal symptoms are observed in more than 50% of patients with mastocytosis. Epigastric pain, lower abdominal cramping, nausea, vomiting, or diarrhea can occur episodically in the context of an acute mast cell degranulation episode or on a chronic basis. Gastric acid hypersecretion induced by mast cell–derived histamine may lead to esophagitis, gastritis, and peptic ulcer disease, although measurements of basal acid output have shown great variability in different studies, ranging from hypersecretion in the range of Zollinger-Ellison syndrome to achlorhydria. Mucosal edema, thickened gastric or duodenal mucosal folds, or nodular lesions may be observed in radiographic or endoscopic evaluations. Diarrhea alternating with constipation may be seen. Severe persistent diarrhea may be complicated by clinically significant malabsorption in patients with aggressive systemic mastocytosis. Hematochezia, hematemesis, and melena are uncommon symptoms and should prompt endoscopic evaluation to rule out coexisting pathology. Mast cells are constituents of the normal lamina propria in gastrointestinal mucosa, and their numbers may be increased in inflammatory states affecting the gastrointestinal tract. However, quantitation of mast cell numbers in gastrointestinal biopsy specimens is generally not helpful, and diagnosis of mast cell disease by a gastrointestinal biopsy, solely based on increased mast cell numbers without evidence for other WHO criteria, should be avoided. Mild to moderate hepatomegaly with or without abnormalities in serum transaminases may be observed, although portal hypertension and ascites are rare and indicate the presence of advanced categories of mastocytosis. Jaundice and findings on cholangiography resembling those of primary sclerosing cholangitis have been reported in some patients.

Musculoskeletal Symptoms

Musculoskeletal pain is common in patients with mastocytosis and is mostly caused by soft tissue pain resembling fibromyalgia. Accelerated osteoporosis may be seen in a subgroup of patients, particularly those with other risk factors, such as postmenopausal women, and those receiving glucocorticoid therapy. Pathologic compression fractures may be the initial finding in some patients. A bone densitometry measurement should be recommended as part of the standard evaluation of women with mastocytosis and of any patient with a history of pathologic fractures. Radiographic abnormalities have been reported in up to 75% of patients with mastocytosis. In addition to generalized osteoporosis, bone surveys may show a mixture of sclerotic or lytic lesions, and skeletal scintigraphy may reveal focal or diffuse radiotracer uptake.

Hematologic Manifestations

Peripheral blood abnormalities have been noted in up to 50% of patients with systemic mastocytosis. Mild normochromic normocytic anemia is the most common abnormality, followed by thrombocytopenia, eosinophilia, monocytosis, and leukopenia. Eosinophilia in mastocytosis rarely causes organ damage, as is observed in chronic eosinophilic leukemia or idiopathic hypereosinophilic syndrome (Chapter 173). It is important to differentiate a primary eosinophilic disorder from mastocytosis with eosinophilia. Some cases of chronic eosinophilic leukemia are associated with the *FIP1L1-PDGFRA* fusion gene and respond to the drug imatinib, whereas systemic mastocytosis is associated with codon 816 point mutations of the *KIT* gene, which confers resistance to this drug.

Approximately 20% of patients with systemic mastocytosis have been reported to display evidence of another clonal non–mast cell hematologic disease. Non–mast cell clonal hematologic neoplasms associated with mastocytosis are commonly myeloid in nature (myeloproliferative disorders, myelodysplastic syndromes, or myeloid leukemias) but may also involve lymphoproliferative disorders such as lymphomas, myelomas, and lymphocytic leukemias.

DIAGNOSIS

The diagnosis and classification of mastocytosis is carried out according to the guidelines published by the WHO. A suggested algorithm for the diagnosis of mastocytosis is shown in Figure 263-2.

Cutaneous Mastocytosis

Diagnosis of cutaneous mastocytosis is made by observing the typical hyperpigmented maculopapular lesions of urticaria pigmentosa and is confirmed by skin biopsy, which shows infiltration of mast cells in the upper dermis, particularly in perivascular locations. It should be noted that mild increases in mast cell numbers can be observed in inflammatory and neoplastic skin diseases, and establishing a diagnosis of cutaneous mastocytosis by a blind skin biopsy or biopsy of a lesion that does not have the typical appearance of urticaria pigmentosa should be avoided. A localized wheal-and-flare reaction limited to the lesional skin within a few minutes after rubbing or scratching the skin is known as Darier's sign. Diagnosis of urticaria pigmentosa in adults should always prompt investigation of possible systemic mastocytosis.

Systemic Mastocytosis

Biopsy

A bone marrow biopsy and aspiration is the recommended diagnostic procedure to evaluate the presence of WHO diagnostic criteria for systemic disease (discussed later). This procedure is recommended for all patients with adult-onset urticaria pigmentosa, patients with recurrent symptoms suggestive of mast cell degranulation (such as flushing and hypotension accompanied by abdominal complaints), patients with unexplained osteoporosis, and patients with suspected hematologic disease (see Clinical Manifestations). Children with an onset of lesions within the first year of life usually do not require a bone marrow biopsy unless they have an abnormal complete blood count, lymphadenopathy, hepatomegaly, or splenomegaly. Children with late-onset skin lesions and those who experience persistence of urticaria pigmentosa into adulthood should be considered for diagnostic evaluation for systemic disease.

World Health Organization Diagnostic Criteria

WHO guidelines for diagnosis of systemic mastocytosis consist of one major and four minor criteria (Table 263-2). Presence of the major criterion with at least one minor criterion, or demonstration of three minor criteria in the

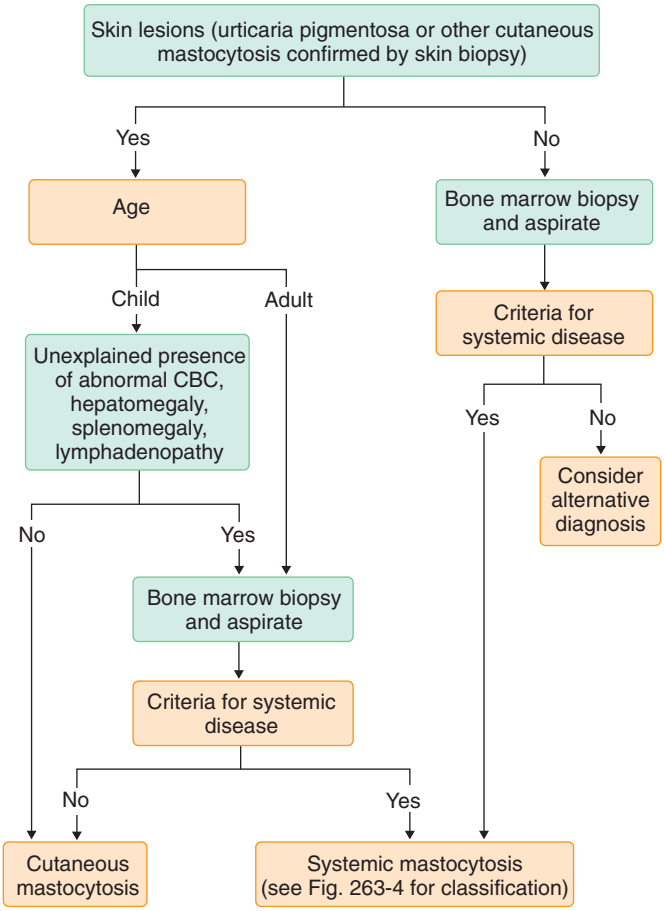

FIGURE 263-2. Suggested diagnostic algorithm for mastocytosis. CBC = complete blood count.

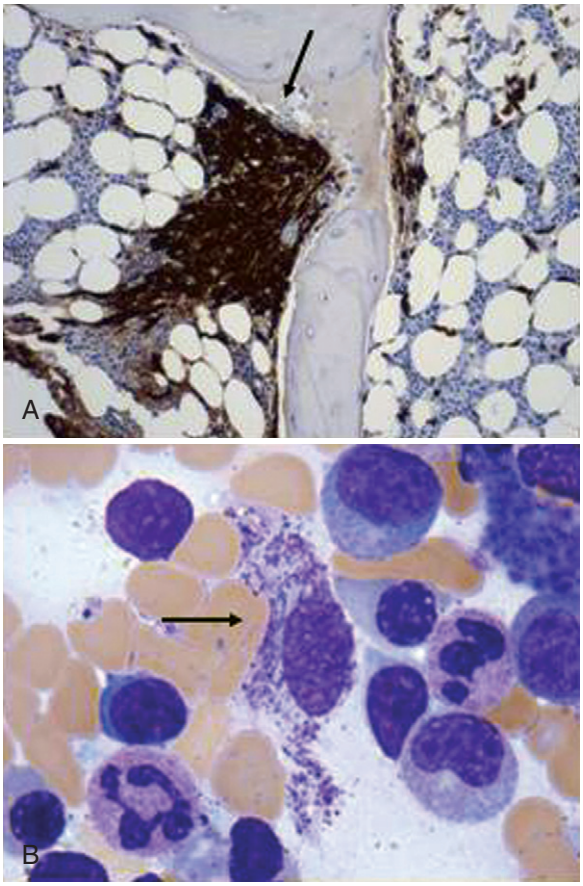

FIGURE 263-3. Diagnostic findings in the bone marrow biopsy and aspirate. A, Characteristic mast cell aggregates on tryptase staining (major criterion) in biopsy section (*arrow*). **B,** Mast cells with atypical spindle shapes in aspirate smear *(arrow)*.

TABLE 263-2 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR SYSTEMIC MASTOCYTOSIS

MAJOR
Multifocal, dense infiltrates of mast cells consisting of 15 or more mast cells in aggregates detected in sections of bone marrow and/or other extracutaneous organs, confirmed by tryptase immunohistochemistry or other special stains
MINOR
More than 25% of mast cells in biopsy sections or bone marrow aspirate smears showing spindle shape or atypical morphology
Detection of a *KIT* codon 816 point mutation in bone marrow, blood, or other extracutaneous organs
Expression of CD2 and/or CD25 by mast cells in bone marrow, blood, or extracutaneous organs
Persistent elevation of serum total tryptase >20 ng/mL*

*Criterion not valid if there is an associated clonal myeloid disorder.
From Horny HP, Metcalfe DD, Bennett JM, et al. Mastocytosis. In: Swerdlow SH, Campo E, Harris NL, et al, eds. *WHO Classification of Tumours of Haematopoietic and Lymphoid Tissues.* Lyon, France: IARC Press; 2008:54-63.

absence of the major criterion, is needed to establish a diagnosis of systemic mastocytosis and distinguish it from reactive mast cell hyperplasia. The major diagnostic criterion is the presence of multifocal, dense aggregates of 15 or more mast cells in bone marrow or other extracutaneous tissue biopsy sections (Fig. 263-3A). Such clusters are frequently observed around blood vessels and next to bone trabeculae in bone marrow biopsies. Immunohistochemical staining for tryptase is the recommended method for visualization of mast cells. Routine hematoxylin and eosin or metachromatic stains such as toluidine blue are not sufficiently sensitive to demonstrate subtle mast cell infiltrates or abnormal morphologic features of mast cells within the infiltrates in decalcified bone marrow biopsy sections.

Mast cell morphology in bone marrow provides important clues to the diagnosis of systemic mastocytosis. Bone marrow mast cells in systemic mastocytosis often display atypical morphology, such as an elongated (spindle) shape, hypogranularity, and an eccentric or lobulated nucleus (see Fig. 263-3B). These atypical mast cells are usually observed in close association with bone marrow spicules in the aspirate smear. Mast cells in mast cell leukemia (MCL) may be very sparsely granulated.

Flow cytometric analysis of the mast cells in a bone marrow aspirate, when performed appropriately, is a very sensitive diagnostic aid. The mean percentage of mast cells in a healthy bone marrow aspirate is approximately 0.02%, and it does not exceed 1% in most patients with mastocytosis. Therefore, to visualize the mast cell population correctly, the total cell numbers analyzed by flow cytometry should be significantly higher than those in other, more routine evaluations (e.g., leukemia phenotyping). The characteristic flow cytometric finding of systemic mastocytosis is the aberrant expression of CD25 and/or CD2 on $CD117^+$ mast cells. Serum tryptase level may be elevated in patients with mastocytosis. Currently available commercial tryptase immunoassays measure levels of total tryptase, the sum of mature tryptase and tryptase precursors. Mature tryptase enzyme is a serine protease stored in mast cell granules and is transiently elevated in serum or plasma after mast cell degranulation episodes such as anaphylaxis. In contrast, tryptase precursor proenzymes (α and β protryptases) are constitutively secreted outside the cell, and their serum levels at baseline correlate with mast cell burden. The median serum tryptase level in a healthy population is approximately 5 ng/mL. A serum tryptase level higher than 20 ng/mL raises suspicion for systemic mastocytosis in the appropriate clinical setting. It should be noted that a normal tryptase level does not rule out a diagnosis of mastocytosis and that increased tryptase levels can be seen in other conditions, such as myelodysplastic syndromes, acute myeloid leukemias, chronic eosinophilic leukemia, and chronic renal insufficiency. Metabolites of histamine, such as *N*-methylhistamine, are found to be elevated in a 24-hour urine specimen but are neither more sensitive nor more specific than the baseline serum tryptase measurement in mastocytosis.

Demonstration of a codon 816 *KIT* mutation (D816V) may be necessary to fulfill the diagnostic criteria in patients lacking the major criterion (see Pathobiology). Examination of lesional tissues such as skin and bone marrow

affords the highest sensitivity. Codon 816 *KIT* mutations have been detected in a variety of other neoplastic diseases, such as core binding factor acute myeloid leukemias, sinonasal lymphomas, and seminomas, in addition to mastocytosis.

World Health Organization Disease Categories

Each patient diagnosed with mastocytosis should be assigned a category of disease according to the WHO classification (see Table 263-1). *Cutaneous mastocytosis* in the absence of bone marrow and internal organ involvement is the most common category in patients with pediatric-onset disease.

Systemic mastocytosis is divided into the categories of indolent systemic mastocytosis, systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease (SM-AHNMD), aggressive systemic mastocytosis, and MCL. An algorithm for classification of systemic mastocytosis is presented in Figure 263-4. *Indolent systemic mastocytosis* is the most common category in adults. Patients in this category usually do not have a decreased life expectancy owing to the mast cell disease, although they experience symptoms related to release of mast cell mediators. Indolent systemic mastocytosis follows a persistent course, and progression to a more advanced category is unusual. *SM-AHNMD* is the second most common category in adults, and a non–mast cell hematologic disease is usually diagnosed at the time that the diagnosis of mastocytosis is made. Therefore, bone marrow biopsy and aspirate specimens should be carefully evaluated for the presence of other hematologic disease in every patient with newly diagnosed systemic mastocytosis. *Aggressive systemic mastocytosis* is a rare category characterized by the presence of organ dysfunction resulting from destructive mast cell infiltration. Aggressive systemic mastocytosis may involve the hematopoietic, gastrointestinal, and skeletal systems in the form of cytopenias, hypersplenism, malabsorption with weight loss, hepatomegaly with portal hypertension and ascites, and large osteolytic lesions with pathologic fractures. MCL is characterized by 10% or more mast cells in the peripheral circulation or 20% or more mast cells in bone marrow aspirate smears, or both. To diagnose MCL, the mast cell percentage in bone marrow aspirate smears should be assessed in an area of the slide that is sufficiently distant from the spicules. *Mast cell sarcoma* and *extracutaneous mastocytoma* are rare diagnoses characterized by malignant and benign solid mast cell collections, respectively.

Recent studies identified a subset of patients with recurrent idiopathic or hymenoptera venom-induced anaphylaxis who had evidence of clonal mast cells carrying the D816V *KIT* mutation or aberrantly expressing surface CD25, without fully meeting the WHO diagnostic criteria and without displaying urticaria pigmentosa skin lesions. Such patients are provisionally referred to as having a "monoclonal mast cell activation syndrome."

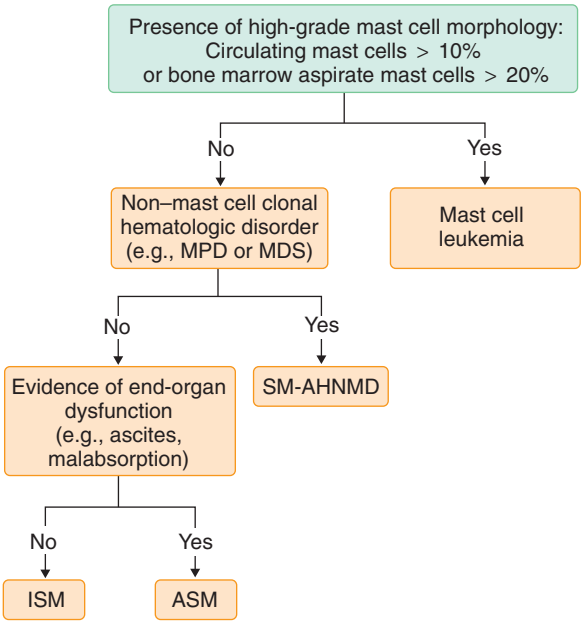

FIGURE 263-4. An algorithm for classification of systemic mastocytosis. ASM = aggressive systemic mastocytosis; ISM = indolent systemic mastocytosis; MDS = myelodysplastic syndromes; MPD = myeloproliferative disorders; SM-AHNMD = systemic mastocytosis with associated clonal hematologic non–mast cell lineage disease.

TREATMENT Rx

The major goal of treatment for all categories of mastocytosis is symptom control. A reduction in mast cell numbers is considered only in disease categories with a poor prognosis (i.e., SM-AHNMD, aggressive systemic mastocytosis, MCL, and mast cell sarcoma). Current treatment modalities have not been shown to change the natural course of the disease.

Medical Therapy

Patients with cutaneous and indolent systemic mastocytosis are treated symptomatically. Pruritus in mastocytosis usually responds to scheduled doses of histamine-1 antihistamines such as fexofenadine or cetirizine, or both. Sedating antihistamines such as hydroxyzine or diphenhydramine may be used before bedtime. Photochemotherapy (oral psoralen plus ultraviolet A) or phototherapy may be helpful in patients with refractory pruritus; it results in symptomatic improvement and temporary fading of the pigmented skin lesions in up to 50% of patients. The side effects of phototherapy, including increased risk of skin cancer, should be taken into account when this treatment is considered.

Histamine-2 antihistamines such as ranitidine or famotidine are usually prescribed as a first-line treatment for patients with gastrointestinal complaints such as heartburn, nausea, and abdominal pain. Proton pump inhibitors may be added in patients whose abdominal symptoms are refractory to histamine-2 antihistamines. Oral cromolyn sodium (adult dose, 200 mg four times daily) has been effective in reducing abdominal pain, diarrhea, nausea, vomiting, and pruritus in various studies, although the beneficial effects are variable among patients. Finally, low to moderate doses of systemic glucocorticoids can be beneficial in unusual cases of aggressive mastocytosis presenting with recalcitrant diarrhea associated with malabsorption or hepatomegaly with ascites.

Cysteinyl leukotrienes, such as LTC_4, that are produced after mast cell activation are thought to contribute to symptoms in mastocytosis. Therefore, drugs targeting the synthesis or receptor binding of leukotrienes are usually added to the treatment regimens of patients who derive suboptimal relief of itching and abdominal pain from histamine receptor–blocking therapy. However, there have been no controlled studies evaluating the clinical efficacy of this class of drugs in patients with mastocytosis.

Self-administered epinephrine should be considered for all patients even if they do not have any history of hypotensive or anaphylactic episodes resulting in presyncope or syncope from acute mast cell degranulation. These episodes should be treated like systemic anaphylaxis (Chapter 261).

Cytoreductive therapy, considered in aggressive disease variants associated with poor prognosis, has yielded disappointing results thus far. Approaches to cytoreductive treatment of mastocytosis have included interferon-α2b (IFN-α2b) and the nucleoside analogue 2-chlorodeoxyadenosine (2-CDA). IFN-α2b (0.5 to 5 million units, three to five times per week), alone or with prednisone, has been reported to improve partially clinical and laboratory abnormalities in approximately 50% of patients with aggressive systemic mastocytosis, patients with osteoporosis and pathologic fractures, and patients with recalcitrant recurrent anaphylaxis, although complete histopathologic and molecular remissions appear to be rare. IFN-α is difficult to tolerate because of its many side effects, including flu-like symptoms, bone pain, and depression. A regimen of 2-CDA (0.10 to 0.17 mg/kg/day for 5 days, repeated at intervals of 4 to 8 weeks) has been reported to result in partial and transient responses in patients with advanced categories of disease in case reports and small series. MCL usually is treated with polychemotherapy as acute myeloid leukemia (Chapter 189), although a successful treatment regimen has not yet been identified.

Imatinib, a tyrosine kinase inhibitor with activity against wild-type *KIT*, *PDGFR*, and *abl*, has been effective in a small number of patients without D816V *KIT* mutation or with the *FIP1L1-PDGFRA* fusion gene, who present with chronic eosinophilic leukemia (Chapter 173) with a modest increase in bone marrow mast cells. However, most patients with mastocytosis have the D816V *KIT* mutation, which confers resistance to imatinib, and therefore are not appropriate candidates for this therapy.

Ancillary and Other Therapies

Avoidance of the triggers of mast cell degranulation is an important adjunct to the pharmacologic treatment of symptoms. These show remarkable individual variation among patients (see Pathobiology), and the individual medical history can be helpful in identifying such triggers. General anesthesia and surgery impose an additional risk to patients with mastocytosis because several agents that are used perioperatively, such as muscle relaxants, opioid analgesics, and NSAIDs, can induce acute mast cell degranulation. Prior surgical and anesthesia records should be obtained if available, and an appropriate strategy for the anesthetic management of the patient should be determined, with close communication involving the patient, anesthesiologist, surgeon, and an allergist.

Non–mast cell clonal hematologic disorders associated with mastocytosis should be treated according to the standard-of-care guidelines for that disorder, regardless of the presence of mastocytosis. Bone marrow transplantation

(Chapter 181) has yielded generally disappointing results for the treatment of mast cell disease, although occasional cases resulting in complete remission have been reported.

PROGNOSIS

The prognosis for mastocytosis varies by the category of disease. At least 50% of patients with pediatric-onset cutaneous mastocytosis have complete resolution of the disease by adolescence, and the rest of those patients experience improvement or fading of the skin lesions. Indolent systemic mastocytosis is a persistent disease but has a good prognosis without a decrease in life expectancy, and progression to a more aggressive disease category is rare. Factors associated with poorer prognosis have been reported as the absence of urticaria pigmentosa, older age at onset of symptoms, elevated serum lactate dehydrogenase or alkaline phosphatase, thrombocytopenia, anemia, peripheral blood smear abnormalities, and detectability of the D816V *KIT* mutation in peripheral blood. The prognosis for SM-AHNMD is determined by the prognosis for the associated hematologic disorder. Aggressive systemic mastocytosis and MCL have poor prognoses, with median survival times of less than 3 years and less than 1 year, respectively.

264 APPROACH TO THE PATIENT WITH RHEUMATIC DISEASE

WILLIAM P. AREND AND GEORGE V. LAWRY

Diseases of the musculoskeletal system are common and may be both disabling and costly. This chapter provides an approach to the evaluation of patients with rheumatic diseases by outlining the components necessary for identifying the patient's problems, formulating a diagnosis, and initiating treatment.

Musculoskeletal disorders may manifest as acute, subacute, or chronic problems. Pain and interference with daily activities are what bring the patient to a physician and determine the impact of the condition. A general medical approach to the patient with rheumatic complaints is paramount, with particular reliance on an accurate history and a thoughtful physical examination. Usually, only limited additional testing is required to diagnose most musculoskeletal disorders, but in some instances, assessment with a number of laboratory analyses, imaging studies, and other disciplines may be necessary.

PATHOBIOLOGY

Categories of Musculoskeletal Diseases

Musculoskeletal diseases can be practically classified into nine categories, defined by the predominantly affected tissues (Table 264-1). At each point in the evaluation (history, physical examination, and laboratory testing), it is important to consider what tissues are involved. Recognition of the pattern of predominant tissue involvement can direct attention toward the disease primarily associated with that tissue. Before consideration of clinical approaches to the evaluation of patients with musculoskeletal problems, it is useful to first review the anatomy and pathophysiology of the affected structures.

Anatomy

The structures that may be involved in musculoskeletal diseases are shown in Figure 264-1A. Foremost is the joint cavity. The lining membrane, known as the *synovium*, consists of a thin layer of macrophages (type A cells) and fibroblasts (type B cells) with a sublining of rich, vascular, loose connective tissue. Hyaline cartilage overlies the bony end plates and provides a cushion to joint motion. The cartilage has high water content and obtains its nutrition solely from the synovial fluid, which is derived from the synovium primarily as an ultrafiltrate of plasma. The synovium also secretes specialized molecules into the synovial fluid, such as hyaluronic acid. An intact bony end plate is required to support the cartilage. The joint capsule and ligaments provide further support and blend with the periosteum. Periarticular anatomy is equally important and includes the tendons, bursae, and muscles associated with each joint.

Pathophysiology

The etiology of musculoskeletal problems is usually inflammatory, metabolic, degenerative, tumor, or some combination thereof. The disorders associated with musculoskeletal tissues are summarized in Table 264-1 and Figure 264-1B. Periarticular inflammation may involve tendons or bursae, and these structures are common causes of pain and stiffness, often misinterpreted as arising from the joint itself. The noninflammatory, degenerative disease osteoarthritis (OA) begins in the cartilage and leads to cartilage loss, subchondral new bone formation, and marginal bony overgrowth. Cartilage loss may also occur secondarily to synovial inflammation or trauma. Synovial inflammatory disorders, such as rheumatoid arthritis (RA), begin in the synovium and secondarily damage the cartilage, joint capsule, and bone. Crystal deposition disorders, such as gout or pseudogout, may also cause articular inflammation. Inflammation at entheses (enthesopathy), the insertion sites of tendons or ligaments on bone, is characteristic of the spondyloarthropathies, such as ankylosing spondylitis. Infections primarily involve the joint cavity (septic arthritis) or bone (osteomyelitis). Osteonecrosis of bone may be associated with secondary cartilage damage after collapse of the bony end plate. Inflammatory diseases of the muscle usually manifest with painless proximal weakness. Lastly, the common clinical problem of fibromyalgia is characterized by soft tissue and joint pain with local tenderness in specific points but without objective evidence of inflammation or swelling.

DIAGNOSIS

History

Demography

An appreciation of the age, gender, and personal history of the patient is helpful, including marital status, occupation, and psychosocial factors.

Age

The age of the patient is the first step in considering a differential diagnosis. For example, arthritis is a major manifestation of hemophilia with onset during childhood. The term *juvenile idiopathic arthritis* refers to three different forms of arthritis with onset before the age of 16 years. In young adults, inflammatory and septic arthritic conditions may be seen, but OA is exceptional. The onset of RA is often in the middle years, whereas elderly people are more prone to OA. Arthritis in elderly people is often assumed to be degenerative, when in fact the patient may have an inflammatory process such as polymyalgia rheumatica, RA, or systemic lupus erythematosus (SLE) (Chapter 274).

Gender

RA and other autoimmune diseases are more common in women, whereas ankylosing spondylitis and the other spondyloarthropathies (Chapter 273) associated with the human leukocyte antigen HLA-B27 are more common in men. Gouty arthritis is more common in men and rarely attacks women before menopause.

Occupation and Recreation

Occupation and recreational activities are also important because of associated physical and psychological stresses. The clinician should inquire about the patient's job to determine how demanding it is. Occupational factors such as repetitive joint trauma may contribute to the development of OA in susceptible individuals. Musculoskeletal symptoms may also be associated with jogging or with trauma from sports activities.

Family History

It is important to obtain a complete family history because autoimmune diseases, spondyloarthropathies, and gout occur with an increased incidence in families.

Onset and Evolution of Symptoms

Knowledge of the pattern of onset, location, and evolution of musculoskeletal symptoms is essential for accurate diagnosis. The development of symptoms over hours to days is characteristic of *acute arthritis* and usually represents an inflammatory or traumatic process. The persistence of symptoms for more than 6 weeks is considered *chronic arthritis,* whereas an intermediate duration of days to weeks is referred to as *subacute arthritis.* Musculoskeletal pain can be further characterized using the mnemonic "OPQRST" where O = onset, P = precipitating (and ameliorating) factors, Q = quality, R = radiation, S = severity, and T = timing. The most common symptom of musculoskeletal disease is pain; a diagnostic approach to the evaluation of patients presenting with musculoskeletal pain is presented in Figure 264-2.

Pattern of Joint Involvement

The distribution of joint involvement is one of the most essential aspects of diagnosis of musculoskeletal diseases. Monoarthritis describes symptoms in a single joint; oligoarthritis (or pauciarthritis), symptoms in two to four joints; and polyarthritis, involvement of five or more joints. Arthritis in an extremity is called *peripheral joint disease,* whereas spinal involvement is termed *axial disease.* It is important to elicit a history of symmetrical versus asymmetrical peripheral joint disease. The predominant involvement of the small joints of the hands and feet or of large joints such as the shoulder, hip, and knee also has diagnostic importance.

A critical feature in clinical diagnosis is the distinction between arthralgia (subjective joint pain) and arthritis (objective joint swelling, deformity, or impaired function). Objective findings on physical examination must be found for a diagnosis of arthritis to be made.

TABLE 264-1 CLASSIFICATION OF MUSCULOSKELETAL DISEASES

CATEGORY	PROTOTYPES	USEFUL TESTS	TREATMENTS
Local and regional conditions	Tendonitis or bursitis	Aspirate bursa if infection is suspected	Local injections
Cartilage degeneration	Osteoarthritis	Radiographs of affected area	NSAIDs, analgesics, and physical therapy
Inflammatory synovitis	Rheumatoid arthritis Autoimmune diseases	Rheumatoid factor, ESR Antinuclear antibody test	DMARDs and biologic agents Prednisone and immunosuppressive drugs
Crystal-induced synovitis	Gout CPPD (pseudogout)	Joint fluid crystal examination Radiographic chondrocalcinosis	NSAIDs NSAIDs
Enthesopathy	Ankylosing spondylitis and biologic agents	Sacroiliac radiographs	NSAIDs, MTX, and spondyloarthropathies
Joint space disease	Septic arthritis	Joint fluid culture	Antibiotics
Osteoarticular disease	Osteonecrosis	Radiographs, magnetic resonance imaging	Core decompression or prosthetic joint replacement
Inflammatory myopathy	Polymyositis Dermatomyositis Inclusion body myositis	Muscle enzymes, electromyography, muscle biopsy	Corticosteroids and immunosuppressive drugs
General conditions	Polymyalgia rheumatica Fibromyalgia	Elevated ESR Normal ESR	Corticosteroids Aerobic exercise, stretches, and sleep medications

Biologic agents = anti-tumor necrosis factor (anti-TNF) drugs and others; CPPD = calcium pyrophosphate dehydrate disease; DMARDs = disease-modifying antirheumatic drugs; ESR = erythrocyte sedimentation rate; MTX = methotrexate; NSAIDs = nonsteroidal anti-inflammatory drugs.

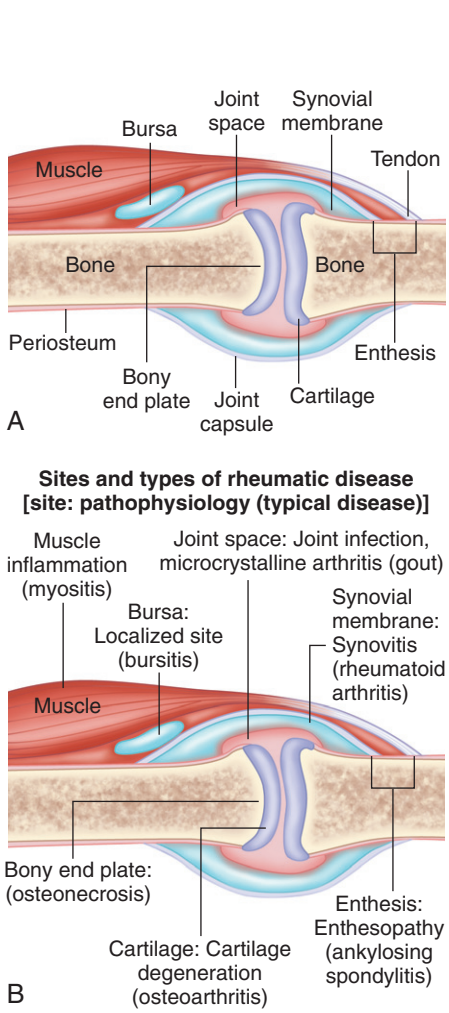

FIGURE 264-1. Structures involved in musculoskeletal diseases. A, Anatomic structures of the musculoskeletal system. **B,** Location of rheumatic disease processes.

Inflammatory versus Noninflammatory Conditions

An important initial step in the evaluation of musculoskeletal symptoms is the differentiation of inflammatory versus noninflammatory disease. A history of warmth and erythema over a joint suggests inflammatory disease. Morning stiffness lasting longer than 60 minutes, a "gel" phenomenon (stiffness after rest that is more than transient), and improvement in pain and stiffness with activity all suggest the presence of inflammatory disease. In contrast, minimal morning stiffness and worsening pain with activity suggest noninflammatory joint disease.

Extra-articular and Systemic Features

A careful history may reveal important systemic and extra-articular manifestations, including fever, fatigue, weakness, dry eyes, ocular inflammation, pulmonary symptoms, or Raynaud's phenomenon (Chapter 80). The finding of musculoskeletal complaints in the setting of systemic symptoms and multiorgan involvement strongly suggests the possibility of a diffuse autoimmune disease such as SLE.

Functional Disability Indices

A number of self-report questionnaires such as the Stanford Health Assessment Questionnaire, Functional Disability Index, and Arthritis Impact Measurement Scales, or modifications of these, have been developed for ongoing evaluation of patients with arthritis. These instruments document patient-reported functional status with results comparable to those of traditional physician-reported measures of joint disease activity, such as tender joint count, or to a radiographic joint erosion score and erythrocyte sedimentation rate.

Physical Examination

Essential Concepts

The physical examination includes a record of the patient's gait and posture as well as examination of the spine and skeletal muscles. The joints shown in Figure 264-3 should be examined systematically, region by region, with a side-to-side comparison to determine whether any are inflamed or damaged. The pattern of joint involvement, whether symmetrical, axial, or peripheral, should be recorded using the diagram. The abnormalities detected in each joint should be recorded as deformity, tenderness, erythema, swelling, and altered range of motion (ROM) to allow comparison between the same or different examiners over time.

Examination Components

There are four essential steps in musculoskeletal physical examination.

Inspection

Inspect for asymmetry, deformity, erythema, and swelling.

Palpation

Palpate for tenderness, warmth, synovial thickening and effusion, bony hypertrophy, and crepitus.

Range of Motion

Take the joint through passive or active ROM (or a combination of both).

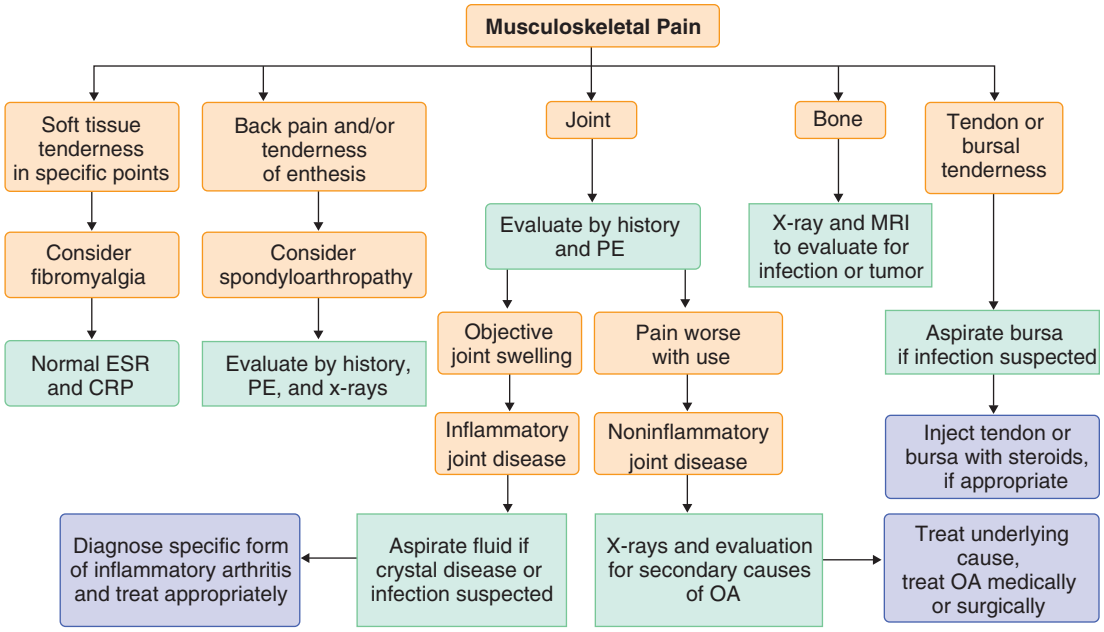

FIGURE 264-2. Diagnostic approach to musculoskeletal pain. CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; MRI = magnetic resonance imaging; OA = osteoarthritis; PE = physical examination.

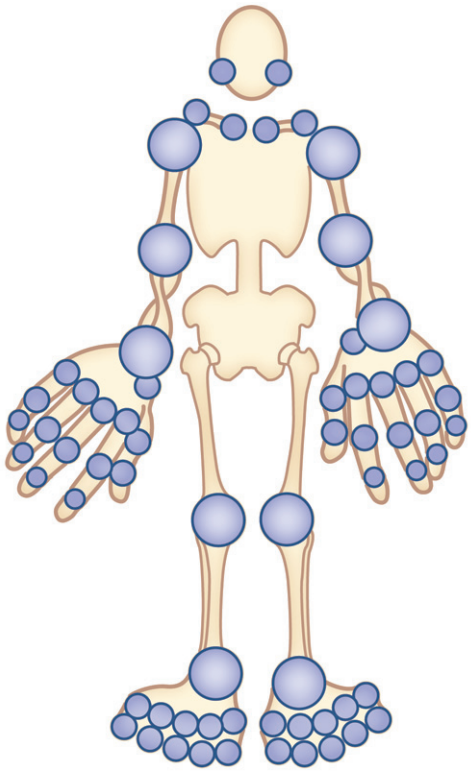

FIGURE 264-3. A pictorial method for recording joint disease activity or destruction. The sketch can be used on a printed form or rubber stamp to chart which joints are active or deformed at the time of each assessment. (Courtesy of Dr. Hugh A. Smythe, Toronto.)

Special Testing

Perform an assessment of supporting structures (such as ligaments and tendons) or for conditions particular to a single region (such as Tinel's sign at the wrist for detection of carpal tunnel syndrome; Chapter 428).

Objective Joint Findings

A careful examination is critical in distinguishing articular from periarticular conditions.

Joint tenderness alone is insufficient for diagnosis and must be correlated with the finding of an objective, visible, or palpable abnormality for a diagnosis of arthritis to be made. Joint redness (erythema) depends on the acuteness and severity of the underlying inflammation, and its presence may suggest the possibility of infection or crystalline arthritis. Joint warmth also depends on the acuteness of the underlying inflammation. Joint swelling is a definitive sign of arthritis and may be caused by either a joint effusion (excess synovial fluid) or an inflamed and swollen synovial membrane (synovitis). Bony hypertrophy around a joint (osteophytic swelling) is characteristic of osteoarthritis. *Crepitus* refers to a continuous grating sensation that is felt by the examiner's hand during joint motion. Fine or velvety crepitus may denote chronic proliferative synovitis, whereas coarse crepitus may indicate either roughening of the cartilage surface or complete loss of hyaline cartilage. Joint damage and deformity are usually signs of prior arthritis or injury (ligamentous laxity, joint subluxation, tendon rupture, or contracture).

Range of Motion

Both active and passive ROM are important in assessing joint function. Active ROM is patient-initiated movement of the joint; it tests integrated function and requires intact innervation and muscle and tendon function, as well as joint mobility. Passive ROM is examiner-initiated movement of a joint; it tests only joint mobility. The combined use of passive and active ROM minimizes the need for patient instruction and maximizes the speed and efficiency of the examination. Whenever joint motion is anticipated to be painful, it is best first to observe active ROM, to appreciate the degree of pain and dysfunction, before gently attempting passive ROM.

Extra-articular Findings

Because many rheumatic diseases are multisystem disorders, physical examination may document the presence of important extra-articular features. In RA, for example, these include subcutaneous nodules, digital vasculitis, and other systemic features as described in Chapter 272.

Classification

Clinical evaluation enables the establishment of which anatomic structures are inflamed, which are damaged, and how function is impaired. Seven types of rheumatic involvement can be identified as a framework for various diagnostic possibilities or hypotheses to be considered (see Fig. 264-1B). The nine categories presented in the following paragraphs are listed in Table 264-1 along with typical diseases, examples of useful diagnostic tests, and treatments. Table 264-1 and the descriptions in this section provide the basis for more detailed information contained in the following chapters.

Local and Regional Conditions

Nonarticular disorders such as tendonitis, bursitis, and neck and low-back strains are very common regional problems. They usually respond to

analgesics or nonsteroidal anti-inflammatory drugs, physical therapy, protective splints, or injection of corticosteroids.

Cartilage Degeneration

OA is defined as loss of articular cartilage with a bony response leading to the formation of osteophytes. Primary OA is thought to be caused by biochemical abnormalities in the cartilage that predispose to microfissures in the surface with subsequent degeneration of the cartilage. Secondary OA may develop as a consequence of inflammatory conditions such as RA, ankylosing spondylitis, septic arthritis, and calcium pyrophosphate deposition disease (CPPD). Previous trauma and joint hypermobility are other mechanical factors that may predispose to OA.

Inflammatory Synovitis

Inflammation of the synovial membrane lining of the joint is typical of inflammatory polyarthritides such as RA and other autoimmune diseases. Synovial inflammation is the dominant clinical feature of RA and may lead to irreversible joint damage. Synovial inflammation may also be present in conditions such as SLE, but the presence of multiorgan involvement should lead to the clinical suspicion of a systemic autoimmune disease.

Crystal-Induced Synovitis

Crystals of monosodium urate (gout), calcium pyrophosphate (pseudogout), or hydroxyapatite are capable of inducing an acute inflammatory reaction in both synovial fluid and synovium. Acute crystalline arthritis usually affects only one or at most a few joints at a time. Joint aspiration and synovial fluid analysis for crystals using polarized light microscopy establish the diagnosis. CPPD is often associated with the radiologic appearance of chondrocalcinosis of hyaline cartilage.

Enthesopathy

The enthesis is the anatomic transition zone where tendons, ligaments, and joint capsules attach to bone. Inflammation in this region is the hallmark of the family of spondyloarthropathies (Chapter 273), of which ankylosing spondylitis is the prototype. Other members of this group include reactive arthritis associated with enteric or urethral infection, the arthropathy associated with inflammatory bowel disease, and psoriatic arthritis. In ankylosing spondylitis, the sacroiliac joints and apophyseal joints of the spine show characteristic inflammation with a tendency to bony ankylosis (axial predominance), whereas in psoriatic arthritis, there is frequently enthesitis with an oligopolyarthritis (peripheral predominance).

Joint Space Disease

Septic arthritis (Chapter 280) may develop from hematogenous spread of microorganisms into the joint space, through local extension from adjacent soft tissues or by joint penetration. Joint infections are usually associated with intense pain even at rest, and the diagnosis is confirmed by joint aspiration with Gram stain and culture of the synovial fluid. A joint prosthesis increases susceptibility to infection in that joint. Blood in the joint space, known as *hemarthrosis,* may result from microfractures, coagulopathy, or tumor.

Osteoarticular Disease

Osteopenia/osteoporosis may complicate many rheumatic conditions and are dealt with in Chapter 251. Osteonecrosis (Chapter 256), which results from collapse of the bony end plate due to vascular insufficiency, causes secondary crushing and fragmentation of the overlying articular cartilage. Osteonecrosis may be idiopathic or associated with systemic conditions such as sickle cell disease or ethanol abuse; it may also occur after treatment with high-dose corticosteroids. Inflammation of the periosteum, known as *periostitis,* may be associated with hypertrophic pulmonary osteoarthropathy and clubbing (Chapter 283). This syndrome may be a clue to underlying lung cancer.

Inflammatory Myopathy

Inflammation and (usually painless) weakness of the proximal skeletal muscles are characteristic of inflammatory myopathies (Chapter 277): polymyositis, dermatomyositis, and inclusion body myositis. Elevated creatine kinase levels, electromyographic abnormalities, and characteristic histologic abnormalities on muscle biopsy are present in inflammatory myopathies.

General Conditions

These nonarticular or extra-articular disorders are not usually associated with arthritis. This group includes polymyalgia rheumatica, complex regional pain syndrome/reflex sympathetic dystrophy, and fibromyalgia. Polymyalgia rheumatica usually affects whites older than 50 years of age and causes proximal muscle pain in the neck, shoulders, and hips, with significant morning stiffness and a high erythrocyte sedimentation rate. It is sometimes associated with giant cell (temporal) arteritis (Chapter 279). Fibromyalgia usually manifests in individuals younger than 50 years; is associated with widespread arthralgia and myalgia (deceptively inflammatory sounding), morning stiffness, significant fatigue, and nonrestorative sleep. It is accompanied by the presence of tender points in characteristic locations, as described in Chapter 282.

TREATMENT

Rx

Effective treatment must be based on accurate diagnosis (see Table 264-1).

If a formal diagnosis is not apparent, generation of a prioritized problem list can be very helpful in suggesting a differential diagnosis and creating an initial management strategy. The acuteness and severity of presentation dictate whether immediate intervention is required or further observation is more appropriate. For example, an acute monarthritis (possible septic or crystalline arthritis) requires immediate attention, whereas a widespread smoldering polyarthritis may not. However, a patient with polyarthritis who is systemically ill requires prompt investigation to exclude a diffuse autoimmune disease, underlying infection, or hidden malignancy.

Arthrocentesis is helpful diagnostically, and aspiration of synovial fluid is also helpful therapeutically in relieving symptoms and permitting injection of corticosteroids when appropriate. *Photographs showing important landmarks for needle aspiration and injection of common joints are present in the online version of this text.*

Regardless of the diagnosis, educating the patient and family is crucial to successful management of any chronic musculoskeletal problem. Informed patients are more likely to comply with treatment and develop more realistic expectations of outcome. The goal of management for patients with musculoskeletal diseases is to control pain, prevent joint destruction, and maintain independence. For this reason, treatment should be individualized and based on early, accurate identification of symptoms and signs, a firm diagnosis, prompt administration of appropriate therapy, and vigilant monitoring of response.

LABORATORY TESTING IN THE RHEUMATIC DISEASES

DAVID S. PISETSKY

The rheumatic diseases are a heterogeneous group of conditions that result from diverse pathophysiologic mechanisms and involve the musculoskeletal system as well as other organs. These conditions range from mild, diffuse joint and muscle pain to severe life-threatening kidney failure and stroke. Although the rheumatic diseases have many origins, immune disturbances resulting in local and systemic inflammation are frequently the underlying cause. The approach to diagnosis therefore entails specific laboratory tests to assess functional disturbances of individual organs and their relationship to inflammation and autoimmunity.

Laboratory testing in patients with rheumatic disease has two main purposes. The first is diagnostic, and the second is prognostic. Some tests are useful in both contexts, but others have different performance characteristics related to their specificity and pattern of expression during disease. Prognostic tests provide critical information to help distinguish activity that is

reversible from damage that is fixed and irreversible. In general, the assessment of damage relies on specific tests of end-organ function or structure rather than process markers. Distinguishing activity from damage is important in patient management, especially with respect to the use of therapies associated with toxicity.

MARKERS OF INFLAMMATION

For many patients, the initial goal of evaluation is to determine the presence of inflammation. Inflammation is the body's response to injury and is characterized by a cascade of cellular and molecular events that arise irrespective of stimulus or locale (Chapter 47). The immediate response to inflammatory stimuli is termed the *acute phase response* and includes a set of proteins produced primarily in the liver in response to cytokines such as interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α), and IL-1. These cytokines are produced by macrophages and dendritic cells after stimulation of pattern recognition receptors (PRRs) that include both toll-like receptors (TLRs) and other non-TLR sensing systems that trigger a system called the *inflammasome*; PRRs recognize intracellular as well as extracellular bacterial and viral products as well as large and small (e.g., uric acid crystals) molecules released from damaged cells. The result is stimulation of innate immunity (Chapters 44 and 47). Many proteins in the acute phase response show dramatic increases in serum levels, although some show a reduction. Because the levels of these proteins can increase hundreds to thousands of times in magnitude, they provide a sensitive and powerful set of markers for inflammation, whether induced by infection, trauma, or autoimmunity.

Of the proteins stimulated during the acute phase response, C-reactive protein (CRP) has received the most attention as a marker of inflammation in both rheumatic and nonrheumatic disease. CRP is a member of the pentraxin family; although its function is not fully known, its ability to bind to phosphocholine suggests a scavenger function to eliminate bacterial products or damaged cells and to attenuate the consequences of infection or tissue injury. Other molecules, such as serum amyloid protein (SAP), fibrinogen, and complement, also show marked elevations in levels during the acute phase response, signifying a broad-based effort at host defense.

The CRP level provides a very useful measure of inflammation and can convey information for categorization of a clinical process (e.g., inflammatory versus noninflammatory arthritis) as well as assessment of disease activity or prognosis (e.g., activity of rheumatoid arthritis [RA] or likelihood of joint erosion). The advantage of measuring CRP in the blood, rather than cytokines, is that the protein levels are much higher. Furthermore, CRP levels remain elevated for a longer period (days) than cytokines; the latter may appear only transiently in the blood and thereby evade detection.

Another simple laboratory test reflecting the acute phase response is the erythrocyte sedimentation rate (ESR). In this test, commonly called the *sed rate*, anticoagulated blood is drawn into a long, thin tube and allowed to settle under the influence of gravity for 1 hour. The distance the blood falls depends on a number of factors, including the concentration of serum proteins such as immunoglobulins and fibrinogen, an acute phase reactant. The sedimentation rate is nonspecific with respect to disease association and also depends on age and gender. The upper limits of normal vary between women and men.

Other simple laboratory tests point to an acute phase response. For example, patients with inflammation frequently exhibit a leukocytosis or thrombocytosis, most likely reflecting the action of cytokines and other mediators, including glucocorticoids, during this process. With chronic inflammation, anemia of chronic disease can also occur, with the hematocrit, in conjunction with the white blood cell and platelet counts, pointing to the presence of an inflammatory process. In systemic lupus erythematosus (SLE), lymphopenia, thrombocytopenia, and low CRP values often characterize active disease, with the discordance between laboratory and clinical findings a clue to diagnosis.

LABORATORY EVALUATION OF MUSCULOSKELETAL DISEASE

The most common presentation of musculoskeletal disease is pain in and around the joints in association with functional impairment. Collectively, diseases causing joint symptoms are called arthritis, implying inflammation. The extent of inflammation in these diseases varies markedly, however, with some forms such as osteoarthritis (Chapter 270) showing scant evidence of inflammation either locally or systemically.

Arthritis results from many different diseases and occurs in various patterns defined by the number and size of joints affected, symmetry, and involvement of the axial as well as peripheral joints. For each pattern (e.g., chronic polyarthritis), a key issue in diagnosis concerns its place in the spectrum of inflammatory versus noninflammatory arthritis. Furthermore, although many diseases can cause arthritis, their prevalence varies enormously, with osteoarthritis or degenerative joint disease being the most common form of noninflammatory arthritis and RA the most common form of inflammatory arthritis.

The differential diagnosis of arthritis is based on a comprehensive history and physical examination to assess symptoms suggesting inflammation (e.g., morning stiffness and fatigue), the presence of synovitis, and results of laboratory tests indicative of inflammation. Of these tests, the ESR and CRP are nonspecific indicators of inflammation. Two autoantibody tests, rheumatoid factor (RF) and antibodies to citrullinated proteins, provide more specific diagnostic information. Given the demographics of inflammatory arthritis, testing for antinuclear antibodies is often part of this evaluation as well.

Rheumatoid Factor

RF comprises a family of specificities that bind to the immunoglobulin G (IgG) molecule. These RFs target primarily the constant region or Fc portion of IgG, reacting with antigenic determinants that are most likely conformational in origin. IgM RFs are the most abundant of these antibodies and have been easiest to measure, using agglutination assays with red blood cells or latex beads coated with IgG. More recently, enzyme-linked immunosorbent assay (ELISA) and nephelometry have been used to detect RFs.

RFs occur in approximately 80% of patients with RA (Chapter 272) and represent one criterion for the classification or diagnosis of this disease. Furthermore, high levels of RFs are often associated with a worse prognosis, the occurrence of joint erosion as measured by radiographs, and deformity. Despite these associations, RFs occur in the sera of patients with a wide range of autoimmune and inflammatory diseases as well as in normal individuals, especially with age (Table 265-1). The frequent occurrence of RFs may reflect their etiology and role in innate immune responses to promote the binding of IgG to antigen by Fc cross-linking. Although RFs may occur in many

TABLE 265-1 RHEUMATIC DISEASES AND NONRHEUMATIC CONDITIONS ASSOCIATED WITH A POSITIVE RHEUMATOID FACTOR

DISEASES	FREQUENCY
Rheumatoid arthritis	50-90%
Systemic lupus erythematosus	15-35%
Sjögren's syndrome	75-95%
Systemic sclerosis	20-30%
Polymyositis/dermatomyositis	5-10%
Cryoglobulinemia	40-100%
Mixed connective tissue disease	50-60%
Aging (>70 yr)	10-25%
Infection	
Bacterial endocarditis	25-50%
Liver disease	15-40%
Tuberculosis	8%
Syphilis	Up to 13%
Parasitic diseases	20-90%
Leprosy	5-58%
Viral infection	15-65%
Pulmonary disease	
Sarcoidosis	3-33%
Interstitial pulmonary fibrosis	10-50%
Silicosis	30-50%
Asbestosis	30%
Miscellaneous diseases	
Primary biliary cirrhosis	45-70%
Malignancy	5-25%

Modified from Shmerling RH, Delbanco TL. The rheumatoid factor: an analysis of clinical utility. *Am J Med.* 1991;91:530.

settings other than RA, depending on the pretest probability, the test nevertheless remains useful in the evaluation of patients with inflammatory arthritis.

Antibodies to Citrullinated Proteins

Antibodies to citrullinated proteins are other autoantibody specificities important in the diagnosis of RA (Chapter 272). Citrulline is a post-translational modification of the amino acid arginine that results from deimidation. This chemical reaction is catalyzed by the enzyme peptidylarginine deiminase (PAD) and may occur in the setting of inflammation; the function of this modification is unknown. Citrullination can affect many different proteins, creating antigenic sites on proteins that include keratin, fibrinogen, and filaggrin. This antibody system can be detected by Western blotting, ELISA, or cellular immunofluorescence.

Although antibodies are directed to citrullinated residues on intact proteins, they can be conveniently measured using synthetic peptides containing citrulline. Among these synthetic antigens, a citrulline-containing protein with a cyclic structure provides sensitive and specific assays in an ELISA format. Antibodies directed to this type of antigen are known as anti-CCP (cyclic citrullinated peptide) and can be formally distinguished from antibodies to the citrullinated proteins themselves (ACPA, or anti–citrullinated protein antibodies). The term *anti-CCP* is commonly used for these specificities, although it is not formally synonymous with ACPA.

Anti-CCP antibodies are highly associated with RA. They occur in 60 to 70% of patients with RA and uncommonly in those with other forms of inflammatory arthritis, making their presence important in diagnosis. Significantly, anti-CCP antibodies can occur before the onset of other signs and symptoms of RA, suggesting utility for screening of at-risk patients. Because anti-CCP antibodies are more specific markers than RFs, their presence in patients with early inflammatory arthritis may indicate the diagnosis of RA and allow more prompt initiation of therapy.

Joint Fluid Analysis

Analysis of joint fluid can provide decisive data in the evaluation of arthritis and, in some instances, a definitive diagnosis. This analysis is essential in the setting of acute monoarthritis to investigate the possibility of infection; for chronic forms of arthritis, joint fluid should be analyzed if there is uncertainty about the diagnosis and involvement of one joint out of proportion to others. Joint aspiration is a sterile procedure performed with a local anesthetic. Although fluid can be analyzed by tests to assess viscosity and mucin content, the cell count, examination of crystals, and stains and cultures to evaluate infection are the most informative.

On the basis of cell counts, joint fluids can be categorized into four main types: noninflammatory, inflammatory, septic, and hemorrhagic. A noninflammatory fluid has fewer than 2000 cells/mm^3 with mononuclear cell predominance. An inflammatory fluid has more than 2000 cells/mm^3, with 50,000 cells/mm^3 frequently used as the upper limit for this type of fluid. In an inflammatory fluid, polymorphonuclear cells predominate. A septic fluid is an inflammatory fluid in which culture or staining for microorganisms demonstrates infection. Suspicion of infection is especially high for fluids with cell counts greater than 50,000/mm^3. However, crystal-induced arthritis can produce cell counts of this magnitude, and an infected fluid can have counts below this level. Hemorrhagic fluids have red cell predominance that can approximate that of blood.

In the setting of an acute monoarthritis, crystal-induced disease is much more common than infection, with the presence of crystals demonstrated by polarization microscopy. With this technique, monosodium urate crystals in gout appear needle-shaped and are negatively birefringent. In contrast, calcium pyrophosphate dihydrate crystals in pseudogout are rhomboidal in shape and are weakly positively birefringent. Infection can coexist with crystal-induced disease, necessitating microbiologic evaluation even when crystals are found. Hemorrhagic fluids can also result from infection, although their presence suggests malignancy or trauma. Figure 265-1 provides an algorithm for the analysis of joint fluid.

Depending on the clinical findings and the results of initial laboratory testing, other studies may be performed to investigate less common diagnostic possibilities such as metabolic disease or malignancy. The laboratory evaluation of inflammatory arthritis may also include serologic tests for infections such as Lyme disease, human immunodeficiency virus (HIV) infection, or hepatitis.

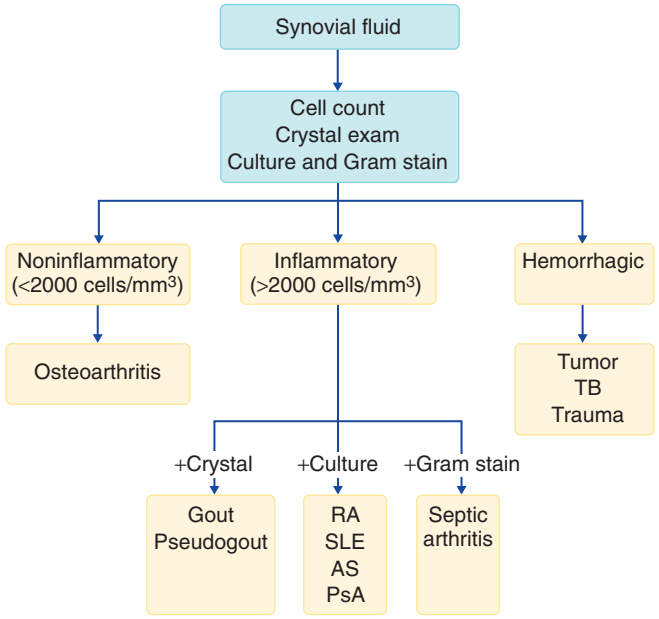

FIGURE 265-1. Algorithm for analysis of joint fluid. Examples of inflammatory arthritis are indicated, although many conditions can produce these findings. AS = ankylosing spondylitis; PsA = psoriatic arthritis; RA = rheumatoid arthritis; SLE = systemic lupus erythematosus; TB = tuberculosis.

LABORATORY EVALUATION OF SYSTEMIC INFLAMMATORY DISEASE

Among rheumatic diseases, some are characterized by severe systemic inflammation that can cause organ-threatening and life-threatening manifestations. These diseases can have arthritis as a component and presenting complaint, although the prominence of extra-articular manifestations, especially as they develop over time and involve organs such as the kidney, points to their systemic nature. These diseases can be categorized on the basis of clinical, serologic, and pathologic findings, with the presence of vasculitis, irrespective of blood vessel size, providing a unifying feature in disease classification.

The terms *connective tissue disease* (CTD) and *collagen vascular disease* are both used to denote a group of diseases that includes RA, SLE, Sjögren's syndrome, polymyositis, dermatomyositis, and progressive systemic sclerosis. Diseases in this group can share common or overlapping clinical features, especially early in their course, when their presentations may be similar. In this stage of disease, the condition may be called *undifferentiated CTD*, with serologic markers sometimes predictive of the eventual diagnosis.

Antinuclear Antibodies

The expression of antibodies to components of the cell nucleus (antinuclear antibodies, or ANAs) is characteristic of CTD and is essentially invariable in patients with SLE (Chapter 274). These antibodies target a host of nuclear macromolecules, including DNA, RNA, and proteins as well as complexes of proteins with nucleic acid. These antigens are ubiquitously expressed in cells and subserve critical processes related to chromosomal structure, cell division, transcription, and translation. The basis for the antigenicity of these molecules is unknown, although DNA and RNA both have intrinsic immunologic activities and can stimulate cytokine production through action on both TLR and non-TLR PRRs, especially when in the form of immune complexes. ANAs are commonly measured by immunofluorescence (IF) assays in which sera are incubated with tissue culture cells (e.g., Hep2 cells) fixed to a glass slide. Antibody binding is revealed by fluorescence microscopy after incubation of the slide with a fluoresceinated anti-immunoglobulin reagent. Results are reported in terms of the pattern of fluorescence as well as the end-point titer of sera at which fluorescence can be observed. The patterns of binding differ depending on the location of the particular macromolecular target, although a few patterns predominate. These patterns include homogeneous, rim, nucleolar, and speckled; in addition, ANA tests can detect antibodies to cytoplasmic antigens. Despite some disease associations, these patterns do not have diagnostic significance. Table 265-2 presents a list of major ANAs with their pattern and disease associations.

A major limitation in the assays of ANA concerns the frequency of positive reactivity in the sera of otherwise normal individuals who lack evidence of a

TABLE 265-2 SELECTED ANTINUCLEAR ANTIBODIES AND RHEUMATIC DISEASES

DISEASE PATTERN	ANTIBODY	ANTIGEN	ASSOCIATION
Homogeneous	Antihistone	Histones H1, H2A, H2B, H3, H4	Drug-induced lupus (>95%)
Rim	Anti-double-stranded DNA	Double-stranded DNA snRNP proteins	SLE (50%)
Speckled	Anti-Sm	snRNP proteins	SLE (30%)
	Anti-U1-RNP	U1 snRNP proteins	SLE (30%); MCTD (>95%)
	Anti-Ro (SS-A)	Two proteins complexed to small RNAs Y1-Y5	SLE (30%); Sjögren's syndrome (70-80%)
	Anti-La (SS-B)	Single protein plus RNA polymerase III transcript	SLE (15%); Sjögren's syndrome (50-70%)
	Anti-Ku	DNA binding protein	SLE (10%)
	Anti-SCL-70	DNA topoisomerase I	PSS (40-70%); CREST (10-20%)
Nucleolar	Anti-PM-Scl	Nucleolar protein complex	PSS (3%); PM (8%)
	Anti-Mi-2	Nuclear protein complex	DM (15-20%)
	Anti-RNA polymerase	Subunits of RNA polymerase I	PSS (4%)
Dividing cell	Anticentromere	Centromere/kinetochore protein	CREST (80%); PSS (30%)
	Antiproliferating cell nuclear antigen	Auxiliary protein of DNA polymerase δ	SLE (3%)
Cytoplasmic	Anti-Jo-1	Histidyl tRNA synthetase	ILD in PM/DM (18-25%)
	Anti-PL-7	Threonyl tRNA synthetase	PM/DM (3%)
	Anti-PL-12	Alanyl tRNA synthetase	PM (4%)
	Anti-SRP	Signal recognition particle	SLE (10%)
	Anti-ribosomal P	Large ribosomal subunit	PM/DM (3%)

CREST = calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia; DM = dermatomyositis; ILD = interstitial lung disease; MCTD = mixed connective tissue disease; PM = polymyositis; PSS = progressive systemic sclerosis (diffuse scleroderma); SLE = systemic lupus erythematosus; snRNP = small nuclear ribonucleoprotein; tRNA = transfer RNA.

CTD. The sera of as many as 5% of normal individuals express reactivity in the IF ANA test. The basis of this reactivity is not well understood, although it may reflect a predisposition to autoimmunity that is manifest in ANA production in the absence of other immunopathologic disturbances for the complete development of a CTD. Because ANA testing is often performed to evaluate nonspecific complaints such as arthralgias, fatigue, and fever, a positive test must be interpreted with caution and not used as proof of a CTD in the absence of correlative clinical or laboratory findings.

Because of detailed biochemical studies, the molecular identity of many ANAs is now known, allowing for the development of specific immunochemical assays using technologies that can eliminate the need for visual inspection of a slide stained for fluorescence. These tests (e.g., ELISA) can be performed individually, although multiplex assays provide simultaneous assessment of multiple specificities. With multiplex assays, the equivalent of an ANA test can be generated by measuring antibodies to a select set of more commonly targeted autoantigens, with positive binding to any one antigen considered indicative of a positive value for an ANA. Because sera of patients with SLE and other systemic inflammatory diseases contain numerous ANAs, focus on a limited set of specificities may fail to detect many positive sera. In addition, because immunochemical assays may detect low levels of antibody binding, the significance of this reactivity is not certain. Thus, although multiplex assays are operationally easier than conventional ANA testing by immunofluorescent staining, in clinical situations, the IF assay remains an important laboratory test for patient evaluation.

Among many ANA specificities now identified, only a few are performed routinely because of their value for diagnosis and prognosis. For several CTDs, diagnosis can be readily determined from clinical findings or other laboratory tests. In these instances, the ANA determination provides confirmatory information as well as clues to the occurrence of certain clinical manifestations.

Antibodies to DNA

Antibodies to DNA (anti-DNA) are serologic markers of SLE and represent a criterion in the classification of patients with this disease (Chapter 274). These antibodies bind sites on both single-stranded (ss) and double-stranded (ds) DNA, although anti-dsDNA antibodies are more specific for SLE and therefore routinely measured. Although these antibodies can bind free DNA, DNA in the cell occurs in association with histones to form a structure called the *nucleosome*, with DNA wrapped around a histone core. Anti-DNA may therefore be considered a subset of antibodies to nucleosomes, with nucleosomes probably serving as the driving antigen for this response.

In clinical practice, the measurement of anti-DNA antibodies is an important element in the evaluation of patients with a broad array of clinical complaints, given the heterogeneity and multisystemic nature of SLE. Anti-DNA determinations, in addition to their value in diagnosis, also convey prognostic information and serve as an index of disease activity. The association with disease activity appears strongest with glomerulonephritis, most likely because of the role of DNA–anti-DNA immune complexes in immunopathogenesis. The association of anti-DNA antibodies with other disease manifestations is less certain, limiting the use of this marker as a measure of overall disease activity.

Several immunochemical approaches can be used to detect anti-DNA antibodies, although solid-phase ELISA assays are convenient and sensitive and eliminate the need for radioactivity. The assays vary in regard to the spectrum of anti-DNA antibodies detected, and results between assays may not correlate. Nevertheless, for each assay, the dynamic range for testing is large. With treatment and disease quiescence, anti-DNA antibodies may essentially disappear; with flare, levels may increase dramatically. This property distinguishes anti-DNA antibodies from other ANAs in SLE, levels of which tend to be more consistent over time.

As is the case for other ANAs, the appearance of anti-DNA antibodies in the serum may precede other manifestations of SLE, suggesting vigilance if these antibodies are present in patients who have symptoms that suggest a CTD but lack other evidence to establish a firm diagnosis.

Other Antinuclear Antibodies

Anti-Sm and anti-RNP antibodies are related specificities that commonly occur together in the sera of patients with SLE, a phenomenon called *linkage*. These antibodies bind proteins on subcellular particles called *snRNPs* (small nuclear ribonucleoproteins) that are composed of a set of proteins and uridine-rich RNAs. Anti-Sm and anti-RNP antibodies differ in protein specificity and in the ability to cause immunoprecipitation of the bound RNA molecules. Anti-Sm antibodies occur only in patients with SLE and represent a serologic marker in disease classification. In contrast, anti-RNP antibodies can appear in the sera of patients with other clinical presentations and, in the absence of anti-Sm, may characterize patients with overlapping CTD features, so-called mixed CTD. In SLE, the frequencies of anti-Sm and anti-RNP antibodies vary among racial and ethnic groups, although a clear association with particular clinical manifestations has not been established.

Anti-Ro and anti-La antibodies (or anti-SS-A and anti-SS-B), another set of linked ANAs, are directed to protein-RNA complexes that are involved in cellular metabolism of RNA. These antibodies are expressed more widely in patients with CTD and appear in the sera of patients with SLE, RA, and

Sjögren's syndrome, among others. Assessment of these antibodies is important because of their association with the neonatal lupus syndrome, which results from the transplacental passage of antibodies and causes congenital heart block as well as rash in the neonate.

Although ANAs are directed to ubiquitous antigens, they nevertheless are expressed in disease-specific patterns and may show association with particular organ-specific manifestations. These associations include anti–ribosomal P antibodies with central nervous systemic involvement in SLE, antibodies to DNA topoisomerase 1 (anti-SCL-70) with progressive systemic sclerosis (diffuse scleroderma), antibodies to centromeres with CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia), and antibodies to histidyl transfer RNA synthetase (anti-Jo-1) with interstitial lung disease in scleroderma (Chapter 275).

In addition to their association with specific disease manifestations, antibodies to both DNA- and RNA-binding proteins such as Sm and RNP may contribute to overall immune dysregulation in patients with autoimmune disease because of their formation of immune complexes containing DNA or RNA. These complexes can stimulate the production of type 1 interferon by triggering both TLR and non-TLR nucleic acid sensors as well as other cellular receptors (e.g., Fc receptors). Because immunoassays of interferon with patient sera are limited, the presence of interferon is observed more clearly in the pattern of gene expression known as the interferon signature in peripheral blood cells. Because antibodies to RNA-binding proteins in particular may promote this pattern, the serologic assay of these ANAs may allow assessment of the likelihood of both nonspecific and specific immunologic disturbances.

Antibodies to Phospholipids

Originally defined by their effects on in vitro clotting tests, antibodies to phospholipids (APLs) are associated with in vivo thrombosis and have been termed *lupus anticoagulants* (LACs). Patients with these antibodies display a clinical condition, termed the *antiphospholipid antibody syndrome*, which is characterized by arterial or venous thrombosis, thrombocytopenia, and first-trimester spontaneous abortions (Chapter 179). This syndrome may occur by itself or in the context of SLE, where it may contribute to the acceleration of atherosclerosis, premature stroke, and myocardial infarction. The laboratory evaluation of this condition involves specific assays of antibodies to phospholipids and related proteins as well as functional assays of clotting. Because expression of these antibodies may vary over time, testing must be performed on more than one occasion at least 6 weeks apart. Furthermore, the results of immunochemical and functional assays may not be congruent, because it is likely related to the heterogeneity of antibodies.

The serology of APLs is complicated because it is related to their antigenic targets as well as heterogeneity. Of phospholipids, cardiolipin is a common antigen for these assessments. Although they are designated as antibodies to cardiolipin or phospholipids, these antibodies may be actually directed to the protein β_2-glycoprotein 1; in the format of an ELISA, this protein may bind to phospholipids to create antigenic sites. ELISA determinations of anticardiolipin (aCL) antibodies can provide quantitative assessment of different isotypes (IgG, IgM, and IgA), although the association with thrombosis appears strongest with IgG antibodies. Importantly, patients with the clinical syndrome may lack antibodies to phospholipids when measured in these assays.

Functional assays for LACs involve tests directed at inhibition of in vitro clotting (e.g., activated partial thromboplastin time, dilute Russell's viper venom time), recognizing the discordance between in vivo thrombosis and in vitro anticoagulation. Functional assays to detect lupus anticoagulants involve a mixing step in which patient plasma is mixed with normal plasma to determine the presence of an inhibitor (i.e., an antibody) as opposed to a deficiency state. The mechanism by which antibodies to phospholipids and related proteins may cause thrombosis in vivo is unknown, although these antibodies may interact with the surface of cells (e.g., endothelium) to promote a prothrombotic state.

Complement

Assessment of the complement system provides valuable information on the presence of activity of diseases in which immune complex deposition may promote inflammation and tissue injury (Chapter 49). This system involves a large number of proteins that function in enzyme cascades to generate degradation products that amplify immunologic reactions and promote the destruction or removal of foreign organisms as well as damaged cells. In the setting of SLE and in certain forms of vasculitis and glomerulonephritis, immune complexes activate complement to promote local inflammation. This activation can be measured in terms of the total complement level in the blood by functional assays of hemolytic activity; by measurement of individual complement components such as C3 and C4, whose levels are reduced by cleavage during activation; by measurement of split products of cleaved complement components; and by measurement of complement fragments bound to red blood cells during complement activation. Proteins of the complement system are acute phase reactants and can increase with inflammation, including active disease. Correspondingly, low levels may reflect inherited complement deficiency rather than consumption; genetic deficiency of C1q, for example, is highly associated with SLE.

Antineutrophil Cytoplasmic Antibodies

Antineutrophil cytoplasmic antibodies (ANCAs) are autoantibodies that react to determinants in the neutrophil and occur prominently in patients with certain forms of necrotizing vasculitis or rapidly progressive glomerulonephritis. Two main forms of ANCA have been distinguished on the basis of the target antigens and pattern of immunofluorescence staining of fixed neutrophils: PR3-ANCA (C-ANCA), which reacts with proteinase-3 (PR3), and MPO-ANCA (P-ANCA), which reacts with myeloperoxidase (MPO). By immunofluorescence, PR3-ANCA shows staining in the cytoplasm; staining by MPO-ANCA localizes in the perinuclear area. ANCAs to other proteins have also been identified, but these may also occur in conditions other than vasculitis.

In the evaluation of severe, multisystem inflammatory disease, ANCA testing is necessary to distinguish possible etiologies. PR3-ANCA occurs commonly in patients with Wegener's granulomatosis, whereas MPO-ANCA marks the course of vasculitis caused by microscopic polyangiitis, polyarteritis nodosa, and Churg-Strauss disease, among others (Chapter 278). In patients with ANCA-associated glomerulonephritis, the kidney lacks evidence of immune deposits, as indicated by the lack of staining for immunoglobulins or complement. Kidney disease of this kind is termed *pauci-immune glomerulonephritis*. Although ANCA testing is useful in initial diagnosis, its role for assessing disease activity is less certain. Occasionally, in patients who are desperately ill and cannot tolerate a lung or kidney biopsy, the presence of an ANCA can be used as preliminary evidence for diagnosis to allow the initiation of immunosuppressive therapy.

Cryoglobulins

Cryoglobulins are serum immunoglobulins that precipitate in the cold and promote the pathogenesis of systemic inflammatory disease through tissue deposition. The presence of a cryoglobulin is detected by allowing blood, collected warm, to remain cool at 2° to 4° C for 1 or more days. After centrifugation, the amount of cryoprecipitate is measured and expressed as a cryocrit. Subsequent analysis of the cryoprecipitate by immunochemical assays allows determination of its components. Cryoglobulins can be classified into three main types on the basis of their composition: (1) single, or type I; (2) mixed, type II; and (3) mixed, type III. A type I cryoglobulin consists of only a monoclonal immunoglobulin that precipitates in the cold. A mixed-type cryoglobulin contains RFs bound to polyclonal IgG to form an immune complex. In type II cryoglobulins, the IgM RF is monoclonal, and in type III, the IgM RF is polyclonal.

Type I cryoglobulins occur in patients with lymphoproliferative disorders such as Waldenström's macroglobulinemia, multiple myeloma, or chronic lymphocytic lymphoma (Chapters 190 and 193). In contrast, patients with mixed cryoglobulins can present with a wide range of signs and symptoms resulting from vasculitis. These manifestations include purpura (a sign of leukocytoclastic vasculitis), weakness, arthritis, and neuropathy; they represent a syndrome known as *essential mixed cryoglobulinemia*. Most patients with this condition have infection with hepatitis C virus, with viral components present in the complexes. These patients have serologic evidence of this infection as well as manifestations attributable to the underlying liver disease. As in the case of other CTDs and systemic inflammatory diseases, the evaluation of patients with essential mixed cryoglobulinemia demands attention to the entire patient and the impact of disease on multiple organs.

IMAGING STUDIES IN THE RHEUMATIC DISEASES

LYNNE S. STEINBACH

Imaging of the rheumatic diseases is essential to diagnosis and assessment of progression of arthropathy. The mainstay for imaging has always been the radiograph. This continues to be the case because radiographs provide a relatively low-cost baseline evaluation of the bones, joints, and soft tissues. Frequently, the information provided is adequate for diagnosis and treatment. Other imaging modalities, such as magnetic resonance imaging (MRI), computed tomography (CT), ultrasound, and bone scintigraphy, can aid in characterization and follow-up of rheumatic disease. This chapter discusses the various imaging options for evaluation of rheumatic disease, providing the reader with their capabilities and appropriate use.

RADIOGRAPHY

The radiographic image represents a map of radiation attenuation through different tissues along the course of the x-ray beam. A white structure such as bone attenuates more radiation than a darker structure such as cartilage, muscle, or joint effusion. An analogue detector with a film cassette has been used to image the body for more than a century.

Digital radiography is being used increasingly for imaging. It employs a photostimulated phosphor imaging plate and an image reader-writer that processes the latent image information. When the plate absorbs x-rays, the energy is converted to light energy by fluorescence, with the intensity of light being proportional to the energy absorbed by the phosphor. The stimulated light is used to create a digital image. This type of image is then transferred to x-ray film or to a picture-archiving system (PACS) that is used for viewing by the clinician. Digital images have advantages over conventional radiography in that they can be manipulated by the technologist or by the clinician at the PACS station for contrast and brightness as well as window width and level. Magnification and quantification are also possible. The images can be easily stored and retrieved from a server.

The radiograph is the initial imaging technique used for evaluation of arthritis. Radiographs are affordable and available, and they render high spatial resolution images of the joint. Frequently, a radiograph is all that is needed to assess joint damage. Radiographs demonstrate joint changes with high resolution down to approximately 0.05 mm in size. No other imaging study is able to accomplish this degree of spatial resolution. The radiograph can provide detailed evaluation of osseous cortex. Features such as joint space narrowing, erosion, subluxation, calcification, new bone formation, subchondral cyst formation, subchondral sclerosis, and soft tissue swelling all can be evaluated on radiographs (Fig. 266-1).

Radiographs should be obtained with at least two views of the involved bone at 90-degree angles to each other in order to detect and characterize abnormalities such as erosion, effusion, soft tissue swelling, subluxation, dislocation, and fracture. Standard views usually comprise frontal and lateral views, but occasionally, oblique and special views are needed, particularly in assessing the elbow, wrist, fingers, ankle, foot, toes, pelvis, and sacroiliac joints. Weight-bearing views of joints may be of value for assessing joint space narrowing. This is particularly true in the knee. Although there is no universal consensus on routine views for the different joints, recommended screening views are listed in Table 266-1.

Because they have poor contrast resolution, radiographs do not reveal all aspects of arthropathy. Unlike MRI, radiography lacks the ability to show early cartilage loss and erosion, especially in the larger joints. Soft tissue pathology and muscle abnormalities cannot be assessed on radiographs as they can with MRI. Radiographs are also not as sensitive for evaluating activity of the disease. Other imaging techniques that will be discussed later in the chapter have these advantages and are considered complementary to radiographs in the assessment of joint and soft tissue disease.

Fluoroscopy, which employs x-ray in real time, is a quick and precise method for needle placement during aspirations and injections, particularly for joints that are deep or complex and difficult to enter with the blind technique, such as the hip, shoulder, and sacroiliac joints. It can also be used to evaluate joint motion and stress. Videotaping of joint motion is useful for recording the kinematics of the joint. Because of the high dose of radiation, one must keep fluoroscopic time to a minimum. CT and ultrasound are other imaging methods that are helpful for joint aspiration and injection and are discussed subsequently in this chapter.

MAGNETIC RESONANCE IMAGING

The demands of imaging are increased in this age of therapeutic approaches designed to halt the progression of arthritis. During the past two decades, MRI has become the imaging modality of choice for evaluation of joint soft tissue, marrow structures, and muscle pathology. This is because MRI has high contrast resolution that enables the differentiation of various soft tissues from each other. Abnormal joint structures usually display different signal intensities than their normal counterparts. Morphologic changes resulting from destruction of tissue by joint and muscle inflammation are also identified.

MRI applies a strong magnetic field with radiofrequency pulses that pass through the different body tissues to produce varying signal intensities. Each soft tissue structure contains unique properties that provide a characteristic signal intensity based on the proton density, T1 relaxation time, and spin density of the tissue. Various pulse sequences can be used to evaluate the joint.

Multiple factors can influence spatial resolution and thus the quality of the MRI. These include field strength and coil selection. Most imaging is done

TABLE 266-1 ROUTINE RADIOGRAPHIC SCREENING VIEWS OF THE SKELETON

UPPER EXTREMITY	
Fingers	PA, lateral (separate fingers)
Hand	PA, oblique, lateral
Wrist	PA, lateral (both with neutral positioning); "ball catcher" oblique useful for inflammatory arthritis
Forearm	AP, lateral
Elbow	AP (supinated), lateral (90-degree flexed), obliques as needed
Humerus	AP, lateral
Glenohumeral joint	AP internal and external rotation (axillary, Grashey, or transthoracic view)
Acromioclavicular joint	AP, 15-degree cephalad AP (bilateral weight-holding if dislocation)
Sternum	AP, oblique AP (also Hobbs view or lordotic view)
LOWER EXTREMITY	
Hip	AP internal rotation, frog-leg lateral (or cross-table)
Femur	AP, lateral
Knee, arthritis	PA flexed and AP weight-bearing views, lateral
Knee, patellofemoral joint	Merchant view (45-degree flexion)
Tibia/fibula	AP, lateral
Ankle	AP, lateral, mortise
Foot	AP, lateral, medial oblique (simulated weight-bearing lateral for foot alignment abnormality)
Subtalar joint	Lateral, Harris-Beath view
Calcaneus	Lateral, AP craniocaudal angulated view
Toes	AP, lateral, AP oblique
AXIAL SKELETON	
Cervical spine	AP, lateral, open mouth (odontoid), swimmer's view for lower C spine, obliques or pillar views for facet joints
Thoracic spine	AP, lateral, swimmer's view for upper T spine
Lumbar spine	AP, lateral; obliques for pars interarticularis, flexion-extension laterals for subluxation
Sacrum	30-degree cephalad angulated AP, lateral
Coccyx	10-degree caudal angulated AP, lateral
Sacroiliac joints	30-degree cephalad angulated AP
Pelvis	AP, Judet views and/or inlet-outlet views for pelvic ring fractures

Modified from Lee JHE. Imaging modalities. In: Johnson T, Steinbach L, eds. *Essentials of Musculoskeletal Imaging.* Rosemont, IL: American Academy of Orthopaedic Surgeons; 2004:6.

on high-field superconducting magnets. Permanent or resistive magnets are also in use at lower field strengths. Field strength is measured in Tesla (T). In general, the higher the field strength, the better the signal from the tissue and the shorter the imaging time.

There are five types of magnets used for clinical imaging of joints: (1) ultra-high-field (3.0 T); high-field (1.0-2.0 T); midfield (0.3-1.0 T); low-field (< 0.1 to 0.2 T); and ultra-low-field (<0.1 T). Most clinical MRI scanners operate between 0.3 and 3 T. Open MRI scanners are less confining for claustrophobic patients but are not usually available at the high-field range above 1.0 T that provides increased resolution. Ultra-high-field 3 T scanners offer the highest spatial resolution and are being increasingly used for imaging small joints and cartilage.

Coils are also important for proper joint imaging in MRI. These are electrical devices that can generate or detect a magnetic field. They are placed over the body region of interest, keeping the field of view as low as possible, and improve spatial resolution. Many types of coils are available for different joint sizes and configurations, including shoulder, extremity, wrist, and flex coils. Phased array coils use several coils in one component, allowing for a larger field of view. These are often used in spine imaging.

The widely used contrast for MRI studies is a neutral, hydrophilic salt of the gadolinium chelate, gadolinium diethylenetriamine-penta-acetic acid (Gd-DTPA). Gadolinium can be injected intravenously or directly into the joint. Intravenous injection (indirect magnetic resonance arthrography) carries the contrast in the vascular system to areas of hyperemia and inflammation. It is recommended for assessment of synovial activity in inflammatory joint diseases. Gadolinium is taken up in inflamed synovium and is able to demonstrate thickened pannus. The slope of the time-signal intensity curve is useful for showing inflammatory activity, and gadolinium is commonly employed in research and clinical trials.

Patients with renal disease who receive intravenous injection of gadolinium can develop nephrogenic systemic fibrosis (NSF). When the kidney cannot sufficiently clear out the gadolinium, it produces fibrosis of many tissues, including the skin, muscle, heart, nerves, and pleura. To date, NSF has been seen only in patients who have been given intravenous gadolinium with acute or chronic renal insufficiency and a glomerular filtration rate (GFR) of less than 30 mL/minute/1.73 m^2, with acute renal insufficiency of any severity due to the hepatorenal syndrome, or in the perioperative liver transplantation period. The changes in the skin with NSF are usually bilateral and symmetrical, primarily involving the extremities and the trunk. These changes can mimic systemic sclerosis but, unlike that disease, the face is usually spared. If renal function improves, the skin lesions may stabilize or get better, although in some patients, the process progresses, affecting mobility and causing severe pain.

Injection of dilute gadolinium into the joint (direct magnetic resonance arthrography) is helpful for outlining structures to determine whether there is morphologic damage. This technique is particularly effective for visualization of small structures such as the labrum of the hip or shoulder if there is no joint effusion. It is also helpful for demonstrating breakdown of soft tissue structures that normally prevent communication between joint compartments such as the rotator cuff, triangular fibrocartilage of the wrist, and ligaments in the various joints.

With special regard to rheumatic disease, MRI demonstrates joint effusion, intra-articular masses, synovitis, damage to hyaline and fibrocartilage, tendons, ligaments, bone, muscle, and surrounding soft tissue (Fig. 266-2). MRI is sensitive for marrow abnormalities such as reactive edema and erosion from arthritis, although it can be nonspecific. Infectious processes can have a similar appearance. Hemosiderin demonstrates a low signal intensity on MRI, which allows for characterization of joint diseases such as pigmented villonodular synovitis and hemophilic arthritis. MRI is useful for early detection of osteonecrosis, particularly when radiographs are normal. It is also used to evaluate the spine for disc disease, nerve root compression, and inflammatory changes.

Disadvantages of MRI include the fact that it is more costly than CT and other imaging modalities and can be claustrophobic. Calcification is not easily identified by MRI, and radiographs and CT are often complementary in this regard. MRI is contraindicated in patients who have certain devices implanted into their tissues. These include cochlear implants, some heart valves, cardiac pacemakers, and spinal implants. Metal implants, such as joint prostheses and spinal hardware, do not represent contraindications for MRI. Although metallic devices can cause some distortion of the image, newer materials such as cobalt-chrome cause less artifact. Various imaging parameters can also be adjusted to improve the visibility of tissues surrounding metallic devices, allowing for diagnostic interpretation.

ULTRASOUND

Ultrasound pulses sound waves through tissues to obtain an image that can localize and characterize pathology. Through the years, resolution has increased markedly. Portable scanners are also being used, especially by nonradiologists. They are adequate for injections and detection of fluid collections and tenosynovitis, but do not provide the detailed anatomy of their high-end counterparts.

Ultrasound provides a less expensive, noninvasive method to visualize joint structures such as tendons, ligaments, and fibrocartilage as well as muscles and soft tissue masses without ionizing radiation. Areas of pain and swelling can be scanned in real time with the opposite side for comparison. Fluid within tendon sheaths can be easily assessed. Fluid, blood, pus, and mucin in ganglia, cysts, bursae (e.g., a popliteal [Baker's] cyst [Chapter 271]), hematomas, seromas, and abscesses can be differentiated from solid masses based on echogenicity (Fig. 266-3). Areas around metallic hardware or other implants are easily assessed for such masses without the artifact that might limit MRI or CT evaluation.

Hypervascularity is a component of inflammatory joint disease. Angiofibroblastic response in tendons can be assessed by Doppler imaging, a

FIGURE 266-2. Sausage digit in psoriatic arthritis demonstrated on radiographs, scintigraphy, and magnetic resonance imaging. **A,** Anteroposterior radiograph of the forefoot demonstrates soft tissue swelling of the second toe without obvious bone involvement *(arrow)*. **B,** There is increased tracer uptake of technetium-99m methylene diphosphonate *(arrow)* in the entire second toe from the metacarpophalangeal joint to the distal phalanx on the bone scan, suggesting osteitis and soft tissue inflammation. **C,** A coronal fat-suppressed T1-weighted magnetic resonance image of the second toe obtained after intravenous gadolinium administration reveals high signal intensity uptake *(arrow)* in the bone and surrounding soft tissues consistent with osteitis and soft tissue inflammation.

sonographic method that assesses vascular flow. This information can be used for diagnosis and assessment of therapeutic response as well as to identify locations for anesthetic or steroid injections.

Ultrasound can demonstrate dynamic properties of tendons and other structures. The real-time capability allows for identification of subluxation and impingement, pinpointing causes of pain with certain movements. Ultrasound is a quick and inexpensive method to perform accurate aspirations and injections of joints and soft tissue structures such as tendon sheaths and bursae. Areas of hydroxyapatite crystal deposition disease can be aspirated and injected.

Ultrasound is an operator-dependent technique with a steep learning curve. It can be time-consuming for the person scanning the patient. Some important joint structures are in sonographically inaccessible areas, such as those obscured by bone. This would include portions of the menisci and the cruciate ligaments of the knee, labra of the hip and shoulder, and some hyaline cartilage that are well seen with MRI.

COMPUTED TOMOGRAPHY

CT employs an x-ray source with multiple detectors housed in a circular gantry that rotates 360 degrees around the patient lying on a table surrounded by the gantry. The computer processes the data that are displayed tomographically in multiple planes with thin slices. There is also a capability to render a three-dimensional reconstruction of the body part. Newer CT scanners have increased numbers of detectors and are able to image more quickly and with thinner slices. They employ spiral or helical scanning through continuous rotation of the x-ray source and the detectors while the patient moves on the table through the gantry.

CT is useful for evaluating vertebral alignment and fractures as well as abnormalities of the flat bones and pelvis. Complex fractures are best evaluated with CT. Joints that are difficult to assess on radiographs, including the sacroiliac, temporomandibular, wrist, and sternoclavicular joints, are well seen with CT. However, internal derangement of these joints is better appreciated on MRI, which has superior soft tissue contrast.

There are many different iodinated contrast agents that can be injected intravenously to enhance the CT study. The contrast has higher attenuation and spreads hematogenously to areas of increased vascularity and inflammation. MRI with gadolinium is the preferred method for demonstrating pannus and joint inflammation and for characterizing a soft tissue mass. CT with contrast can be used to determine whether the mass is cystic or solid in patients in whom MRI is contraindicated (e.g., those with claustrophobia, aneurysm clips, or cardiac pacemakers). Ultrasound can also be used for this purpose. Fluid collections, such as abscesses, seromas, bursae, and ganglia, are identified on all three imaging modalities.

CT arthrography may also be performed. This is useful when MRI is contraindicated. Intra-articular injection of iodinated contrast or room air, or both, coats the joint structures and can be useful to see small and large cartilage defects, fibrocartilage, tendon and ligament tears, and ossified and cartilaginous bodies.

The radiation dose from CT is high, especially when using the newer scanners. Repeated imaging with CT or requesting a CT in children or pregnant women must be carefully considered as far as risk versus benefit. Algorithms to reduce tissue dose are used for children and other vulnerable patients. These images are lower resolution but usually provide adequate information for diagnosis.

ARTHROGRAPHY

Arthrography involves placement of a needle intra-articularly with aspiration of joint fluid and injection of a contrast agent to enhance imaging. It is often performed to exclude an infection in patients with hip pain or in patients with total joint prostheses. It is also occasionally used to determine whether there is a full-thickness tear of the rotator cuff, triangular fibrocartilage and ligaments of the wrist, or collateral ligaments of the elbow and ankle. However,

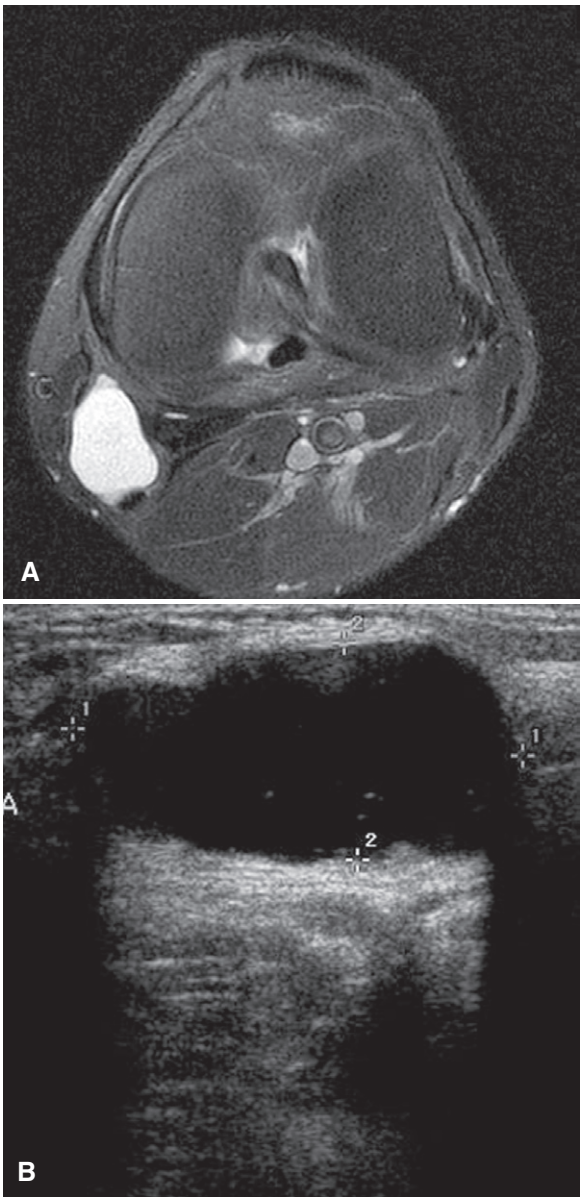

FIGURE 266-3. Knee ganglion demonstrated on magnetic resonance imaging and ultrasound. A, A fat-suppressed T2-weighted axial magnetic resonance image of the knee demonstrates a high signal intensity mass in the posterior aspect of the knee. Without intravenous gadolinium to show enhancement pattern, it is difficult to determine whether this is cystic or solid. **B,** An ultrasound demonstrates that this mass is hypoechoic—a finding consistent with a ganglion. This hypoechogenic appearance is also seen with bursae, such as a popliteal cyst, but a popliteal cyst lies between the gastrocnemius and semimembranosus tendons, unlike this ganglion.

MRI has replaced conventional arthrography for these indications in most centers.

Arthrography can be combined with MRI or CT to evaluate more precisely the internal structures through joint distention and contrast coating of structures along the articular surface, including the labrum, ligaments, and capsule. This is discussed in the sections of those imaging modalities.

SCINTIGRAPHY

Scintigraphy employs detectors in the form of a gamma camera that can identify the decay of radioactive isotopes that have been injected intravenously. Bone scintigraphy is used to identify sites of activity in the rheumatic diseases. The bone scan employs technetium-99m methylene diphosphate as the radioactive tracer. The isotope goes to areas of high bone turnover and vascular flow as well as areas of calcium or bone deposition. Three-phase bone scans are obtained at different intervals following injection. Images are obtained at three time points: the early vascular phase, the intermediate blood pool phase, and the late phase. Each phase allows for further characterization of the disease process. Abnormal tracer uptake is seen in areas of inflammation, infection, neoplasm, osteonecrosis, and fracture (see Fig. 266-2). The scan is most useful to identify the location of lesions within the skeleton but is nonspecific. Further imaging of the abnormal areas is often necessary to characterize the pathology.

CONNECTIVE TISSUE STRUCTURE AND FUNCTION

RICHARD F. LOESER

Connective tissue forms the architectural framework of the musculoskeletal system and serves as a scaffold that supports various organs and tissues. Many important structures within the body are composed primarily of connective tissue (Table 267-1). For example, articular cartilage is made up exclusively of a specialized dense connective tissue without blood vessels, nerves, or lymphatics. Tendons, ligaments, intervertebral discs, and fascia are structures also consisting of dense connective tissue, although of a different composition from cartilage. Bone contains both dense and loose connective tissue; the latter provides support for bone marrow cells and helps to fill the space within the bone cavity. Adipose tissue is also often considered to be a specialized connective tissue that has both metabolic and structural functions.

Articular joints are formed by several common types of connective tissue, including muscle, bone, tendon, ligament, cartilage, meniscus, and synovium, which function as a unit during joint movement. These tissues demonstrate distinct characteristics when imaged by magnetic resonance because of their unique cellular and matrix composition (Fig. 267-1). In this type of image, tissues with a higher water content, such as adipose tissue and cartilage, appear lighter than very dense tissues, such as the subchondral bone, which appear dark.

Despite their diversity, what connective tissues have in common is that they contain cells, usually of mesodermal origin, that have an abundant extracellular matrix. The cells within a particular connective tissue control the composition of the extracellular matrix, which, in turn, determines the physical properties of the tissue. The many types of connective tissue cells range from fibroblasts, which are present in the connective tissue found in skin, synovium, tendons, ligaments, and fascia, to more specialized cells such as chondrocytes and osteoblasts, which are found in cartilage and bone, respectively (see Table 267-1). Basement membranes are a more special form of connective tissue in that they are produced by epithelial and endothelial cells, rather than by mesenchymal cells. The connective tissue matrix consists of an intricate mixture of proteins and other macromolecules, which are responsible for the unique function of each particular type of connective tissue (E-Fig. 267-2). Connective tissues that must withstand high tensile loads, such as tendons, have a high content of collagen fibers, whereas tissues that must resist compression, such as cartilage, have a high content of proteoglycans.

Because of the wide distribution of connective tissues within the human body, diseases that affect connective tissue cells or extracellular matrix proteins often have systemic effects. These connective tissue disorders can be divided into three general types: those that arise from a mutation within a gene encoding a connective tissue protein (e.g., Marfan syndrome, Chapter 268); those that are the result of an inflammatory, sometimes autoimmune, process centered in connective tissues (e.g., rheumatoid arthritis, Chapter 272); and those that are the result of a degenerative type of process often associated with aging (e.g., osteoarthritis, Chapter 270). A basic understanding of the composition of the various connective tissues and of the way in which this composition relates to structure and function is important for understanding the clinical presentation, as well as management, of the spectrum of musculoskeletal and connective tissue disorders.

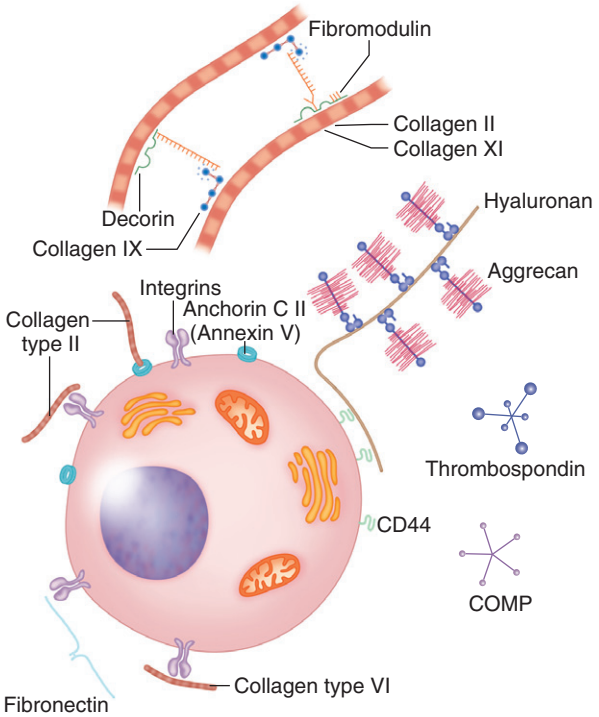
CONNECTIVE TISSUE PROTEINS AND MACROMOLECULES

Each different type of connective tissue has a unique composition based on the amount and specific forms of extracellular matrix proteins and macromolecules. The extracellular matrix components can be grouped into families that include the collagens, proteoglycans, elastins, and other noncollagenous glycoproteins. These extracellular matrix components not only provide the scaffolding that forms the tissue but also, importantly, create an information-rich environment that provides external cues to the connective tissue cells. Intracellular signaling, initiated through the interaction of extracellular matrix components with cell surface receptors, regulates certain important processes, including cell growth, differentiation, and survival and remodeling of the matrix. The integrins, named for their ability to integrate the extracellular matrix with intracellular cytoskeletal components, are a large and important family of cell surface receptors that recognize and bind some different extracellular matrix proteins initiating intracellular signaling (see E-Fig. 267-2). The signals generated by extracellular matrix proteins are integrated with signals generated by soluble mediators, also present in the matrix, including

FIGURE 267-1. Magnetic resonance image of a knee joint demonstrating the diversity of connective tissue structures. The image was obtained with a 1.5-Tesla magnet using a fast spin-echo T2-weighted imaging protocol. Tissues with a higher water content, such as adipose and articular cartilage, appear lighter, as does the synovial fluid. The subchondral bone is dark because of a high mineral and low water content and can be seen just below the very thin layer of articular cartilage. (Courtesy of Dr. Carol Muehleman, Rush Medical College, Chicago.)

TABLE 267-1 DIVERSITY OF CONNECTIVE TISSUE–CONTAINING STRUCTURES

STRUCTURE	FUNCTION	CELLS	KEY MATRIX COMPONENTS
Adipose tissue	Energy storage, organ protection	Adipocytes, fibroblasts	Fine reticular fibers
Basement membrane	Support and filtration barrier	Epithelial and endothelial cells	Type IV collagen, laminin
Bone	Skeletal support, blood cell production, mineral storage	Osteoblasts, osteoclasts, osteocytes	Type I collagen, osteocalcin, bone sialoprotein, hydroxyapatite
Cartilage	Allows joint motion, transmits loads	Chondrocytes	Type II collagen, aggrecan
Dermis	Support and resiliency	Fibroblasts	Type I collagen, elastin
Ligament	Connects bone to bone	Fibroblasts	Type I collagen, small proteoglycans
Tendon	Connects muscle to bone	Fibroblasts	Type I collagen, small proteoglycans
Stroma	Support of organs	Fibroblasts, organ-specific cells	Type I, VI collagen, fibronectin
Synovium	Joint lining, produces synovial fluid	Fibroblasts, macrophages	Type I, III collagen
Vessel wall	Structural support of blood vessels	Vascular smooth muscle cells	Type III collagen, elastin



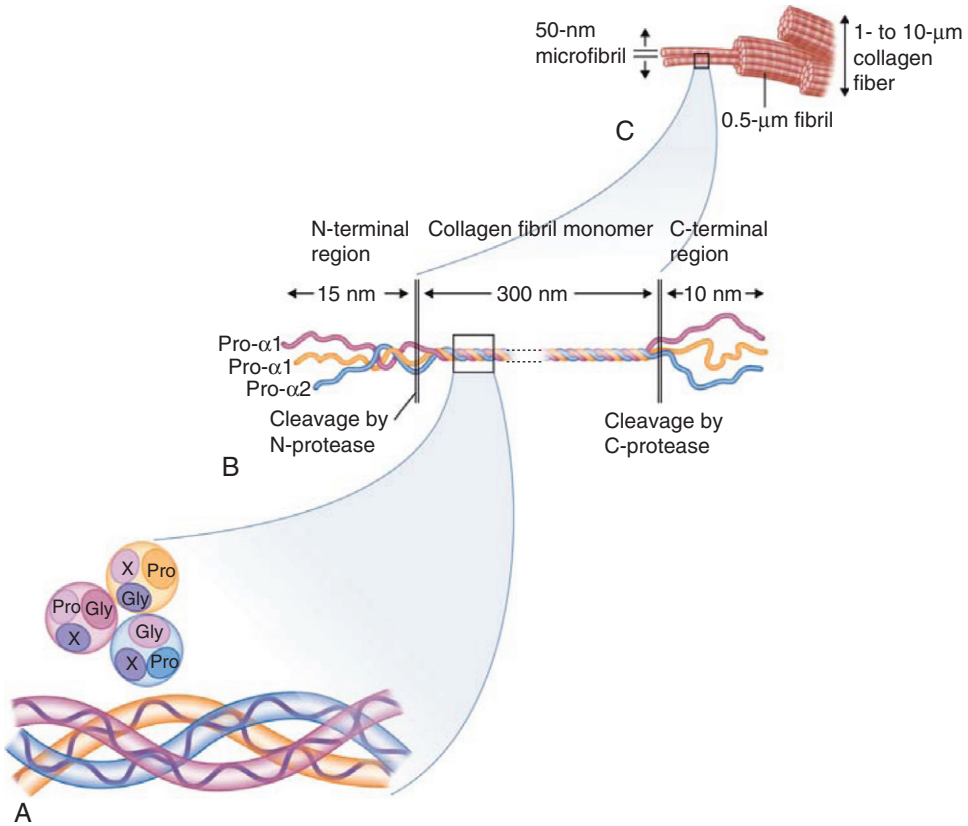
E-FIGURE 267-2. Model of extracellular matrix proteins and their interaction with each other and with matrix receptors on a chondrocyte. Decorin, fibromodulin, and types IX and XI collagen all interact with type II collagen and regulate collagen fiber assembly and structure. Types II and VI collagen bind matrix receptors called *integrins*. Type II collagen can also bind to anchorin CII, whereas fibronectin binds to integrins. A large proteoglycan aggregate forms when multiple aggrecan molecules bind to a long strand of hyaluronic acid, which, in turn, is anchored to the cell by CD44. Additional matrix proteins shown include thrombospondin and cartilage oligomeric protein (COMP). (Adapted from Knudson W, Loeser RF. CD44 and integrin matrix receptors participate in cartilage homeostasis. *Cell Mol Life Sci*. 2002;59:36-44.)

growth factors and cytokines. In normally functioning connective tissues, the cells, extracellular matrix proteins, and soluble mediators all work beautifully in concert to maintain the tissue and to adapt the tissue to meet changes in physical or biomechanical demands.

Collagens

Collagen is a major component of the extracellular matrix and is the most abundant protein in the body; it accounts for about 25 to 30% of the total protein mass. Collagens are triple-helical proteins formed when three polypeptide chains, called *α chains*, wind around each other to form a collagen molecule (E-Fig. 267-3). The α chains are rich in the amino acids proline and glycine, which are important in forming the helical conformation of the polypeptide chain. Because of its ring structure, proline stabilizes the helix. Glycine, the smallest of the amino acids, is spaced at every third position in the chain such that it occupies the tightly spaced inside portions of the triple helix. Mutations that result in the substitution of a much larger amino acid for glycine can severely disrupt the triple helical structure. Post-translational modifications, including hydroxylation of specific proline and lysine residues, occur during the processing of the collagen molecules; these modifications are important in stabilizing the collagen structure and in forming interchain and intrachain cross-links.

More than 30 collagen genes code for the collagen α chains. The α chains specific for each collagen type combine to form at least 19 different collagens. The types of collagen can be grouped by structure and function (E-Table 267-2). In the fibrillar collagens (collagen types I, II, III, V, and XI), individual collagen molecules are packed in a staggered and ordered fashion to form a collagen fibril, which has a characteristic banding pattern when observed by high-power microscopy. Fibril formation occurs outside the cell after the N-terminal and C-terminal propeptides present on procollagen molecules are proteolytically removed to form mature collagen. The fibrils, in turn, are packed together to form fibers. Further cross-linking of collagen fibrils strengthens the structure. These rather stiff, ropelike structures provide the tensile strength for connective tissues. The fibril-associated collagens (collagen types IX, XII, XIV) help to form and stabilize the collagen fibrils. Unlike the fibrillar collagens, this group of collagens contains regions where



E-FIGURE 267-3. Collagen structure. Three α chains (in this case, two procollagen α_1 chains and one procollagen α_2 chain) containing a high content of the amino acids glycine (Gly) and proline (Pro) wind together to form a triple helical collagen molecule (**A**). After secretion from the cell, the N-terminal and C-terminal ends are removed by proteases to form a collagen fibril monomer (**B**). Monomers are assembled to form a microfibril, which, in turn, is assembled into fibrils; finally, multiple fibrils form a complete collagen fiber (**C**).

the triple helical structure is interrupted, and this can result in a bend in the collagen molecule, hence the name *fibril-associated collagens with interrupted triple helixes.* Type IV collagen is the classic basement membrane collagen that forms in aggregates to provide structural support to the basement membrane.

The type and amount of collagen found in a particular connective tissue are important contributors to tissue function. Tissues such as bone, tendon, and cartilage, which must withstand high biomechanical loads, are packed with large amounts of long fibrillar collagens, primarily type I collagen in bone and tendons and type II collagen in cartilage. The loose connective tissues, such as basement membranes and organ stroma, experience much less mechanical force but require a matrix that allows more rapid diffusion of molecules and so contain a higher content of aggregating or anchoring types of collagen and less fibrillar collagen. Recent work correlating mutations in particular collagen genes with disease phenotypes in humans and studies of phenotype after gene disruption in transgenic mice have added to our knowledge of collagen function (see E-Table 267-2). Some examples include "brittle-bone disease" or osteogenesis imperfecta resulting from type I collagen mutations, severe premature osteoarthritis from type II collagen mutations, and fragile blood vessel and visceral walls in Ehlers-Danlos syndrome type IV from mutations in type III collagen. Excess collagen production can also disrupt tissue function, usually by causing tissue fibrosis as seen in scleroderma. Finally, fragile connective tissues can result from inadequate collagen production and cross-linking, as occurs in scurvy from vitamin C deficiency. Vitamin C (ascorbic acid) serves as a cofactor for the hydroxylation reaction necessary to modify specific prolyl and lysyl residues in procollagen, and a deficiency in ascorbic acid reduces collagen secretion, stability, and cross-linking.

Proteoglycans

These matrix macromolecules consist of a protein core to which short oligosaccharides and longer chains of glycosaminoglycans are covalently attached. The large variety of proteoglycans is based on the types and lengths of glycosaminoglycans as well as the sequence and length of the protein core. Chondroitin sulfate, keratan sulfate, heparan sulfate, and dermatan sulfate are four different forms of glycosaminoglycans that consist of repeating disaccharide units. The sulfates present on the glycosaminoglycans create a highly negatively charged environment that is hydrophilic. Thus, connective tissues that contain large amounts of proteoglycans also contain relatively large amounts of water bound to the proteoglycans. In addition to water, proteoglycans bind cationic proteins, which, in some cases, include growth factors resulting in a mechanism by which tissues can store growth factors in the matrix.

Aggrecan is a very large (>200,000 kD) proteoglycan found in cartilage that contains a protein core of more than 2000 amino acids to which are attached approximately 100 long chondroitin sulfate chains, approximately 30 shorter keratan sulfate chains, and approximately 50 short oligosaccharides. Decorin, biglycan, fibromodulin, asporin, and lumican are examples of small proteoglycans that have much shorter protein cores (30 to 60 kD), possess fewer glycosaminoglycan side chains, and contain leucine-rich repeats. These small proteoglycans form β-sheets and interact with collagen to regulate the formation of collagen fibrils and help to stabilize the collagen network (see E-Fig. 267-2). Although their functions are not completely understood, they also likely have other roles because of their ability to bind matrix molecules, in addition to collagen, and as a result of their affinity for growth factors. For example, recent studies have shown that asporin binds to transforming growth factor-β and polymorphisms that increase this binding may contribute to the development of osteoarthritis.

Hyaluronic acid is a nonsulfated glycosaminoglycan that is synthesized in very long linear polymer strands. Hyaluronic acid is produced by chondrocytes and by synovial cells and is a major component contributing to the viscosity of the synovial fluid. Unlike the other glycosaminoglycans, hyaluronic acid is not attached to a protein core and so is not directly used to form proteoglycans. In cartilage, however, strands of hyaluronic acid bind aggrecan molecules through a noncovalent interaction with a globular portion of the N-terminus of the aggrecan core protein and a second small protein called *link protein.* The resulting macromolecular complex containing 100 or more aggrecan molecules linked to each long strand of hyaluronic acid forms a gel-like substance in cartilage as a result of its high sugar and water content.

E-TABLE 267-2 CONNECTIVE TISSUE COLLAGENS

COLLAGEN TYPE	CHAINS	MOLECULES	TISSUE DISTRIBUTION	SELECTED DISEASES FROM MUTATIONS
FIBRILLAR COLLAGENS				
I	α_1(I) α_2(I)	$[\alpha_1(I)]_2\ \alpha_2(I)$ $[\alpha_1(I)]_3$	Skin, bone, tendon, organ capsules, arteries	Osteogenesis imperfecta, Ehlers-Danlos type VIIA
II	α_1(II)	$[\alpha_1(II)]_3$	Cartilage, vitreous humor	Stickler's syndrome, osteoarthritis
III	α_1(III)	$[\alpha_1(III)]_3$	Skin, vessels, uterus	Ehlers-Danlos type IV, aortic aneurysms
V	α_1(V) α_2(V) α_3(V)	$[\alpha_1(V)]_3$ $[\alpha_1(V)]_2\ \alpha_2(V)$ $\alpha_1(V)\ \alpha_2(V)\ \alpha_3(V)$	Skin, vessels, placenta, chorion, uterus	Ehlers-Danlos syndrome
XI	α_1(XI), α_2(XI)	$\alpha_1(XI)\ \alpha_2(XI)\ \alpha1(II)$	Cartilage	Chondrodysplasia, osteoarthritis
BASEMENT MEMBRANE COLLAGENS				
IV	α_1-α_5(IV)	$[\alpha_1(IV)]_2\ \alpha_2(IV)$	Basement membranes	Alport's syndrome, porencephaly
FIBRIL-ASSOCIATED COLLAGENS WITH INTERRUPTED TRIPLE HELIXES (FACIT)				
IX	α_1-α_3(IX)	$\alpha_1(IX)\ \alpha_2(IX)\ \alpha_3(IX)$	Cartilage, intervertebral discs	Degenerative disc disease, osteoarthritis
XII	α_1(XII)	$[\alpha_1(XII)]_3$	Tendons, ligaments, other soft tissues	
XIV	α_1(XIV)		Ubiquitous	
NETWORK-FORMING COLLAGENS				
VIII	α_1(VIII), α_2(VIII)		Cornea, vessels	Fuchs' endothelia, corneal dystrophy
X	α_1(X)	$[\alpha_1(X)]_3$	Growth plate cartilage	Spondylometaphyseal dysplasia
LONG-CHAIN, ANCHORING-FIBRIL COLLAGEN WITH INTERRUPTED TRIPLE HELIX				
VII	α_1(VII)	$[\alpha_1(VII)]_3$	Anchoring fibrils	Epidermolysis bullosa
OTHERS				
VI	α_1-α_3(VI)	$\alpha_1(VI)\ \alpha_2(VI)\ \alpha_3(VI)$	Cartilage, stroma	Bethlem myopathy
XIII	α_1(XIII)		Skin, gut	

The proteoglycan aggregates provide articular cartilage with resiliency. When cartilage is compressed during joint loading, water is pushed out from the proteoglycans, and the negative charges on the glycosaminoglycans become closer; this helps to resist further compression through charge repulsion. When the load is released, water is drawn back to the proteoglycans, and the result is fluid flow responsible for part of the biomechanical stimulation of the cells. The fluid flow also helps to move nutrients through the tissue, a feature that is particularly important for articular cartilage, a connective tissue that depends on diffusion from the synovial fluid for most of its nutrition. The network of collagen fibers that surrounds aggrecan prevents the proteoglycans from swelling beyond a certain size, thus creating a swelling pressure in cartilage that also helps to resist compression.

Noncollagenous Fibrillar Proteins

Elastic fibers are composed of elastin and proteins, often referred to as *microfibrils,* such as fibrillin, because their fibrils are much smaller than the classic collagen fibrils. Elastic fibers must withstand repeated stretching and deformation and must be capable of returning to a relaxed state. Tropoelastin is the precursor to elastin and is synthesized by several cell types, including vascular smooth muscle cells and dermal fibroblasts, where it contributes to the elasticity of the blood vessel wall and skin, respectively. Elastin also plays a similar role in the lung. Elastin, like collagen, forms interchain and intrachain cross-links that help to stabilize and strengthen the elastic fibers, although the stiffness of the elastin fibers is less than that of the collagen fibers. Many of the cross-links in elastin are formed through the hydroxylation of two unique amino acids found in tropoelastin: desmosine and isodesmosine. Fibrillin is found in several elastic tissues and is particularly abundant in the aorta, the suspensory ligament of the lens, and the periosteum. Fibrillin was a little-known protein until investigators discovered that fibrillin mutations are the cause of most cases of Marfan syndrome (Chapter 268).

Noncollagenous Glycoproteins

Along with the proteoglycans, the many other noncollagenous matrix glycoproteins found in connective tissues form much of what is sometimes described as the *ground substance* in histologic terms. This rather inert-sounding description should in no way be taken to suggest that these matrix components simply fill in or hold the tissue together. Rather, these proteins participate actively in creating the information-rich environment described earlier. Proteins in this group include fibronectin, vitronectin, osteopontin, laminin, and thrombospondin. Fibronectin is found in most connective tissues throughout the body. Laminin is particularly prominent in basement membranes, and osteopontin is found in greater amounts in cartilage and bone. All these proteins bind to cells through specific cell surface receptors to promote attachment of cells to the matrix. The proteins also interact with other matrix proteins, such as collagen and proteoglycans, to integrate the cells further with the extracellular matrix. Through the interactions with cell receptors and other matrix proteins, the noncollagenous glycoproteins function in regulating tissue morphogenesis as well as in tissue repair and remodeling. They also appear to play a role in other diverse processes, including tumor growth and metastasis.

Other Matrix Proteins

Many other matrix proteins present in connective tissues, such as tenascin, osteonectin, the matrilins, cartilage oligomeric protein, matrix Gla protein, and osteocalcin, are less completely understood but are probably no less important. Matrix Gla protein and osteocalcin are both found in bone, whereas matrix Gla protein is also present in cartilage and other soft tissues, including blood vessel walls. Both proteins require reduced vitamin K as a cofactor for a post-translational carboxylation reaction important to the cation binding properties of the proteins. Inhibition of vitamin K reduction by the drug warfarin interferes with this reaction, as it does for the coagulation factors. Warfarin is contraindicated in pregnancy because it has been shown to cause embryopathy, which includes abnormalities in skeletal formation likely secondary to effects on matrix Gla protein or osteocalcin, or both. The matrilins (1 to 4) contain von Willebrand factor A domains, epidermal growth factor–like domains, and coiled-coil domains, and they form either homo- or hetero-oligomers in various connective tissues. They help form networks with other matrix proteins and may bind growth factors as well. Similar functions are proposed for tenascin, osteonectin, and cartilage oligomeric protein, which in addition may regulate cell-matrix interactions.

Extracellular Matrix Protein Receptors

Connective tissue cells use several different types of cell surface receptors to bind extracellular matrix proteins. The major types of receptors include integrins, CD44, discoidin domain receptors (DDRs), and proteoglycan family receptors such as the syndecans (see E-Table 267-3). CD44 is expressed by several different connective tissue cell types as well as by nonconnective tissue cells such as lymphocytes. On connective tissue cells, CD44 is the principal receptor for hyaluronan. CD44 binding of hyaluronan is particularly important in forming a gel-like pericellular coat found around certain connective tissue cells such as chondrocytes. DDR1 and DDR2 are receptor tyrosine kinases found on epithelial and mesenchymal cells. DDR1 can bind types I through VI and type VIII collagen, whereas DDR2 is activated only by fibrillar collagens. Syndecans contain a transmembrane protein core to which heparan sulfate proteoglycans are attached to the extracellular domain. The proteoglycans bind growth factors such as fibroblast growth factor. Syndecans also appear to interact with integrins and may modulate integrin function.

The integrins represent the largest family of cell surface matrix receptors and have been found to be the primary receptors for many matrix proteins, including collagens, fibronectin, laminin, vitronectin, osteopontin, and thrombospondin (E-Table 267-3). Integrins are heterodimeric transmembrane proteins consisting of one α- and one β-subunit. More than 20 known integrins are formed by 14 types of α-subunits and at least nine types of β-subunits. The two major subfamilies of integrins function in mediating interactions between cells and extracellular matrix proteins. These are the β1 subfamily and the αv subfamily. The specificity of extracellular matrix protein binding is determined by both the α- and the β-subunit, although more than one integrin type can bind to the same matrix protein, often at different sites within the protein. For example, the α1β1, α2β1, α3β1, and α10β1 integrins are all capable of binding collagen, whereas α3β1, α4β1, α5β1, and αvβ3 integrins can all bind fibronectin. In addition, each type of integrin can bind more than one different type of extracellular matrix protein; for example, αvβ3 can bind vitronectin, osteopontin, or fibronectin.

Each connective tissue cell expresses a combination of integrins that is regulated, at least in part, by the mix of proteins present in the extracellular matrix. In addition, integrin expression and affinity for matrix ligands can change in response to cues from the matrix, including stimulation by growth factors and cytokines. The exact function of each particular integrin is currently a topic of investigation by numerous research laboratories. Research in bone has found that the αvβ3 integrin present on osteoclasts plays an important role in the ability of these cells to resorb bone. For this reason, chemical inhibitors of αvβ3 are being developed for the treatment of osteoporosis.

E-TABLE 267-3 CELL SURFACE RECEPTORS FOR EXTRACELLULAR MATRIX COMPONENTS

RECEPTOR	LIGANDS
CD44	Hyaluronan
Syndecan (1-4)	Tenascin, fibronectin, fibroblast growth factor
Discoidin domain receptors 1, 2	Collagen
Integrins	
α1β1	Collagen, laminin, cartilage matrix protein
α2β1	Collagen, laminin, chondroadherin
α3β1	Laminin, fibronectin, collagen, epiligrin
α4β1	Fibronectin, VCAM-1
α5β1	Fibronectin
α6β1	Laminin
α7β1	Laminin
α8β1	Tenascin, nephronectin, fibronectin, vitronectin
α9β1	Laminin, collagen, tenascin
α10β1	Collagen
αvβ1	Fibronectin, vitronectin
αvβ3	Vitronectin, fibrinogen, osteopontin, fibronectin, thrombospondin
αvβ5	Vitronectin, fibronectin
αvβ6	Fibronectin, tenascin
αvβ8	Vitronectin, laminin, collagen, fibronectin

Binding of extracellular matrix proteins to integrins activates certain signal transduction pathways that regulate cell responses to the matrix, including changes in gene expression. Signaling complexes are formed at sites, often referred to as *focal adhesions,* where close contact is made between the integrins and the extracellular matrix. The signaling complexes include activation of several different pathways involving tyrosine and serine-threonine kinases, phosphoinositide, and arachidonic acid, as well as inducing ion fluxes. Accompanying, and intimately tied to, activation of cell signaling are changes in the organization of the cytoskeleton. In this way, integrins can mediate processes that require changes in cytoarchitecture such as cell migration and wound repair. Integrins also provide signals necessary to promote cell survival in cells that require attachment to a matrix to survive. Given the diverse roles of integrins in mediating events important to connective tissue development, repair, and remodeling, studies of integrin function should provide important new information needed to understand connective tissue in health and disease.

SPECIALIZED CONNECTIVE TISSUE STRUCTURES

Cartilage

Cartilage consists of several different types, including hyaline, elastic, and fibrocartilage. Hyaline cartilage includes articular cartilage, which is present at the ends of bones (see Fig. 267-1) and is responsible for the normal smooth gliding motion of the joints. Elastic cartilage, which is more flexible than hyaline cartilage, is found in the external ear and epiglottis. Fibrocartilage is found in the menisci and in ligaments at the site of insertion to bone or where tendons wrap around a bony pulley. Cartilage contains only one cell type, the chondrocyte, which is responsible for the synthesis and breakdown of the cartilage matrix. Very little to no cell division occurs in normal adult cartilage, so the resident chondrocytes must maintain the tissue for the lifetime of the individual.

The extracellular matrix is very abundant in cartilage, where the cells make up only about 2 to 5% of the volume of the tissue. The matrix contains large amounts of type II collagen and the large aggregating proteoglycan aggrecan (see E-Fig. 267-2). The high aggrecan content is accompanied by a high water content, thus making cartilage about 70 to 80% water. Articular cartilage must resist compressive forces that occur during joint loading, so the proteoglycan content is appropriately high. In the superficial region of cartilage, the collagen fibers are arranged parallel to the surface of the tissue to withstand the shear forces occurring at the joint surface during movement. The surface of cartilage is very smooth, with an extremely low coefficient of friction (less than that of ice on ice), which is critical for providing smooth and rapid joint movements. A protein called *lubricin* (also known as *superficial zone protein* or PRG4), produced by chondrocytes and synovial cells, appears to be important for this function. When cartilage is damaged, normal movement is impaired, but pain usually does not result because of the lack of a nerve supply in cartilage. Pain, which occurs during the development of arthritis, results from pathologic lesions in other tissues such as bone, synovium, and the joint capsule.

Tendons and Ligaments

Tendons connect muscle to bone, and ligaments connect bone to bone. Both are composed of connective tissue that must withstand the high tensile loads occurring during movement. Tendons transmit the force from muscle contraction to bone, and the result is movement. Ligaments serve to stabilize joints, thereby allowing for a certain degree and direction of movement but resisting excessive displacement between bones. Tendon and ligament fibroblasts are responsible for synthesis and maintenance of the matrix. Tendons and ligaments contain a very high content of type I collagen, which is found in long and densely packed parallel fibers. The noncollagenous proteins include proteoglycans such as decorin and biglycan, which are much smaller than the aggrecan found in cartilage, a feature that gives them a relatively reduced water content.

Synovium

The synovium lines diarthrodial joints and is composed of loose connective tissue. In most places within normal joints, the surface area of synovium is only a few cell layers thick. Unlike cartilage, synovium contains blood vessels, lymphatics, and nerves. It is the major source of nutrients for the cartilage and produces many of the major constituents found in the synovial fluid (see Fig. 267-1), including hyaluronic acid. The two types of cells in the synovial matrix are fibroblasts (sometimes called *type B synovial cells*) and macrophages (type A cells). The synovial fibroblasts are responsible for matrix protein production. The macrophages are responsible for removing cell debris and any microorganisms that could gain entrance. The synovium is a major site of inflammation in arthritic diseases, where it becomes thickened by proliferation of resident cells and by an influx of inflammatory cells from the circulation. In inflammatory arthritis, activated synovial fibroblasts produce enzymes, including the matrix metalloproteinases (MMPs), which degrade joint structures, whereas inflammatory cells produce cytokines, such as tumor necrosis factor-α and interleukin-1 among others, which stimulate MMP production and drive the inflammatory process.

Intervertebral Discs

The intervertebral discs, which assist in movement and provide flexibility to the spine, have distinct regions consisting of the inner nucleus pulposus and an outer fibrotic rim, the annulus, along with an intermediate area between the two. Blood vessels are present in the outer region of the annulus but not in the nucleus pulposus, which must obtain its nutrients by diffusion. The annulus contains denser connective tissue to provide structural support, whereas the nucleus pulposus has a higher water content and is more gel-like. Discs contain both types I and II collagen along with proteoglycans, including aggrecan, found predominantly in the nucleus pulposus. The cells in this region more closely resemble chondrocytes, whereas those in the outer fibrotic regions are more similar to fibroblasts. By adulthood, very few cells are present in the nucleus pulposus. This scarcity, along with the changes associated with aging discussed in the next section, make discs very susceptible to degeneration, with an inability to repair damaged matrix.

CHANGES IN CONNECTIVE TISSUES ASSOCIATED WITH AGING

Aging has an important impact on both the structure and function of connective tissues. General age-related changes in connective tissue cells include reductions in mitogenic response and synthetic capacity, likely the result of a diminished cellular response to growth factor stimulation. In the extracellular matrix, modified and, in some cases, degraded matrix components accumulate. The matrix changes appear to decrease the capacity of aging connective tissues to resist tensile forces and to reduce resiliency. Age-related changes in elastin contribute to a loss in tissue elasticity. These changes make connective tissues more susceptible to injury and less capable of repairing damage and in this way contribute to age-associated conditions.

Evidence is mounting that age-related nonenzymatic glycation occurs in the collagen found in several different connective tissue structures, including cartilage, tendons, ligaments, and intervertebral discs. Because collagen has such a long half-life (estimated to be >100 years for type II collagen in cartilage), the progressive accumulation of collagen contains advanced glycation end products, which, in turn, can form intrachain and interchain cross-links that stiffen the collagen fibers. Increased collagen stiffness may contribute to the reduced flexibility noted in ligaments and tendons with age. Although the collagen is stiffer with age, it appears to be less able to resist tensile forces and so could be characterized as being more brittle.

Changes in proteoglycan size and sulfation also occur with age. These changes result in a reduced capacity for binding water, which contributes to an age-related decrease in hydration of connective tissues. Decreases in water content with age have been measured in articular cartilage and in intervertebral discs. Reduced hydration makes the tissues less able to respond to compression. The decreased water content of the discs, along with increased collagen cross-linking from nonenzymatic glycation, may explain why disc herniations are less common in older adults but disc degeneration is more common. Less is known about age-related changes in matrix proteins other than fibrillar collagen and the large proteoglycans. Fibronectin increases in some connective tissues with age, but the consequences of this change are not known.

CONNECTIVE TISSUE DEGRADATION

Connective tissues need to repair and remodel in response to injury, growth, and changes in the biomechanical demands at specific tissue sites. Repair and remodeling of connective tissues require that some components of the tissue be removed and replaced with new components. Healing of wounds in the skin also requires migration of cells into the damaged area, and cell migration is facilitated by matrix degradation. To accomplish these tasks, a set of enzymes capable of degrading extracellular matrix proteins is required (E-Table 267-4). These enzymes are produced by connective tissue cells and are released, where they act locally to degrade specific matrix components. In certain disease states (e.g., osteoarthritis and rheumatoid arthritis), excess

E-TABLE 267-4 MATRIX-DEGRADING ENZYMES

PROTEINASE	SUBSTRATES
MATRIX METALLOPROTEINASES (MMPS)	
MMP-1, MMP-8, MMP-13 (collagenase 1, 2, 3)	Fibrillar collagens, fibronectin, aggrecan
MMP-3, MMP-10, MMP-11 (stromelysin 1, 2, 3)	Proteoglycan, procollagenase, fibronectin
MMP-2, MMP-9 (gelatinase A, B)	Denatured collagen, aggrecan, fibronectin
MMP-7 (matrilysin)	Proenzymes, fibronectin, other matrix proteins
MMP-12 (macrophage elastase)	Elastin, fibronectin, laminin
MMP-14, MMP-15, MMP-16, MMP-17 (MT1-MT4-MMP)	Procollagenase
ADAM-17 (TACE)	Tumor necrosis factor-α
ADAMTS-4, ADAMTS-5 (aggrecanase 1, 2)	Aggrecan
SERINE PROTEASES	
Plasmin	Fibrin, pro-MMPs
Plasminogen activators	Plasminogen
Neutrophil elastase	Elastin
CYSTEINE PROTEASES	
Cathepsin K	Type I collagen
Cathepsin B	Broad specificity
ASPARTATE PROTEASES	
Cathepsin D	Aggrecan, denatured collagen
Pepsin	Broad specificity

ADAM = a disintegrin and a metalloproteinase; ADAMTS = a disintegrin and a metalloproteinase with a thrombospondin motif; MT-MMP = membrane-type MMP; TACE = tumor necrosis factor-α–converting enzyme.
Adapted from Mort JS, Poole AR. Mediators of inflammation, tissue destruction, and repair. D. Proteases and their inhibitors. In: Klippel JH, ed. *Primer on the Rheumatic Diseases,* 12th ed. Atlanta: Arthritis Foundation; 2001:72-81.

production of matrix-degrading enzymes occurs and overwhelms the capacity of the cells to replace the lost matrix components; the results are net tissue destruction and loss.

The largest family of matrix-degrading enzymes, the MMP family, consists of enzymes that share functional domains, require zinc for activity, and are active at neutral pH. The MMPs either are released into the extracellular matrix or, in some cases, such as the membrane-type MMPs, are directly anchored to the cell. MMP-1, MMP-8, and MMP-13 are collagenases, which are the primary enzymes capable of degrading native collagen, whereas MMP-2 and MMP-9 are gelatinases, which degrade denatured collagen. MMP-3, MMP-10, and MMP-11 are stromelysins responsible for degrading noncollagen proteins such as proteoglycans and fibronectin, whereas MMP-12 functions as an elastase. The membrane-type MMPs can serve to activate other MMPs at the cell surface. More recently discovered members of the MMP family include the ADAMs (*a d*isintegrin *a*nd a *m*etalloproteinase) and the ADAMTSs (*a d*isintegrin *a*nd a *m*etalloproteinase with a *t*hrombospondin motif). Enzymes of the ADAMS family are localized to the cell surface, at least in part through the disintegrin domain. ADAM-17 is also known as *TACE* (tumor necrosis factor-α–converting enzyme) because of its ability to cleave tumor necrosis factor-α to an active form. Finally, the ADAMTSs use the thrombospondin motif to interact with proteoglycans, which can serve as substrates for these enzymes. ADAMTS-4 and ADAMTS-5 are aggrecanases that have been shown to cleave the large proteoglycan aggrecan. Studies have suggested that ADAMTS-5 may play an important role in matrix degradation in osteoarthritis.

The MMPs are normally kept in an inactive state by a propeptide region that interacts with the zinc moiety at the active site. Cleavage of the propeptide by other MMPs or members of other protease families results in the release of active enzyme. Further control of MMP activity is provided by specific inhibitors of MMPs present in the extracellular matrix, including the tissue inhibitors of metalloproteinases. The expression of MMPs and tissue inhibitors of metalloproteinases is regulated at the transcriptional level by cytokines, growth factors, and matrix components, including, in some cases, fragments of proteins degraded by MMPs providing for a feedback loop during matrix remodeling.

Other matrix-degrading enzymes are the serine proteases, which include plasmin and elastase, the aspartic proteases, which include pepsin and cathepsin D, and the cysteine proteases, including papain and cathepsins B, C, K, L, and S. Plasmin, the cleavage product of plasminogen, can cleave MMP propeptides and can result in MMP activation. Elastase, often a product of neutrophils, can degrade elastin and some fibrillar collagens. Cathepsin K has been recognized as a key mediator of bone resorption, where it functions to cleave collagen under the acidic conditions found at the osteoclast ruffled border. As with the MMPs, production and secretion of these proteases are controlled by signals from growth factors, cytokines, and matrix components. Thus, a delicate and intricate balance in connective tissues controls the integrity of the tissue and the response to injury. This balance is disturbed in disease states that cause connective tissue destruction.

Research advances that have improved our knowledge of the biology of connective tissue are being applied in the design of new therapies. We are witnessing the emergence of anticytokine therapies, such as anti–tumor necrosis factor-α and antagonists to interleukin-1, aimed not only at reducing inflammation in connective tissues but also at halting tissue destruction. Growth factors capable of stimulating repair are being studied for treatment of chronic wounds, nonhealing bone defects, and cartilage lesions. Small molecule inhibitors of MMPs and other matrix-degrading enzymes are in development and early testing. Finally, advances in tissue engineering should make it possible to reconstruct or replace many damaged connective tissue structures. Undifferentiated mesenchymal precursor cells found in the bone marrow and some connective tissues, including adipose tissue, can be induced in vitro to differentiate into cells capable of producing bone, cartilage, muscle, or adipose tissue, depending on culture conditions. These exciting advances will certainly lead to better treatments for the many common conditions affecting connective tissues.

INHERITED DISEASES OF CONNECTIVE TISSUE

REED E. PYERITZ

MUCOPOLYSACCHARIDOSES

DEFINITION

Proteoglycans are ubiquitous components of the extracellular matrix (ECM) and the surfaces of cells, and they are among the largest and most complex of human molecules. Proteoglycans consist of a protein core to which are covalently bound glycosaminoglycans (GAGs; formerly called *mucopolysaccharides*) of several types: dermatan sulfate, heparan sulfate, keratan sulfate, and chondroitin sulfate. These four polymeric molecules are cleaved from their protein core in lysosomes; then they, plus hyaluronan (a GAG lacking a protein core), are catabolized further in lysosomes in a stepwise fashion by more than a dozen enzymes. Genetic defects in any one of these enzymes lead to the accumulation of GAG metabolites in lysosomes, with profound disruption of cellular physiology. The phenotypes resulting from deficiencies of these catabolic enzymes are termed *mucopolysaccharidoses* (MPSs) and are classified into seven types (Table 268-1). Several additional storage disorders, termed *mucolipidoses* (MLs), are caused by a genetic defect in post-translational modification of lysosomal enzymes and share features with the MPS.

EPIDEMIOLOGY

All MPS disorders are rare, each with an incidence of 1 or fewer cases per 100,000 births, and are without ethnic predilection.

PATHOBIOLOGY

With the exception of MPS II (Hunter's syndrome), which is X-linked, each of these disorders is autosomal recessive. All MPSs are caused by deficiency of a single lysosomal enzyme responsible for a specific step in GAG metabolism. Catabolism of GAG proceeds normally until the step requiring the defective enzyme, when further normal metabolism halts. Although a minor degree of nonspecific breakdown occurs, resulting in urinary excretion of cleaved GAG that can be useful diagnostically, the accumulation of GAG within lysosomes of cells of mesenchymal origin, endothelium, and, in most cases, neurons causes widespread, progressive cellular dysfunction and clinical effects. Lysosomal enzymes are targeted to lysosomes by post-translational addition of mannose 6-phosphate. Deficiency of the phosphotransferase that catalyzes the first step in this reaction results in an inability to catabolize any GAG molecules. The catabolic enzymes, which normally would be transported into lysosomes, instead are secreted from the cell and are found in unusually high concentrations in plasma, providing one diagnostic test for ML.

TABLE 268-1 MUCOPOLYSACCHARIDOSES AND MUCOLIPIDOSES

TYPE	EPONYM OR COMMON NAME	CLINICAL FEATURES	INHERITANCE	OMIM*	ENZYMATIC DEFECT
MPS IH	Hurler's syndrome	DM and short stature; MR; corneal clouding; HS; heart disease; death in childhood	AR	252800	α-L-iduronidase
MPS IS	Scheie's syndrome	Coarse facies; stiff joints; corneal clouding; aortic valve disease; normal intelligence and lifespan	AR	252800	α-L-iduronidase
MPS II	Hunter's syndrome	Severe form: coarse facies, DM, and short stature; HS; MR; no corneal clouding; death by late adolescence Mild form: coarse facies, short stature; normal intelligence; survival to adulthood	XL	309900	Iduronate sulfatase
MPS IIIA	Sanfilippo's A	Severe MR and hyperactivity; mild somatic changes	AR	252900	Heparan *N*-sulfatase
MPS IIIB	Sanfilippo's B	Same as MPS IIIA	AR	252920	α-*N*-acetylglucosaminidase
MPS IIIC	Sanfilippo's C	Same as MPS IIIA	AR	252930	Acetyl-coenzyme A: α-glucosaminide acetyltransferase
MPS IIID	Sanfilippo's D	Same as MPS IIIA	AR	252940	*N*-acetylglucosamine 6-sulfatase
MPS IVA	Morquio's A	Short stature and distinct skeletal dysplasia with odontoid hypoplasia and myelopathy; corneal clouding; normal intelligence; valvular heart disease	AR	253000	Galactose 6-sulfatase
MPS IVB	Morquio's B	Same as MPS IVA	AR	253010	β-Galactosidase
MPS VI	Maroteaux-Lamy	DM and short stature; corneal clouding; normal intelligence; aortic stenosis; leukocyte inclusions; hydrocephalus in severe form	AR	253200	*N*-acetylgalactosamine 4-sulfatase
MPS VII	Sly's syndrome	DM; HS; widely variable, including MR	AR	253220	β-Glucuronidase
MPS IX	—	Short stature; periarticular soft tissue masses	AR	601492	Hyaluronidase
ML II	I-cell disease	Similar to but more severe than MPS IH but with cellular inclusions; no mucopolysaccharidoses	AR	252500	UDP-*N*-acetylglucosamine: lysosomal enzyme *N*-acetylglucosaminyl-1-phosphotransferase
ML III	Pseudo-Hurler polydystrophy	Short stature and mild DM; stiff joints, arthropathy, coarse facies; variable but mild MR; survival to adulthood	AR	252500	Same as ML II

*Entries in Online Mendelian Inheritance in Man, OMIM. Bethesda, MD, National Center for Biotechnology Information, National Library of Medicine. http://www.ncbi.nlm.nih.gov/omim. Accessed Sept. 11, 2009.
AR = autosomal recessive; DM = dysostosis multiplex; HS = hepatosplenomegaly; MR = mental retardation; XL = X-linked.

Pathology

All pathologic manifestations of MPS and ML disorders worsen with age, and some are present from early developmental stages. Gross anatomic hallmarks are hepatosplenomegaly, marked skeletal alterations (termed *dysostosis multiplex*) that result in short stature and thoracic cage deformity, thickening and narrowing of airways and arteries, and coarsening of facial features. Although mental retardation is a prominent feature of some of these conditions, the brain may show only ventriculomegaly secondary to communicating hydrocephalus. On microscopy, mesenchymal cells show a cytoplasm full of apparently empty vacuoles; these are lysosomes from which GAG has been removed by fixation. Cells cultured from patients show greatly enlarged lysosomes filled with granular material. In the severe form of ML, dense inclusions are present, which gave rise to the common name, *I-cell disease.*

CLINICAL MANIFESTATIONS

Each of the disorders in Table 268-1 shows a wide spectrum of clinical severity. This wide spectrum has led to a classification that gives the impression of separate disorders within some of the MPS and ML types, but these represent the apparent ends of the continuum. Some of the disorders result in death by adolescence (Hurler's syndrome, severe Hunter's syndrome, ML II), whereas others are commonly compatible with survival to adulthood. The latter group of disorders is emphasized here.

The milder end of the MPS I spectrum, Scheie's syndrome, may not be diagnosed until adulthood; patients present with stiffened joints, corneal clouding and glaucoma, carpal tunnel syndrome, and aortic valvular disease. Stature and intelligence are not affected. The main health risks are valvular involvement, thickening of meninges that can produce a myelopathy, and thickening of the upper airways that can produce obstructive symptoms and sleep apnea.

The milder form of MPS II, Hunter's syndrome, is distinctive because it is X-linked (affecting males almost exclusively), and the cornea shows little overt clouding. Cervical myelopathy, obstructive airway disease, and cor pulmonale are important concerns. A combined conductive-neurosensory hearing loss is common.

Neither MPS IV (Morquio's syndrome) nor MPS VI (Maroteaux-Lamy syndrome) affects intelligence. Both syndromes often are associated with severe skeletal changes, which are distinct radiographically but produce similar problems of kyphoscoliosis, pectus carinatum, restrictive lung disease, severe short stature, and joint degeneration. Cervical myelopathy resulting from a thickened dura is common to both disorders and is accentuated by odontoid hypoplasia in MPS IV. Thickening of the aortic and mitral valves may produce severe dysfunction necessitating their replacement. General anesthesia is especially hazardous because of the narrow upper and middle airways and cervical instability.

Patients with ML III (pseudo-Hurler's polydystrophy) resemble patients with MPS VI but often have mild-to-moderate mental retardation. Aortic regurgitation is common.

DIAGNOSIS

Differential Diagnosis

Diagnosis of these conditions is difficult in the young child, before most of the clinical features have progressed, but should be considered in any person with hepatosplenomegaly and coarsening of the facial features. Evaluation requires a pedigree analysis, skeletal radiographic survey, echocardiogram, and analysis of the urine for excretion of GAGs. Often the specific MPS is evident from radiographs, the presence or absence of corneal clouding, and the pattern of mucopolysaccharidiuria. Enzymatic analysis of leukocytes confirms the diagnosis. Patients with MLs do not show mucopolysaccharidiuria but have marked elevation of all the GAG catabolic lysosomal enzymes in plasma.

TREATMENT Rx

Ventriculoperitoneal shunting is necessary if intracranial pressure is elevated. Close attention to hearing and visual problems is essential throughout life. Many adults with MPS or ML require surgery for carpal tunnel syndrome. Cardiovascular surgery for valvular or coronary disease may be necessary. All use of anesthesia is high risk because of the narrow airways and, in the case of MPS IV, atlantoaxial instability. For patients who remain ambulatory, selective joint replacement can be beneficial. Because of the morbidity associated with thoracic cage deformity, consideration should be given to stabilizing the spinal deformity before it becomes severe.

Replacement of the deficient enzyme by intravenous infusion is being studied for most of the MPS disorders. Laronidase (Aldurazyme) has been approved in the United States for treatment of MPS I. An infusion every 2 weeks for 1 year in adolescent and adult patients resulted in substantial reduction in hepatosplenomegaly and modest improvement in pulmonary function, sleep apnea, and joint mobility. Whether early institution of therapy in young children modulates mental retardation in the Hurler's variant of MPS I is uncertain. Galsulfase (Naglazyme) has been approved for the treatment of MPS VI, in which somatic rather than neurologic problems predominate. Bone marrow transplantation has been attempted in many of the MPS disorders, with mixed success. The earlier transplantation occurs, the better the outcome in terms of somatic problems, but prevention of mental retardation has not occurred.

MARFAN SYNDROME

DEFINITION

Marfan syndrome is an autosomal dominant, pleiotropic disorder caused by defects in the principal component of the extracellular microfibril, the large glycoprotein fibrillin-1. The disease manifests in multiple systems, especially the eye, skeleton, heart, aorta, lung, and integument. Notable features include dislocation of the ocular lens, tall stature with particularly long limbs and digits, deformity of the thoracic cage from pectus carinatum or excavatum with abnormal curvature of the spine, mitral and tricuspid valve prolapse, dilation of the sinuses of Valsalva and predisposition to aortic dissection, spontaneous pneumothorax, abnormal skin stretch marks, hernias, and dural ectasia. If untreated, patients often die before 30 or 40 years of age from aortic dissection or congestive heart failure.

EPIDEMIOLOGY

Marfan syndrome is a common mendelian disorder, with an estimated incidence of about 1 per 5000 births. Marfan syndrome is found throughout the world, without ethnic or geographic predilection.

PATHOBIOLOGY

Pathogenesis

Mutations in *FBN1,* which maps to human chromosome 15q21.1 and encodes fibrillin-1, cause Marfan syndrome and related connective tissue disorders. More than 800 distinct mutations have been found, and few occur in more than one family. Patients are heterozygous for mutations in *FBN1,* leading to autosomal dominant inheritance. Extracellular microfibrils are polymers of many fibrillin-1 molecules and are ubiquitous in the ECM of most tissues. Latent transforming growth factor-β (TGF-β) binding protein, which keeps the cytokine inactive, bears striking homology to regions of fibrillin. Abnormalities of either the quality or the quantity of microfibrils disrupt normal signaling by TGF-β, especially during embryonic development and postnatal growth. Studies in mice engineered to harbor human mutations in *FBN1* showed that excessive TGF-β signaling causes abnormal lung septation (the precursor to pneumothorax), mitral valve prolapse, muscular hypoplasia, and aortic dilation. This fundamental shift in understanding of the pathogenesis of Marfan syndrome has suggested novel therapies, such as with small molecules that affect the activity of TGF-β.

The features of Marfan syndrome are highly variable, even among relatives who share the same mutation in *FBN1.* This variability persists after accounting for the effects of age. Men tend to be affected more severely, for unclear reasons.

Pathology

The features of Marfan syndrome are age dependent. Some severely affected infants have flagrant features and often die of mitral regurgitation and heart failure despite aggressive management. At the other end of the clinical spectrum, Marfan syndrome merges with several related disorders, and patients may not come to medical attention, let alone receive a definitive diagnosis, until adulthood.

None of the gross or microscopic pathologic changes is specific for Marfan syndrome. The medial degeneration of the aortic wall, characterized by disarray and fragmentation of the elastic fibers and increased proteoglycan (often inappropriately termed *cystic medial necrosis*) also can be seen in other disorders and in older people with hypertension. Aortic dissection (Chapter 78)

usually begins just superior to the aortic valve (type A) and often progresses to the bifurcation. Death usually results from retrograde dissection and hemopericardium. About 10% of dissections begin in the descending thoracic aorta (type B).

CLINICAL MANIFESTATIONS

The lens tends to be displaced superiorly, and usually the zonules remain intact. The retina is at increased risk for detachment, especially in patients who are highly myopic. Tubular bones overgrow, accounting for the disproportionate tall stature (dolichostenomelia), long digits (arachnodactyly), and sternal deformity. Ligaments may be lax, causing scoliosis and joint hypermobility. Alternatively, congenital contractures are common, especially of the elbows and digits. The palate typically is highly arched, and the dentition can be crowded and malocclude. Mitral valve prolapse occurs in about 80% of cases, and the valve leaflets become progressively thickened (myxomatous on histopathology) (Chapter 75). The mitral annulus may dilate and calcify. Aortic root dilation begins in the sinuses of Valsalva and progresses with age, albeit at highly variable rates (Chapter 78). Most males with Marfan syndrome have an aortic root dimension above the upper limit of normal for their body surface area by adolescence. Some females show a slower progression and may have a root diameter near the upper limit of normal well into adulthood. The dilation usually does not involve the distal ascending aorta. Spontaneous pneumothorax, resulting from rupture of apical blebs, occurs in about 5% of patients. Stretch marks (striae atrophicae) occur over areas of flexural stress, such as the shoulders, breasts, and lower back. The neural canal in the lumbosacral region is enlarged in most people with Marfan syndrome; this may be visible on plain radiographs, especially if the neuroforamina are widened. Computed tomography or magnetic resonance imaging is diagnostic and should be used in patients with back pain and radicular symptoms. Large anterior meningoceles in the pelvis are a severe manifestation of dural ectasia. Simple cysts in the liver and kidneys are common, increase with age, and seldom cause clinical problems.

DIAGNOSIS

Differential Diagnosis

The conditions that overlap clinically and genetically with Marfan syndrome include familial aortic aneurysm, familial ectopia lentis, MASS phenotype (which includes many families with mitral valve prolapse syndrome), and Loeys-Dietz syndrome. Most of these conditions are diagnosed clinically, so differentiating among them is arbitrary. A careful family history is essential to this process. Molecular genetic testing has a limited role. However, if the mutation in *FBN1* is known in a family, analysis of DNA can be used effectively for presymptomatic or prenatal diagnosis. Loeys-Dietz syndrome, which is associated with generalized arterial tortuosity and susceptibility to dissection, is caused by mutation in either of two receptors for TGF-β, *TGFBR1* and *TGFBR2,* and molecular analysis is clinically available.

A question of Marfan syndrome arises most commonly in the tall, lanky adolescent who has several minor skeletal features, nearsightedness, and athletic desires. A detailed ophthalmologic examination with full pupillary dilation and a transthoracic echocardiogram are essential components in the evaluation. If these tests are negative and no one in the family has a history of Marfan syndrome or aortic dissection, the patient probably can be reassured.

TREATMENT

Rx

Life expectancy in Marfan syndrome has improved markedly, to the point that many patients can expect survival to advanced years. All patients should be seen at least annually by a physician who manages the overall care. Most patients require annual ophthalmologic and cardiologic consultation and orthopedic consultation as required by specific problems. A number of studies, but only one randomized clinical trial, support the prophylactic use of β-adrenergic blockade from an early age to slow the rate of aortic root dilation and protect against aortic dissection.■ Prophylactic surgical repair of the aortic root has had the greatest beneficial impact. The composite graft, involving a prosthetic valve in a Dacron tube and implantation of the coronary ostia into the graft, was the first approach to produce markedly improved survival in these patients. More recently, replacement of the aneurysm and preservation of the native aortic valve have shown promise and should be considered first. For the adult, aortic root surgery should be recommended when the maximal aortic diameter reaches 50 mm, and a strong family history of aortic dissection should prompt earlier repair.

EHLERS-DANLOS SYNDROMES

DEFINITION

The Ehlers-Danlos syndromes (EDSs) are clinically variable and genetically heterogeneous. Diagnoses still are based largely on the bedside examination. The unifying themes among these disorders are fragility of tissues, joint hypermobility, and skin hyperextensibility.

EPIDEMIOLOGY

No accurate data exist, but an incidence of about 1 in 5000 births is a reasonable estimate of how many individuals qualify for one of the EDS diagnoses. Each type represents something of a clinical spectrum, with the mild end merging with what might be considered normal variation. Just as the diagnostic criteria are arbitrary, so would be any determination of prevalence based on phenotypic criteria. The extent to which normal variation in joint hypermobility, skin elasticity, and tissue fragility represents genetic variation at loci that encode collagen or other ECM genes requires considerable research.

PATHOBIOLOGY

Pathogenesis

Defects in collagen and other proteins in the ECM of various tissues underlie all forms of EDS that have been elucidated so far. The specific mutations occur in a variety of genes, with the effect of altering the structure, synthesis, post-translational modifications, or stability of the collagens involved. The known molecular defects are listed in Table 268-2.

Pathology

Few findings in the routine pathologic evaluation distinguish among the various types of EDS or even distinguish individual types from normal. Thickness of the dermis is decreased in some forms, especially the vascular type, and the walls of arteries are reduced in thickness in this type. By electron microscopy, the classic, hypermobile, and kyphoscoliotic types have abnormal collagen fibers, especially when viewed in cross section (variable and often increased fiber diameter with an irregular outline). In the vascular type, some patients have dilated endoplasmic reticulum consistent with aberrant secretion of type III collagen molecules.

CLINICAL MANIFESTATIONS

The major and minor features of each EDS are detailed in Table 268-2. Infants with classic EDS often are born prematurely by 4 to 8 weeks because of rupture of fetal membranes. Diagnosis of the vascular and kyphoscoliotic types is important because of their cardiovascular features. The vascular type, previously termed *EDS IV,* is characterized by a troublesome tendency toward spontaneous rupture of large arteries and hollow organs, especially the colon and uterus. Because these events carry considerable morbidity, life expectancy is reduced, on average, by more than half. During pregnancy, women with this form of EDS are especially vulnerable to rupture of major arteries and the uterus. In the kyphoscoliotic type, aortic root dilation and aortic regurgitation can develop. Patients with most forms of EDS are prone to develop mitral valve prolapse, and progression to mitral regurgitation (Chapter 75) occurs more often than in the common form of mitral valve prolapse.

DIAGNOSIS

Differential Diagnosis

By careful adherence to the clinical features shown in Table 268-2 and judicious use of laboratory tests, the various defined types of EDS can be differentiated. Many specific non-EDS syndromes need to be excluded. The kyphoscoliotic type of EDS in infants shares some features with severe Marfan syndrome. Patients with Larsen's syndrome may resemble patients with the arthrochalasis type of EDS. The skin redundancy and loss of elasticity of the dermatosparaxis type of EDS are reminiscent of autosomal dominant cutis laxa, which is not associated with easy bruising or tissue fragility.

The most difficult decision is whether any diagnosis of EDS is warranted. Patients who have only joint hypermobility without skin changes should not be labeled with EDS; a diagnosis of familial joint hypermobility might be more appropriate. Familial joint instability involves a predisposition to dislocations of major joints that is rare in most types of EDS except for arthrochalasis.

TABLE 268-2 EHLERS-DANLOS SYNDROMES

TYPE	FORMER NAME	CLINICAL FEATURES*	INHERITANCE	OMIM†	MOLECULAR DEFECT
Classic	EDS I and II	Joint hypermobility; skin hyperextensibility; atrophic scars; smooth, velvety skin; subcutaneous spheroids	AD	130000 130010	Structure of type V collagen due to mutations in *COL5A1, COL5A2*
Hypermobility	EDS III	Joint hypermobility; some skin hyperextensibility, with or without smooth, velvety texture	AD AR	130020 225320	? Tenascin-X *(TNX)*
Vascular	EDS IV	Thin skin; easy bruising; pinched nose; acrogeria; rupture of large-caliber and medium-caliber arteries, uterus, and large bowel	AD	130050 (225350) (225360)	Deficient type III collagen *(COL3A1)*
Kyphoscoliotic	EDS VI	Joint hypermobility; congenital, progressive scoliosis; scleral fragility with globe rupture; tissue fragility, aortic dilation, MVP	AR	225400	Deficiency of lysyl hydroxylase
Arthrochalasis	EDS VII A and B	Joint hypermobility, severe, with subluxations, congenital hip dislocation; skin hyperextensibility; tissue fragility	AD	130060	No cleavage of amino terminus of type I procollagen due to mutations in *COL1A1* or *COL1A2*
Dermatosparaxis	EDS VII C	Severe skin fragility; decreased skin elasticity, easy bruising; hernias; premature rupture of fetal membranes	AR	225410	No cleavage of amino terminus of type I procollagen due to deficiency of peptidase
Unclassified types	EDS V	Classic features	XL	305200	?
	EDS VIII	Classic features and periodontal disease	AD	130080	?
	EDS X	Mild classic features, MVP	?	225310	?
	EDS XI	Joint instability	AD	147900	?
	EDS IX	Classic features; occipital horns	XL	309400	Allelic to Menkes' syndrome
	EDS, progeroid form	Classic features and premature aging	AR	130700	Deficiency of galactosyltransferase I

*Listed in order of diagnostic importance.
†Entries in Online Mendelian Inheritance in Man, OMIM. Bethesda, MD, National Center for Biotechnology Information, National Library of Medicine. http://www.ncbi.nlm.nih.gov/omim. Accessed Sept. 11, 2009.
AD = autosomal dominant; AR = autosomal recessive; EDS = Ehlers-Danlos syndrome; MVP = mitral valve prolapse; XL = X-linked.

TREATMENT

Rx

Management of most skin and joint problems should be conservative and preventive. Sutures need to be placed with careful attention to approximating the margins and avoiding tension; removable sutures should be left in place for twice the usual time. Most instances of joint hypermobility and pain in EDS do not require surgical treatment. Benefit often is derived from physical therapy designed to strengthen the muscles that provide support for the loose ligaments. All patients should receive genetic counseling about the mode of inheritance and their risk of having children affected with EDS. The possibility of prenatal diagnosis exists for all of the EDS types with defined molecular or biochemical defects.

The vascular type of EDS requires particular surgical care; the ruptured arteries are difficult to repair because of the pronounced vascular fragility. Rupture of the bowel is a surgical emergency. Because the risk for uterine and vascular rupture is especially high during pregnancy in women with the vascular form, affected women should be advised that there is a substantial risk for death related to pregnancy and delivery. Patients should be advised to avoid contact sports and to treat blood pressure elevations aggressively. Arteriography and arterial lines should be avoided if possible. Biochemical and genetic screening holds the potential for reassuring relatives at risk that they do not have a defect in type III collagen.

The kyphoscoliotic type of EDS may improve with large doses of vitamin C (1 to 4 g/day) because ascorbate is a cofactor for the enzyme that is deficient. Celiprolol, a cardioselective β_1-blocker with β_2 agonist vasodilatory properties (titrated up by 100 mg every 6 months up to a maximum of 400 mg twice daily), reduced cardiovascular events by 64% in patients with EDS. No other metabolic or genetic therapy is effective in other forms of EDS.

OSTEOGENESIS IMPERFECTA SYNDROMES

DEFINITION

The heterogeneous group of disorders called *osteogenesis imperfecta* (OI) includes, at one end of the severity spectrum, a type that is lethal prenatally or in the neonatal period and, at the other, such mild features that distinguishing affected individuals from the general population is difficult. The unifying feature is hereditary osteopenia (insufficient bone), with primary defects in the protein matrix in bone and other tissues. The clinical syndromes all involve osteoporosis with liability to fracture (Chapter 251).

EPIDEMIOLOGY

No careful epidemiologic study has been performed, and the milder forms of type I OI merge with the phenotypes of familial osteoporosis, fracture susceptibility, and joint hypermobility found in the general population. A crude estimate of the overall prevalence of OI is 1 to 2 per 20,000 births. The neonatal lethal form (type II), which is almost always caused by a new mutation in a parental gamete, has an incidence of about 1 in 50,000 births.

PATHOBIOLOGY

Pathogenesis

Most patients in whom mutations have been found usually have defects in the two genes that encode the procollagen chains of type I collagen, *COL1A1* and *COL1A2*. Type I collagen is composed of two $\alpha 1$(I) and one $\alpha 2$(I) procollagen chains; the mature fiber requires considerable post-translational modification, which occurs appropriately only if the three procollagen chains have intertwined to form a triple helix that is perfect and completed at the right speed. A mutation that affects formation of the triple helix, such as substitution of one of the mandatory glycine residues that occurs at every third position, also has adverse effects on the modifications that render the molecule capable of forming effective mature fibers. As a result, a single nucleotide change resulting in a missense mutation can have profound effects on the ECM and produce a severe condition. Alternatively, and at first glance paradoxically, a mutation that eliminates an entire allele, or at least production of any product capable of intertwining with normal procollagen chains, has a much milder effect on the ECM and on the severity of OI. Examples of the most common classes of mutations are shown in Table 268-3. Hundreds of mutations have been described. Patients with mutations in *COL1A1* or *COL1A2* are heterozygous, and thus the most common forms of OI are inherited as autosomal dominant traits. Several autosomal recessive forms of OI occur because of mutations in genes that encode enzymes that process type I collagen into mature fibrils.

Pathology

Other than the gross pathology associated with the clinical manifestations, the most characteristic pathology is a primary reduction in bone matrix with secondary undermineralization.

CLINICAL MANIFESTATIONS

The major phenotypic features of OI are shown in Table 268-3. Among the most common forms, the most severe type is type II, followed in decreasing order by types III, IV, and I. In type II, infants either are stillborn or die soon after birth of pulmonary failure secondary to the small thorax, which usually is compromised further by myriad rib fractures. A few infants have survived for at least a few years but require enormous attention to their medical needs.

Type III OI may be confused with type II at birth, but survival alone helps make the distinction. Bony deformity is pronounced and not necessarily due

TABLE 268-3 OSTEOGENESIS IMPERFECTA

TYPE	CLINICAL FEATURES	INHERITANCE	OMIM*	BASIC DEFECTS
I	Fractures variable in number; little deformity; stature normal or nearly so; blue sclerae; hearing loss common but not always present; DI uncommon	AD	166200	Typically, one nonfunctional *COL1A1* allele
II	Lethal in utero or shortly after birth; many fractures at birth typically involving ribs (may appear "beaded") and other long bones; little calvaria; pulmonary hypertension	AD	166210	*COL1A1* or *COL1A2*: substitution of glycyl residues; occasionally deletions of a portion of the triple-helical domain
		AR	259400	Deletion in *COL1A2* plus a nonfunctional allele
III	Fractures common, but long bones progressively deform starting in utero; stature markedly reduced; sclerae often blue but become lighter with age; DI and hearing loss common	AD AR (rare)	259420 259440	One single–amino acid substitution Two mutations in *COL1A1* and/or *COL1A2* (rarely)
IV	Fractures common; stature usually reduced; bone deformity common but rarely severe; scleral hue normal to grayish; hearing loss variable; DI common	AD	166220 166240	Point mutations in *COL1A1* or *COL1A2* Exon skipping mutations in *COL1A2*
V	Similar to type IV without DI or blue sclerae; fractures develop hyperplastic callus; calcification of the interosseous membrane between the radius and ulna	AD	610967	?
VI	Similar to type IV without DI, blue sclerae or wormian bones; excess osteoid present in bone	?	610968	?
VII	Similar to types II or III with fractures at birth, blue sclerae, no DI; presence of rhizomelic limb shortening and coax vara	AR	610682	Mutations in *CRTAP*
VIII	Similar to types II or III with fractures at birth	AR	610915	Mutations in *LEPRE1*
IX	Similar to types II or III with fractures at birth	AR	259440	Mutations in *PPIB*

*Entries in Online Mendelian Inheritance in Man, OMIM. Bethesda, MD, National Center for Biotechnology Information, National Library of Medicine. http://www.ncbi.nlm.nih.gov/omim/. Accessed June 11, 2009.
AD = autosomal dominant; AR = autosomal recessive; DI = dentinogenesis imperfecta.

to fractures. Mobility is impaired, and most patients require a wheelchair at an early age. Stature may be severely compromised. Because of progressive vertebral column deformity and rib fractures, restrictive lung disease is a common problem as patients age; many die of pulmonary complications. Basilar impression causing compression of the brain stem and the craniocervical junction can produce central sleep apnea, headache, and upper motor neuron signs.

Patients with type IV OI generally have reduced stature, some bony deformity, and abnormal teeth that are opalescent and wear easily (dentinogenesis imperfecta). As in type I OI, the tendency to fracture is highest in childhood and lessens with adolescence. A distinguishing characteristic of type IV OI is a normal scleral hue.

Type I OI is probably the most common form and is associated with a bluish or blue-gray scleral hue. People with type I OI who also have dentinogenesis imperfecta tend to have more severe skeletal problems. The risk of fracture diminishes during adulthood but reemerges as a major concern for women after menopause. Hearing impairment in all forms of OI is common and age related, being rare before adolescence. The deficits are of either a mixed or a predominantly conductive form.

The recessive forms of OI (types VI to IX) range in severity from type IV to type II and may have distinctive radiologic or histopathologic findings.

DIAGNOSIS

Differential Diagnosis

The range of diagnostic possibilities in a person with multiple fractures largely depends on age. In infancy, the genetic conditions hypophosphatasia, severe osteochondrodysplasias (e.g., achondrogenesis and forms of spondyloepiphyseal dysplasia), and Menkes' syndrome need to be excluded when a diagnosis of type II or type III OI is considered. The radiographic features eventually become entirely diagnostic, but often the neonatologist has to arrive at a definitive answer in short order. Analysis of serum alkaline phosphatase and copper can be helpful. In childhood, the most common situation leading to consideration of a mild form of OI is child abuse. In this situation, the pattern of fracture is usually distinct, and bone mineralization should be normal if the child is the object of nonaccidental or repeated accidental trauma. Abnormal scleral hue, dentinogenesis imperfecta, and wormian bones (microfractures along the cranial sutures) all support the diagnosis of OI. The legal and child-protective systems often request exclusion of OI by analysis of collagen production from cultured skin fibroblasts.

In older children, the disorder idiopathic juvenile osteoporosis should be considered in any patient seen initially with repeated fractures. Occasionally, studies of skin fibroblasts are needed to document whether a defect in type I collagen (which would be characteristic of OI) is present. Many osteochondrodysplasias are associated with short stature, skeletal deformity, and a tendency to fracture. Pyknodysostosis and osteopetrosis are associated with sclerotic bones rather than osteoporotic ones. In adulthood, early-onset osteoporosis may be confused with OI (Chapter 251). Mutations in type I collagen also cause familial osteoporosis, and the skeletal phenotypes merge; patients with true OI may have scleral, hearing, or dental abnormalities and a positive family history.

Analysis of the specific enzymes defective in the recessive forms of OI is useful for establishing the diagnosis and enabling reproductive counseling and prenatal diagnosis if desired.

TREATMENT

Rx

Management of the skeletal complications largely depends on orthopedic, physical, and occupational therapy approaches. Although no medical treatment has yet been demonstrated to improve the quality of the bone, studies of mesenchymal stem cell transplantation and bisphosphonates are underway. The latter treatment clearly can increase bone mineral density. The long-term goals are for the patient to maintain function and independence as an individual. These goals can be advanced in some patients by judicious use of intramedullary rods in the long bones of the legs; if mobility and especially ambulation can be maintained, the demineralization associated with inactivity can be avoided.

Unaffected parents of a child with OI and all affected individuals should have genetic counseling. For the parents of a child with type II OI, the possibility of germinal mosaicism (which has been well documented in this condition) should not be overlooked. If one parent has a "new" mutation in one of the type I procollagen genes and multiple gonadal cells carry this mutation, the risk for recurrence in future children is not negligible. If the mutation in the affected child can be defined, the risk for recurrence can be quantified (through molecular analysis of sperm) if the mutation arose in the father.

PSEUDOXANTHOMA ELASTICUM

DEFINITION

Pseudoxanthoma elasticum (PXE) is a heritable disorder of connective tissue with pleiotropic manifestations wherever elastic fibers are found but primarily in the skin, eye, and vasculature. Life expectancy is reduced, on average, because of a predisposition to myocardial infarction and gastrointestinal hemorrhage.

EPIDEMIOLOGY

The exact frequency of PXE is unknown, but it is probably underdiagnosed. Rough approximations suggest a prevalence of 1 in 25,000 to 100,000 births.

Males and females are equally affected, although women are more likely to seek medical attention out of concern for the skin changes.

PATHOBIOLOGY

Pathogenesis

In most families, PXE occurs as an autosomal recessive trait, which means, given relatively small sibships, that many patients will have no affected relatives. Apparent autosomal dominant inheritance may reflect expression in occasional heterozygotes. The gene for PXE maps to human chromosome 16 and encodes one of the adenosine triphosphate–binding cassette transporters *(ABCC6)*. Because of the prominent histopathologic feature of calcification of elastic tissue, this gene may be important in calcium homeostasis. It is unclear, however, whether calcification is a primary or a secondary phenomenon in PXE.

Pathology

The hallmark of PXE, and an important diagnostic clue, is the histopathologic finding of hyperproliferated elastic fibers in the mid-dermis; these fibers become fragmented, clumped, and calcified. An arteriolar sclerosis develops in the media of muscular arteries and arterioles; the lumen may become progressively and concentrically narrowed. Alternatively, microaneurysms can form. Thickening of the endocardium, especially the atrial endocardium, develops in some patients. In the eye, Bruch's membrane becomes calcified and fragmented.

CLINICAL MANIFESTATIONS

Because of the pleiotropic nature of PXE, the diagnosis initially may be suspected by any of a variety of clinicians, especially dermatologists, ophthalmologists, cardiologists, and gastroenterologists. The condition gains its name from the dermatologic feature of yellowish papules that appear at areas of flexural stress, especially the neck, groin, and popliteal and cubital fossae; in periumbilical regions; and on the buccal mucosa. The appearance of affected skin has been likened to that of a "plucked chicken." Over time, affected areas coalesce and become thickened.

Changes in the eye begin as a generalized, subtle, mottled pattern in the retina (peau d'orange) and progress to the characteristic angioid streaks. The latter changes are not specific for PXE and can be seen in diabetes mellitus, sickle cell disease, and a variety of other conditions. Streaks represent breaks in Bruch's membrane, an elastic lamina that lies between the retinal vasculature and the choroid. Spontaneous hemorrhages, especially those involving the macula, lead to progressive visual loss.

Involvement of arteries of various calibers produces problems because of occlusion and hemorrhage. The lifetime risk of serious gastrointestinal hemorrhage from any site, but especially the stomach, is about 10%. Hypertension is relatively common, in part because of involvement of the renal vasculature. Progressive occlusion of peripheral arteries leads to absence of pulses; acral ischemia is rare because of the development of collaterals. The risk for stroke, myocardial infarction, abdominal angina, and intermittent claudication is increased independent of other risk factors.

DIAGNOSIS

Differential Diagnosis

An acquired form of PXE has been reported and is also of unclear etiology. This form is difficult to differentiate from a sporadic case in a family due to heterozygosity in the parents, but it tends to affect only the skin. As suggested by the name, the cutaneous features of PXE need to be differentiated from those of true xanthoma, which results from a disorder of lipid metabolism (Chapter 213). The dermatologic manifestations need to be differentiated from those of Miescher's elastoma, elastic tissue nevi (Buschke-Ollendorff syndrome), and solar elastosis.

TREATMENT Rx

No cure for or means of preventing PXE is known. In many instances, careful attention to the ocular features by a retinal specialist experienced in PXE can delay but not prevent loss of vision. The risk of gastrointestinal hemorrhage suggests that patients should avoid gastric irritants such as aspirin, nonsteroidal anti-inflammatory drugs, and excessive alcohol. Stool should be checked regularly for occult blood, and angiography may be necessary to detect the source of bleeding. All standard risk factors for atherosclerosis should be managed aggressively. Complaints of chest pain should prompt a rigorous investigation for coronary artery disease. Angioplasty has not been reported to be effective, and the coronary lesions tend to be diffuse. Coronary artery bypass graft surgery has been performed, but long-term results have not been reported. It may be theoretically advantageous to use vein grafts rather than the internal mammary artery for bypass. The excessive wrinkling and pseudoxanthoma in exposed areas can be ameliorated by plastic surgery.

FUTURE DIRECTIONS

Each of these disorders poses special considerations in clinical diagnosis, utility of molecular testing, genetic counseling, and management. For the storage disorders, the clinical utility of enzyme replacement therapy is actively being pursued by several pharmaceutical companies. For several of the other conditions, somatic stem cell therapy offers some promise but is years away from routine clinical use. In Marfan syndrome, clinical trials of drugs that modulate activity of TGF-β are under way. Considerable progress will be made over the next few years in delineating the milder ranges of the phenotypes in Marfan syndrome, OI, and EDS. Molecular testing will have an increasing role in specific circumstances, especially as the costs of screening large genes for mutations decreases. Additionally, close medical management for individuals detected as being at heightened risk for cardiovascular, skeletal, and ocular complications will remain a mainstay.

DANIEL L. KASTNER

DEFINITION

The systemic autoinflammatory diseases (Table 269-1) are a group of illnesses characterized by seemingly unprovoked inflammation, without evidence of high-titer autoantibodies or antigen-specific T cells, thus distinguishing them from the more classic autoimmune diseases. The first conditions recognized as autoinflammatory were the hereditary recurrent fevers, a group of mendelian disorders characterized by episodic or fluctuating degrees of fever and localized inflammation. The scope of autoinflammatory disease has been broadened to include other heritable illnesses, including disorders in which purulent or granulomatous inflammation predominates, as well as inherited disorders of the complement system (Chapter 49). In addition, in numerous autoinflammatory conditions, some of which present in childhood and others that occur later in life, there is a complex interaction

of genetic susceptibilities and environmental factors. These illnesses include systemic-onset juvenile idiopathic arthritis (Still's disease), Behçet's disease, and even the crystalline arthritides. Recent advances in the genetics and pathophysiology of the inherited autoinflammatory diseases suggest that these conditions are inborn errors of innate immunity, the phylogenetically more primitive part of the immune system that uses germline membrane and intracellular receptors expressed in granulocytes and macrophages to mount the body's first line of defense against pathogens (Chapters 44 and 47).

HEREDITARY RECURRENT FEVER SYNDROMES

Familial Mediterranean Fever

DEFINITION

Familial Mediterranean fever (FMF) is a recessively inherited illness that typically manifests with 12- to 72-hour episodes of fever and localized serosal, synovial, or cutaneous inflammation. Between attacks, patients usually feel completely well, although biochemical evidence of inflammation may remain, and some patients eventually develop systemic amyloidosis. Before the identification of the causative gene, FMF was defined purely clinically; clinical features remain an important part of the diagnosis, because some patients with typical disease have only one, or sometimes no, demonstrable mutation in *MEFV,* the only known causative gene.

EPIDEMIOLOGY

FMF is most common in individuals of Jewish, Arab, Armenian, Turkish, and Italian ancestry. The frequency of asymptomatic carriers of a single *MEFV* mutation in these populations is as high as 1 in 5, a finding that suggests a selective advantage for heterozygotes. With genetic testing, FMF is now frequently recognized in both Ashkenazi (eastern European) and non-Ashkenazi Jewish populations, as well as in Mediterranean populations previously thought not to be at risk. Mutation-positive individuals with typical symptoms have been documented worldwide. FMF usually manifests in childhood, sometimes even in infancy, although approximately 10% of patients experience their first attack as adults; infrequently, FMF first occurs in persons older than 40 years.

PATHOBIOLOGY

MEFV, the gene for FMF, was identified by positional cloning in 1997, and it encodes a 781–amino acid protein denoted pyrin (or marenostrin) that is expressed in granulocytes, monocytes, and dendritic cells, as well as in peritoneal, synovial, and dermal fibroblasts. The N-terminal 92 amino acids of pyrin are the prototype for a motif, the PYRIN domain, that is involved in protein-protein interactions; this domain defines a family of more than 20 human proteins, including pyrin itself, involved in the regulation of cytokine production (particularly the interleukin-1 [IL-1] family), nuclear factor kappa B (NF-κB) activation, and apoptosis. More than 50 FMF-associated

mutations in pyrin have been identified, many of which reside in the C-terminal domain encoded by exon 10 of *MEFV.*

CLINICAL MANIFESTATIONS

Episodes of FMF are more properly termed recurrent than periodic, and some patients associate attacks with psychological stress or physical exertion. Women of childbearing age sometimes experience their attacks with menses, with remissions during pregnancy. Some patients are unaware of fever during the attacks, but it is almost always observed when sought.

Serosal involvement in FMF is usually peritoneal or pleural. Abdominal attacks are the most frequent, and they may vary from mild discomfort to frank peritonitis, with board-like rigidity, direct and rebound tenderness, and air-fluid levels on upright films of the abdomen. Regardless of the severity of the abdominal attack, constipation is much more common than diarrhea. When a laparotomy or laparoscopy is performed during an attack, a small amount of sterile exudate rich in polymorphonuclear leukocytes is found. Except for serosal inflammation, the appendix is normal. Repeated abdominal attacks may cause peritoneal adhesions, but ascites is rare. Pleurisy, usually unilateral, may accompany abdominal pain, or it may occur independently. Physical findings, if present, may include diminished breath sounds and a friction rub, whereas radiographs may show a small effusion or atelectasis. With multiple attacks, pleural thickening may develop. Symptomatic nonuremic pericardial involvement in FMF has been reported but is unusual.

In adults, the arthritis of FMF typically manifests as monoarticular involvement of the knee, hip, or ankle, and attacks of arthritis may persist for up to 1 week at a time. In children, oligoarticular or polyarticular joint involvement may occur. Large joint effusions are sometimes present, and the synovial fluid may have as many as 100,000 leukocytes/mm^3. In approximately 5% of patients who are not treated with prophylactic colchicine, chronic arthritis (usually of the hip or knee) may develop, often necessitating joint replacement surgery. Regardless of colchicine treatment or a particular human leukocyte antigen (HLA-B27) status, some patients with FMF develop sacroiliitis. Arthralgia without frank arthritis is common in FMF.

Cutaneous manifestations of FMF tend to be less common than serosal or synovial involvement. The characteristic skin lesion of FMF is erysipeloid erythema, a painful, demarcated erythematous area most often seen on the lower leg, ankle, or dorsum of the foot. This rash may occur independently, or it may accompany an episode of arthritis. Histologically, one sees a mixed perivascular cellular infiltrate. Other acute manifestations of FMF include unilateral scrotal inflammation (the tunica vaginalis is an embryologic remnant of the peritoneal membrane) and myalgia, either with fever or, especially in children, without fever and induced by vigorous exercise. Various forms of vasculitis have also been associated with FMF; Henoch-Schönlein purpura may occur in children with FMF; less frequently, polyarteritis nodosum is seen.

COMPLICATIONS

Before the widespread use of colchicine prophylaxis, systemic AA amyloidosis (Chapter 194) was a frequent complication of FMF, caused by the ectopic deposition of a misfolded fragment of serum amyloid A (SAA), an acute phase reactant, in the gastrointestinal tract, kidneys, spleen, lung, testes, and adrenals. Malabsorption and nephrotic proteinuria leading to renal failure are the most common manifestations of AA amyloidosis. Cardiomyopathy is less common, and neuropathy and arthropathy are rare. Several risk factors for amyloidosis development in FMF have been identified, including late diagnosis of FMF, colchicine noncompliance, male gender, and specific genotypes of the *MEFV* and *SAA* genes. Amyloidosis in FMF is less common in the United States than in the Middle East. Abdominal fat aspirates are much less sensitive than rectal or renal biopsy in detecting the amyloidosis of FMF. The latter procedure may be preferred, because of the increasing recognition of nonamyloid glomerular disease in FMF. With early diagnosis, aggressive suppression of the acute phase response with colchicine or adjunctive agents may lead to improvement, but for patients with renal failure, early renal transplantation is preferred.

DIAGNOSIS

Based on a simple recessive model of inheritance, two mutations in *MEFV,* in *trans,* should be identified to establish the genetic diagnosis of FMF. Nevertheless, the interpretation of genetic testing is complicated by complex alleles consisting of various combinations of mutations in *cis,* as well as by the observations that as many as one third of patients with clinically typical FMF have only one demonstrable mutation in *MEFV,* and a few patients with typical disease have no identifiable *MEFV* mutations. These latter two findings suggest that, under some circumstances, one *MEFV* mutation may be sufficient for symptoms or that additional genes for FMF exist.

For these reasons, clinical data remain an essential part of the diagnosis of FMF, and genetic testing plays an adjunctive role in settings where clinical experience is limited. Clinical criteria emphasize attack duration (12 to 72 hours); recurrence of symptoms (three or more episodes); documented fever (rectal temperature >38° C); painful manifestations in the abdomen, chest, joints, or skin; and the absence of other causative factors. The differential diagnosis includes the other hereditary recurrent fever syndromes (Table 269-2), as well as other conditions specific to the clinical setting. For patients with recurrent abdominal pain, considerations include gynecologic disorders, porphyria (Chapter 217; which can be distinguished by hypertension during attacks, dominant inheritance, and urine porphyrins), and hereditary angioedema (Chapter 260; which usually does not cause fever). The syndrome of periodic fever with aphthous stomatitis, pharyngitis, and cervical adenopathy is probably the most common cause of unexplained recurrent fever in children and is also included in the differential diagnosis. In patients presenting primarily with recurrent monoarthritis, joint aspiration for cultures and crystals may aid in excluding bacterial and crystalline arthritis, respectively.

Still's disease in children (systemic-onset juvenile idiopathic arthritis) and adults (adult-onset Still's disease) is also considered in the differential diagnosis. Adult-onset Still's disease (see Table 269-1) is an uncommon autoinflammatory condition of unknown cause that is not considered to be hereditary. It is characterized by spiking fever, an evanescent salmon-pink maculopapular rash, arthritis, and neutrophilic leukocytosis. It can be clinically distinguished from FMF by the pattern of fever (intermittent quotidian in Still's disease vs. discrete episodes in FMF), the pattern of arthritis (chronic polyarthritis vs. intermittent monoarthritis), the characteristic skin involvement (evanescent rash vs. erysipeloid erythema), and the presence of lymphadenopathy (more common in Still's disease).

TREATMENT

Rx

The mainstay of therapy for FMF is daily oral colchicine, which can prevent both acute attacks of FMF and the development of systemic amyloidosis. Colchicine probably works by several mechanisms, including its effects on inhibiting leukocyte adhesion and modulating cytokine production. In adults, the therapeutic dose is 1.2 to 1.8 mg/day, and nearly 90% of patients note significant improvement at this dose. The major side effects are gastrointestinal, and they can usually be minimized by gradually increasing the dosage and avoiding milk products in patients who develop lactose intolerance. Most experts continue to prescribe colchicine to patients during pregnancy, with the recommendation that amniocentesis be performed to exclude trisomy 21, for which there may be a slightly increased risk. Use of colchicine in lactating women is considered safe. Intravenous colchicine should be used with extreme caution, if at all, in FMF, because fatal toxicity has been reported in patients already receiving oral colchicine who are given the drug intravenously. IL-1 inhibitors are investigational in patients who are poorly responsive to colchicine or who cannot tolerate therapeutic doses.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

DEFINITION

Worldwide, the tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS) is the second most frequently diagnosed hereditary recurrent fever syndrome, behind FMF. TRAPS is defined by recurrent episodes of fever and localized inflammation, in many ways resembling FMF, but differing in key details (noted later) and caused by mutations in the 55-kD receptor for TNF (TNFRSF1A, TNFR1, p55, CD120a). Whereas a positive genetic test is not necessary to diagnose FMF, the diagnosis of TRAPS requires the identification of a TNF receptor mutation. One of the first well-characterized families with what was later defined as TRAPS was of Irish ancestry, and the condition was termed *familial Hibernian fever* to emphasize the ethnic background and clinical differences from FMF. However, with the discovery of TNF receptor mutations in families of other ancestries, the ethnically neutral TRAPS nomenclature was proposed.

TABLE 269-2 CLINICAL FEATURES OF THE HEREDITARY RECURRENT FEVER SYNDROMES

CLINICAL FEATURE	FMF	TRAPS	HIDS	FCAS	MWS	NOMID/CINCA
Typical ethnicity	Arab, Armenian, Italian, Jewish, Turkish	Any ethnicity	Dutch, other North European	European	European	Any
Attack duration	12-72 hr	Days to weeks	3-7 days	12-24 hr	1-2 days	Continuous, with flares
Abdominal attacks	Sterile peritonitis, constipation more often than diarrhea	Severe pain, vomiting, peritonitis	Sterile peritonitis, diarrhea, rarely constipation	Nausea	Abdominal pain	Not common
Pleural attacks	Common	Common	Rare	Not seen	Rare	Rare
Joint/bone involvement	Monoarthritis, rarely protracted arthritis in knee or hip	Arthritis in large joints, arthralgia	Arthralgia, symmetrical polyarthritis	Polyarthralgia	Polyarthralgia, oligoarthritis, clubbing	Epiphyseal overgrowth, contractures, intermittent or chronic arthritis, clubbing
Skin rash	Erysipeloid erythema on lower leg, ankle, foot	Migratory rash, underlying myalgia	Diffuse maculopapular rash, urticaria	Cold-induced urticaria-like rash	Urticaria-like rash	Urticaria-like rash
Lymphatic involvement	Splenomegaly, occasional lymphadenopathy	Splenomegaly, occasional lymphadenopathy	Cervical adenopathy in children	Not seen	Rare	Hepatosplenomegaly, adenopathy
Neurologic involvement	Aseptic meningitis?	Controversial	Headache	Headache	Sensorineural deafness	Sensorineural deafness, chronic aseptic meningitis, mental retardation, headache
Ophthalmologic involvement	Rare	Conjunctivitis, periorbital edema, rarely uveitis	Uncommon	Conjunctivitis	Conjunctivitis, episcleritis	Uveitis, conjunctivitis, progressive vision loss
Vasculitis	Henoch-Schönlein purpura (HSP), polyarteritis nodosa	HSP, lymphocytic vasculitis	Cutaneous vasculitis common, rarely HSP	Not seen	Not seen	Occasional
Systemic amyloidosis	Risk depends on *MEFV* and *SAA* genotypes; more common in Middle East	Occurs in ~10%; risk increased with cysteine mutations	Rare	Rare	Occurs in ~25%	May develop in some, usually in adulthood

FCAS = familial cold autoinflammatory syndrome; FMF = familial Mediterranean fever; HIDS = hyperimmunoglobulinemia D with periodic fever syndrome; MWS = Muckle-Wells syndrome; NOMID/CINCA = neonatal-onset multisystem inflammatory disease/chronic infantile neurologic cutaneous and articular syndrome; TRAPS = tumor necrosis factor receptor–associated periodic syndrome.

PATHOBIOLOGY

The p55 TNF receptor is composed of four cysteine-rich extracellular domains, a transmembrane region, and an intracellular death domain. To date, all of the more than 60 mutations described are in the extracellular domains, and approximately half are missense substitutions of cysteine residues that abolish highly conserved disulfide bonds. The initial description of TRAPS documented a defect in activation-induced ectodomain cleavage of the p55 receptor in patients with the C52F *TNFRSF1A* mutation, possibly leading to a defect in homeostasis by impaired downregulation of membrane receptors and diminished shedding of potentially antagonistic soluble receptor molecules. More recent studies indicate a more complex pathogenetic picture, because not all mutant receptors exhibit this shedding defect. Additional mechanisms by which p55 mutations may lead to autoinflammation include impaired leukocyte apoptosis and impaired intracellular receptor trafficking, with possible constitutive activation of mitogen-activated protein (MAP) kinases by intracellular aggregates of mutant receptors.

DIAGNOSIS

Although genetic testing is necessary for the diagnosis of TRAPS, certain clinical clues can help distinguish TRAPS from FMF. These include ethnicity (FMF is seen predominantly in Mediterranean and Middle Eastern populations, whereas TRAPS has a more widespread distribution), mode of inheritance (autosomal recessive in FMF, dominant in TRAPS), and duration of attacks, which tends to be longer in TRAPS and sometimes approaches continuous symptoms. The rash of FMF is typically erysipeloid erythema on the lower extremity, whereas patients with TRAPS often have a distinctive erythematous rash, often with underlying myalgia, which may migrate on the trunk or centrifugally on the extremities. Ocular involvement, with periorbital edema, conjunctivitis, and occasionally even uveitis, is observed in TRAPS but not in FMF. Finally, whereas colchicine is much more effective than corticosteroids in FMF, the opposite is true in TRAPS. Nevertheless, aside from the difference in duration and susceptibility to pharmacologic intervention, the abdominal, pleural, synovial, and even scrotal manifestations of the two diseases are rather similar. The usual age of onset for TRAPS is also in childhood, and systemic AA amyloidosis is seen in about 10% of untreated patients with TRAPS. As in FMF, life expectancy in TRAPS is normal in patients whose disease is not complicated by amyloidosis.

As noted earlier, the diagnosis of TRAPS is established by the identification of *TNFRSF1A* mutations in the appropriate clinical setting. One variant, the substitution of glutamine for arginine at residue 92 (R92Q), is present in more than 1% of whites and may be associated with a broader spectrum of symptoms than is typically seen in TRAPS, including early inflammatory arthritis or, in some cases, no symptoms at all. The substitution of lysine for proline at residue 46 (P46L) is common among African American patients with TRAPS and is associated with a receptor shedding defect, but it is also seen among healthy African American controls. These findings establish a "gray zone" for the diagnosis of TRAPS and emphasize the potential role of polymorphisms in the recurrent fever genes in other more common phenotypes.

TREATMENT

Rx

The treatment of TRAPS depends on the frequency and severity of attacks. Patients with relatively infrequent, mild episodes may respond to nonsteroidal anti-inflammatory drugs. Patients with more severe attacks that occur infrequently may be treated with corticosteroids, although increasing doses may be required as the episodes become more frequent, and toxicities may become limiting. For patients with severe attacks occurring once a month or more frequently, treatment with etanercept, the soluble p75 TNF receptor:Fc fusion protein, may be warranted. More recently, some patients with TRAPS who did not respond to TNF inhibition did respond to anakinra, the IL-1 receptor antagonist.

Hyperimmunoglobulinemia D with Periodic Fever Syndrome

DEFINITION AND EPIDEMIOLOGY

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) was first described in 1984 as an FMF-like illness seen in six patients of Dutch ancestry. Besides the difference in ethnicity, a key distinction was the

observation of extremely high levels of immunoglobulin D (IgD) in the serum of the Dutch patients, thus prompting the HIDS nomenclature. HIDS is now recognized in a broader ethnic distribution, although northern Europeans still predominate. Overall, HIDS is still quite rare.

PATHOBIOLOGY

Family studies documented autosomal recessive inheritance. In 1999, patients with HIDS were found to have mutations in *MVK*, which encodes the mevalonate kinase enzyme involved in the biosynthesis of cholesterol and nonsterol isoprenes. Enzyme activity in patients is markedly reduced, but not absent.

The elevated IgD levels seen in HIDS appear to be an epiphenomenon. They do not correlate with disease severity either among patients or in a given patient over time, although IgD may contribute to the release of proinflammatory cytokines in vitro. Moreover, modest elevations of IgD are seen in several inflammatory conditions, including chronic infections, and can be observed in other hereditary recurrent fever syndromes. Up to 20% of patients (particularly young children) with typical recurrent fevers and *MVK* mutations have normal serum IgD levels. Current data suggest that isoprenoid deficiency may play a more important pathogenic role in the pathophysiology of HIDS. In vitro studies suggest that isoprenoid deficiency may lead to excessive IL-1β production, and increased body temperature can further decrease mevalonate kinase enzymatic activity, thereby creating a vicious circle in which infection or immunization can precipitate HIDS attacks.

CLINICAL MANIFESTATIONS

One of the well-recognized clinical characteristics of HIDS is the provocation of attacks by immunizations. Other distinguishing clinical features include a very early age of onset (average age, 6 months), a duration of attacks intermediate between FMF and TRAPS (3 to 7 days), prominent cervical lymphadenopathy during attacks, polyarticular joint involvement, a diffuse maculopapular rash, the predominance of diarrhea over constipation with abdominal attacks, and the infrequency of pleuritic attacks or systemic amyloidosis.

DIAGNOSIS

Based on our current understanding of the genetics and pathophysiology of HIDS, the diagnosis can be established in a patient with recurrent episodes of fever and typical associated findings by documenting either two mutations in *MVK* or elevated levels of mevalonic acid, the substrate for mevalonate kinase, in the urine during attacks. Approximately 10% of patients with otherwise typical disease have only a single identifiable *MVK* mutation. The significance of elevated IgD without genetic or biochemical findings remains unknown.

TREATMENT AND PROGNOSIS Rx

Nonsteroidal anti-inflammatory drugs or corticosteroids are sometimes useful in the treatment of the arthritic manifestations of HIDS. Colchicine is generally not effective. Numerous agents are investigational in HIDS, including the statins, TNF inhibitors, and IL-1 receptor antagonists. Patients with HIDS have a normal lifespan, and attacks may become somewhat less frequent in adulthood.

Cryopyrin-Associated Periodic Syndromes: The Cryopyrinopathies

Three rare, recurrent febrile disorders usually beginning early in life have been associated with mutations in *NLRP3* (formerly *CIAS1*), the gene encoding a protein variously named cryopyrin, NLRP3, NALP3, PYPAF1, or CATERPILLER 1.1. The least severe clinical phenotype is familial cold autoinflammatory syndrome (FCAS; formerly called familial cold urticaria), which is dominantly inherited and is notable for day-long attacks of chills, fever, headache, diffuse urticarial skin rash, arthralgia, and conjunctivitis, precipitated by generalized cold exposure. Amyloidosis is rare in FCAS. Of intermediate severity is Muckle-Wells syndrome (MWS), also dominantly inherited, in which 1- to 2-day episodes of chills, fever, urticarial rash, limb pain, and arthritis occur independently of cold exposure. Sensorineural hearing loss is common in MWS, and systemic amyloidosis may also occur. The most severe *NLRP3*-associated phenotype is neonatal-onset multisystem inflammatory disease (NOMID), known in Europe as chronic infantile neurologic cutaneous and articular (CINCA) syndrome. It is usually sporadic owing to the reduced reproductive fitness of most affected individuals. Fever and constitutional symptoms occur almost daily, often from birth, with generalized urticarial skin rash, a peculiar arthropathy characterized by epiphyseal overgrowth of the long bones, and central nervous system involvement that includes chronic aseptic meningitis, uveitis, and cochlear inflammation, which may lead to mental retardation, blindness, and deafness. In all three cryopyrinopathies, the rash is not true urticaria because there is a neutrophilic rather than a mast cell infiltrate, and serum histamine levels are normal.

The protein mutated in all three disorders is a critical component of a newly recognized macromolecular complex termed the *inflammasome*, which serves as an intracellular scaffold for the processing of IL-1β from its 31-kD precursor form to the biologically active 17-kD form. Cryopyrin is so named because it has an amino-terminal PYRIN domain; thus it bears a structural and functional relationship to the protein mutated in FMF. Disease-associated cryopyrin mutations are thought to decrease the threshold for inflammasome activation, thereby increasing IL-1β production. In vitro studies also suggest a role for cryopyrin/NALP3 in NF-κB activation and apoptosis.

Because there are patients with FCAS, MWS, and NOMID/CINCA without demonstrable *NLRP3* mutations, these diagnoses remain clinical, although genetic testing serves as a valuable adjunct and has greatly increased the recognition of all three conditions. In addition, overlap syndromes that are intermediate between FCAS and MWS and between MWS and NOMID/CINCA have been reported.

Data indicate that IL-1 blockade with anakinra, the IL-1 receptor antagonist, appears to be effective in controlling fever and acute phase reactants in all three cryopyrinopathies. Moreover, in a large series completed at the National Institutes of Health, anakinra markedly decreased central nervous system inflammation in NOMID/CINCA. Recent studies have also documented the efficacy of two other IL-1 inhibitors, rilonacept and canakinumab, in FCAS and MWS. Such data suggest that the major biologic effect of cryopyrin in humans is mediated through IL-1β rather than by other distinct inflammatory pathways.

OTHER INHERITED SYSTEMIC AUTOINFLAMMATORY DISEASES

Deficiency of Interleukin-1 Receptor Antagonist

Deficiency of the IL-1 receptor antagonist (DIRA) is a newly described clinical entity characterized by the neonatal onset of a pustular skin rash, multifocal osteomyelitis, periostitis, and, rarely, vasculitis. Fever is not a prominent finding, although acute phase reactants are markedly elevated. DIRA is caused by recessively inherited loss-of-function mutations in *IL1RN*, which encodes the IL-1 receptor antagonist (IL-1Ra). Patients usually present within the first 2 weeks of life with skin lesions ranging from discrete crops of pustules to generalized severe pustulosis or ichthyosiform lesions. Histologic examination demonstrates extensive neutrophilic infiltrates in the dermis and epidermis. Typical radiographic findings include multifocal osteolytic lesions, periosteal elevation of the long bones, heterotopic ossification of the proximal femurs, and widening of the anterior rib ends. Bone biopsies demonstrate sterile purulent osteomyelitis, fibrosis, and sclerosis. To date, four different *IL1RN* mutations have been identified, three of which are truncating point mutations that drastically reduce IL-1Ra messenger RNA and protein levels. The fourth is a 175-kilobase genomic deletion in chromosome 2q that subsumes *IL1RN* and five other genes in the IL-1 family. In DIRA, the lack of IL-1Ra leads to unopposed IL-1β and IL-1α signaling, whereas in the cryopyrinopathies, *NLRP3* mutations lead to inflammasome activation and increased IL-1β production. DIRA patients respond dramatically to anakinra, the recombinant form of the protein they lack.

Syndrome of Pyogenic Arthritis with Pyoderma Gangrenosum and Acne

The syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA) is a rare, dominantly inherited autoinflammatory disease characterized by intermittent episodes of sterile pyogenic arthritis, pyoderma gangrenosum, and severe cystic acne. It is caused by mutations in proline-serine-threonine phosphatase–interacting protein 1 (PSTPIP1), also known as CD2BP1. PSTPIP1 is a cytoskeletal protein that interacts with certain other proteins involved in the immune response, including CD2; the

Wiskott-Aldrich syndrome protein (WASP); a phosphatase denoted PTP-PEST; and pyrin, the FMF protein. PAPA mutations abrogate the binding of PSTPIP1 to PTP-PEST, leading to hyperphosphorylation of PSTPIP1 and increased binding to pyrin. Both in patients and in cell lines, this finding is associated with markedly increased IL-1β production. Early in life, PAPA tends to present with monoarticular or pauciarticular pyogenic arthritis, sometimes induced by trauma. In the absence of treatment, arthritis may progress to severe joint damage and ankylosis. As patients reach puberty, skin manifestations begin to predominate, including disfiguring cystic acne. Pathergy may also develop, and extensive pyoderma gangrenosum may require opiates for pain control. The diagnosis of PAPA syndrome is made by documenting *PSTPIP1* mutations in the appropriate clinical setting. High doses of corticosteroids have been used in PAPA, with varying success, and patients with arthritis sometimes require aspiration, intra-articular corticosteroids, or open drainage. Newer investigational approaches for PAPA syndrome focus on the use of targeted cytokine inhibitors. Anecdotal evidence supports the use of anakinra for the arthritis and infliximab for the pyoderma gangrenosum of PAPA.

Granulomatous Inflammatory Arthritis, Dermatitis, and Uveitis (Blau's Syndrome)

Blau's syndrome is a rare, dominantly inherited illness characterized by the following features: early-onset granulomatous synovitis often complicated by cyst formation and camptodactyly (flexion contractures of the fingers and toes); granulomatous anterior and posterior uveitis, sometimes causing retinal detachment, glaucoma, cataracts, and blindness; and an intermittent papular rash with noncaseating granulomas. Lung or other visceral involvement is generally not present. However, visceral involvement of the liver and spleen is observed in early-onset sarcoidosis (Chapter 95), which is phenotypically quite similar to Blau's syndrome. Both Blau's syndrome and some cases of early-onset sarcoidosis are caused by mutations in *NOD2/CARD15.* Distinct variants of *NOD2/CARD15* have been associated with susceptibility to Crohn's disease, which manifests as granulomatous inflammation of the gastrointestinal tract (Chapter 143). The protein encoded by this gene is thought to be an intracellular sensor of bacterial products. Crohn's disease–associated mutations in the ligand-binding, leucine-rich repeat region of the protein may require bacterial contact in the gastrointestinal tract to cause inflammation, whereas Blau's syndrome mutations in the nucleotide binding domain may lead to constitutive extraintestinal inflammation. Topical and systemic corticosteroids are currently the mainstay of treatment of Blau's syndrome.

270 OSTEOARTHRITIS

NANCY E. LANE AND THOMAS J. SCHNITZER

DEFINITION

Osteoarthritis (OA) is a disorder of diarthrodial joints that is characterized clinically by pain and functional limitations, radiographically by osteophytes and joint space narrowing, and histopathologically by alterations in cartilage and subchondral bone integrity. OA is the most common of all joint diseases, and its importance derives from its economic impact, in terms of both productivity (single greatest cause of days lost from work) and cost of treatment (chronic use of analgesics and anti-inflammatory drugs). Although the etiology of OA is still not clearly understood, it has been shown to be a family of disorders with cartilage as a target organ in which biomechanical factors play a central role and risk factors such as age, weight, and occupation are also of major importance. Because there is currently no treatment to prevent or ameliorate the basic disease process, medical treatment is aimed primarily at relieving pain and improving joint function, with orthopedic intervention largely reserved for those situations that cannot be controlled with more conservative therapy.

EPIDEMIOLOGY

OA is by far the most common joint disorder, one of the most common chronic diseases in elderly people, and a leading cause of disability. Because OA can be defined both radiographically and clinically, with little correlation between the two, the prevalence of this condition has been variously estimated in epidemiologic studies. Using radiographic criteria, the prevalence of the joint findings of OA steadily increases, from less than 2% in women younger than 45 years of age, to 30% in those aged 45 to 64 years, and to 68% in those older than 65 years of age. Prevalence in men is slightly higher in the younger age groups (<45 years of age), whereas women are affected more commonly at ages older than 55 years, except for disease of the hip.

The pattern of joint involvement in OA is strikingly affected by age, gender, previous joint injury, and occupational history. Before age 55 years, there is little difference in joint pattern between men and women. In older men, hip OA is more common, whereas older women tend to have more involvement of the proximal interphalangeal (PIP) joints and the base of the thumb (first carpometacarpal [CMC] joint). Joints subjected to repeated trauma or overuse demonstrate a higher prevalence of OA. Cotton and mill workers have increased OA of the hand and involved fingers; miners and warehouse workers who bend, squat, and lift heavy loads frequently demonstrate increased knee and spine involvement; and pneumatic drill workers experience increased elbow and wrist disease.

Racial and genetic factors are also important in OA prevalence and pattern. Chinese, Jamaican blacks, South African blacks, and Asian Indians have a lower incidence of OA of the hip than whites, whereas Japanese have an increased incidence, apparently related to the more frequent occurrence of congenital hip dysplasia. Black women have a higher prevalence of knee OA than white women but a lower prevalence of involvement of the distal interphalangeal (DIP) joints of the hand (Heberden's nodes). Involvement of the DIP joints of the hands is particularly common in women and is often found to have a familial pattern of inheritance; female relatives of a proband have similar joint findings with a two- to five-fold increased prevalence.

Large cohort studies of subjects with radiographic evidence of OA report a significant genetic contribution to the disorder. A heritable component of OA is reported from family and twin studies to be between 60 and 65%, and the genetic predisposition appears to differ by OA site. Single nucleotide polymorphisms in genes that code for structural proteins in the extracellular matrix (e.g., collagen type II), hormones and growth factors that influence cartilage and bone metabolism (vitamin D receptor, estrogen receptor a, insulin-like growth factor-1, and frizzled-related protein), and cell signaling proteins involved with joint development increase the risk of OA in weight-bearing joints.

Modifiable risk factors for OA have also been identified in recent studies. Increased weight is the most significant independent predictor of both incidence and progression of OA in weight-bearing joints, and weight reduction has been shown to reduce the development and progression of knee OA. Certain types of high-impact repetitive activities are associated with an increased risk for development of OA in the stressed joint (see earlier discussion), whereas other activities are not. In particular, there appears to be an increased risk of hip and knee OA in elite, highly competitive runners, but no increased prevalence in participants in low-impact activities such as marathon running. However, this difference may be the result of a self-selection process in which those individuals who experience knee pain are unable to continue the activity. Smoking and osteoporosis have both been shown to be negatively associated with OA, but the explanations for these associations are unknown.

PATHOBIOLOGY

Pathology

The hallmarks of OA on gross or arthroscopic examination are focal ulcerated areas of cartilage exposing underlying eburnated (ivory-appearing) bone that

occur at the load-bearing areas of the joint surface, as well as juxta-articular osteophytes that grow at the joint margins. These states represent the end stage of the continuum of OA as a pathologic process. At its earliest stage, it manifests as softening of the cartilage surface, progressing to fibrillation of the surface layers, loss of cartilage thickness, development of clefts into the depth of cartilage, and eventual loss of cartilage integrity with release of shards of cartilage. Bone participates in this process as well, with reactive changes (bony subchondral sclerosis) underlying the areas of cartilage loss, development of subchondral bone cysts that may communicate with the joint space and expand into geodes, and marginal osteophytes (new cartilage and bone growth) at non–weight-bearing areas. Magnetic resonance imaging (MRI) has identified additional alterations in bone associated with OA progression accompanied by pain.

The earliest histologic changes in OA reveal loss of extracellular cartilage matrix, loss of chondrocytes in the surface layers of articular cartilage, and reactive changes in the deeper chondrocytes manifested by cellular division and "cloning" in an apparent attempt at repair. Later, there is progressive loss of chondrocytes at all levels, with marked thinning of the cartilage matrix and, in some instances, development of fibrocartilage in place of lost hyaline articular cartilage. The surrounding synovium is largely unaffected, although in later disease, cartilage fragments may incite focal inflammatory lesions without the progressive and destructive pannus seen in typical inflammatory arthropathies.

Pathogenesis

Articular cartilage serves two major functions: (1) to permit nearly frictionless joint motion; and (2) to act as a "shock absorber" and transmit loads across joint surfaces to the surrounding tissues. The requisite properties of elasticity and high tensile strength are imparted by proteoglycans and collagen of the extracellular matrix, which comprise more than 90% of the cartilage macromolecules. The proteoglycan elements of the matrix are actively metabolized and turned over, with a half-life of weeks. The highly negatively charged sulfated glycosaminoglycan components of the proteoglycans impart the elastic properties to cartilage. The collagen component of cartilage matrix is characterized by a unique structure (type II collagen) that provides the tensile strength and tightly constrains the proteoglycan molecules in a three-dimensional framework. The collagen fibers are covalently linked by other matrix molecules, which are believed to provide the "glue" to hold the matrix intact. Collagen itself is metabolized very slowly (half-life of many years) in the normal state.

In OA, there is an initial phase in which chondrocyte metabolic activity is upregulated (enhanced proteoglycan synthesis), followed by eventual chondrocyte loss (apoptosis). The reason for failure of repair is unclear but may relate to the inability to re-form, once it is disrupted, the three-dimensional architecture of cartilage in mature individuals.

Degradation of collagen and proteoglycans in OA is carried out by proteolytic enzymes (matrix metalloproteinases [MMPs]) that are synthesized by and released from the chondrocytes themselves. A number of cytokines and other mediators of inflammation, including interleukin-1β (IL-1β), tumor necrosis factor-α (TNF-α), IL-6, IL-8, nitric oxide (NO), and prostaglandins, can be produced by the chondrocyte and act within the cartilage to promote a catabolic state by activating MMPs. The subsequent activation of these potent enzymes overwhelms the natural matrix defenses and ultimately results in collagen breakdown and proteoglycan cleavage. Fragments from these molecules are then released into the synovial fluid and enter the circulation, where they provide "markers" of degradation and can be used as a means to detect and measure disease activity.

The factors responsible for activating chondrocytes to release MMPs are currently being elucidated. However, those conditions that cause alteration in biomechanical loading of cartilage are known to lead to OA: joint injury; abnormal joint loading due to neuropathic changes (Charcot's joint); ligamentous damage (anterior cruciate ligament [ACL]) or meniscus injuries; altered joint surface congruity, as in dysplasias or malalignment or joint laxity; and muscle atrophy in elderly people. A number of metabolic conditions are known to predispose to the early onset of OA, including ochronosis with the deposition of homogentisic acid (Chapter 212) and hemochromatosis with the deposition of iron (Chapter 219). Gene defects affecting matrix structures might be expected to lead to OA, but thus far genetic factors have been shown to play a role only in the development of dysplasias with secondary OA. The pathogenetic mechanisms and feedback loops associated with structural damage to the cartilage structure and associated alteration in chondrocyte function are demonstrated in Figure 270-1.

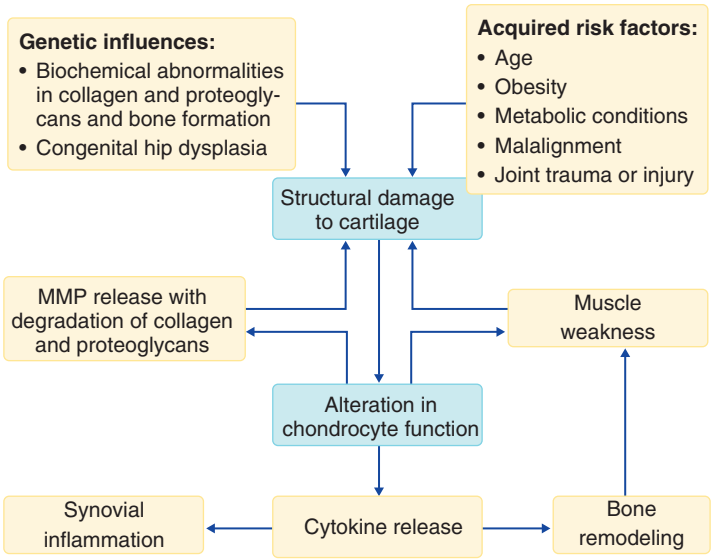

FIGURE 270-1. Summary of the pathophysiology of osteoarthritis with emphases on structural damage to the cartilage and alteration in chondrocyte function. MMP = metalloproteinase.

CLINICAL MANIFESTATIONS

The initial stages of the OA disease process are clinically silent, which explains the high prevalence of radiographic and pathologic signs of OA in clinically asymptomatic patients. Even in later stages of OA, there is a poor correlation between clinical symptoms and alterations in cartilage and bone integrity, defined arthroscopically or by indirect imaging techniques (radiography, MRI). The factors or events that make the OA disease process clinically apparent are unknown but are likely to be heterogeneous in nature and invoke changes within the synovium, bone, and surrounding supporting structures (muscle, ligaments) that produce pain. Pain does not derive from cartilage, a tissue without any innervation.

Pain is the predominant symptom that prompts the diagnosis of OA; often only one joint is involved initially, with others becoming painful subsequently. The pain of OA is most often described as a deep ache, accompanied frequently by joint stiffness after periods of inactivity (on arising in the morning or after sitting). Pain is aggravated by use of the involved joints, may radiate, and may be referred to surrounding structures. In the early stages of the disease, pain is commonly relieved by rest. With more severe disease, pain may be persistent, interfering with normal function and preventing sleep, even with medical management. Even in severe disease, however, systemic manifestations such as fever, weight loss, anemia, and elevated erythrocyte sedimentation rate (ESR) are not present.

The joints most commonly involved in OA are the metatarsophalangeal (MTP) joint of the great toe (hallux valgus or "bunion"); the PIP and DIP joints of the fingers, the CMC joint of the thumb, hips, knees, and the lumbar and cervical spine (Fig. 270-2). Other joints, even major weight-bearing joints such as the ankle, are typically spared unless involved in secondary forms of OA (Table 270-1). On physical examination, the joints may demonstrate tenderness, crepitus, and a limited range of motion. Joint swelling may be caused by an accompanying synovial effusion or by bony enlargement and the presence of osteophytes. Joint instability is seen only in severe disease or after internal derangement of the knee with disruption of one or more of the major supporting structures (e.g., ACL, medial collateral ligament). Patients with far-advanced disease exhibit gross deformity with subluxation of the involved joints. Although OA is thought to be a uniformly progressive disease that invariably leads to joint replacement, this is not the case. The disease appears to stabilize in many patients, with no worsening of signs or symptoms, and there may be actual improvement in some patients.

Specific Joint Involvement

Hand

Firm, slowly progressive bony enlargements of the DIP joints are called *Heberden's nodes* and represent marginal osteophytic spurs (Fig. 270-3). Occasionally, the onset of symptoms in the hand is acute, with sudden

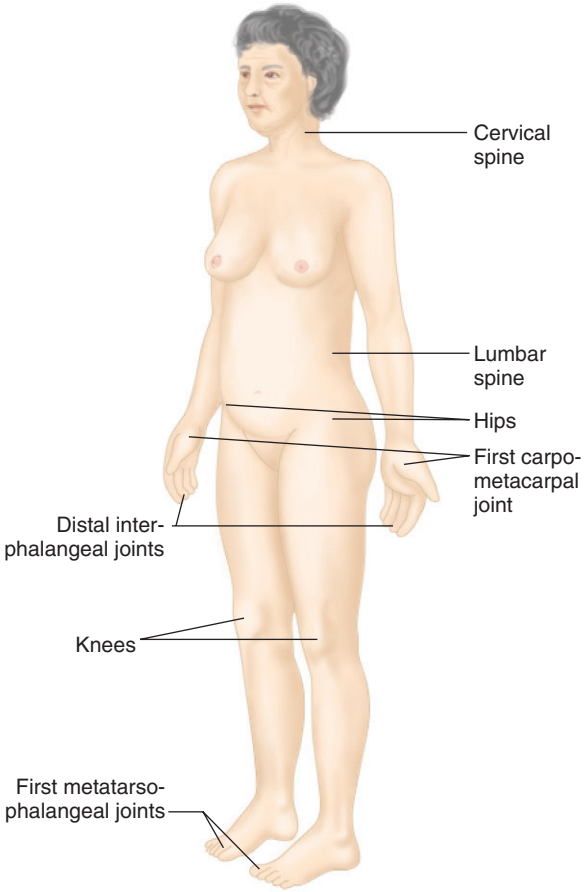

FIGURE 270-2. Joints commonly affected by osteoarthritis.

TABLE 270-1 ETIOLOGIC CLASSIFICATION OF OSTEOARTHRITIS

IDIOPATHIC (PRIMARY)
Localized
Hands: Heberden's nodes, erosive interphalangeal arthropathy
Feet: hallux valgus, hammer toes; talonavicular
Knees: medial, lateral, patellofemoral compartments
Hips: sites of cartilage loss—eccentric (superior), concentric (axial, medial), diffuse, and femoral osteophytes
Spine: zygapophyseal joints, intervertebral discs (spondylosis); ligaments (e.g., disseminated idiopathic skeletal hyperostosis) with osteophytes as most common radiographic findings
Other single sites: shoulder, temporomandibular joints, carpometacarpal joints
Generalized—includes three or more areas listed above
Mineral deposition diseases
Calcium pyrophosphate deposition disease
Hydroxyapatite arthropathy
Destructive disease (e.g., Milwaukee shoulder)
SECONDARY
Post-traumatic
Congenital or developmental
Legg-Calvé-Perthes hip dislocation
Epiphyseal dysplasias
Articular cartilage disorders associated with a gene deficiency (e.g., association with type II procollagen gene mutation)
Disturbed local tissue structure by primary disease (e.g., ischemic necrosis, tophaceous gout, hyperparathyroid cysts, Paget's disease, rheumatoid arthritis, osteopetrosis, osteochondritis)
Miscellaneous additional diseases
Endocrine: diabetes mellitus, acromegaly, hypothyroidism
Metabolic: hemochromatosis, ochronosis, Gaucher's disease
Neuropathic arthropathies
Miscellaneous: frostbite, Kashin-Beck disease, caisson disease
Mechanical: obesity, unequal lower extremity length; valgus/varus deformities, ligamentous laxity (including associations with type I procollagen gene mutations of Ehlers-Danlos syndrome)

Compiled in part by Osteoarthritis Diagnostic Criteria Committee, American Rheumatism Association, 1983.

FIGURE 270-3. Typical hand deformities in osteoarthritis. Heberden's nodes are seen on the distal interphalangeal joints, and Bouchard's nodes are at the proximal interphalangeal joints. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003).

redness and tenderness in the involved joint. These changes can lead to deformity, with lateral and flexor deviation at these joints. A related disorder, erosive OA, is associated with repetitive episodes of acute symptoms and is differentiated by the additional finding of erosive changes on radiographs of the involved joints and a tendency to bony ankylosis. A genetic basis for Heberden's nodes appears to exist, the condition demonstrating a distinct female-dominant familial tendency (women are affected 10 times more commonly than men).

Changes similar to those in the DIP joints occur in the PIP joints and are termed *Bouchard's nodes* (see Fig. 270-3). The only other hand joint to be commonly involved is the CMC joint of the thumb. Patients often complain of pain on use of the thumb, as in wringing out clothes (washerwoman's hands) or grasping objects such as screwdrivers and doorknobs. The condition leads to a squared appearance of the base of the hand.

Knee

Idiopathic knee OA is a leading cause of painful ambulation and is more common in women than in men. The medial compartment of the femorotibial joint space is most commonly affected, resulting in varus deformity (bow legs). Lateral compartment disease may lead to valgus deformity (knock-knee). Patellofemoral disease is also common and may represent a substantial portion of knee pathology in patients presenting with knee pain. It is important to exclude other causes of knee pain, such as internal derangements of the knee (e.g., meniscal tears, ligament tears) that may lead to secondary knee OA; soft tissue sprains; bursal inflammation; and Baker's cysts (which may coexist with knee OA). In young women, the possibility of chondromalacia patellae should always be considered. Its cause is not known; it is almost always self-limited and is not thought to lead to OA. In idiopathic knee OA, physical examination of the involved joint often elicits crepitation of the tibiofemoral joint, pain, and decreased range of motion. Effusions are not infrequently present but are often small and may be difficult to appreciate.

Hip

Although congenital (Legg-Calvé-Perthes disease) and developmental (slipped femoral capital epiphysis) abnormalities have long been implicated in secondary hip OA, most cases of primary hip OA are now believed to be the consequence of mild dysplasia of the femoral head or acetabulum resulting in incongruity of the articulating surfaces. With use of the joint, there is progressive cartilage degeneration and secondary bony productive changes typical of OA. Pain is usually referred to the groin, with anterior thigh and knee symptoms occasionally predominant. Many patients presenting with pain in their "hip" may have referred pain from degenerative disc disease or OA of the lumbar spine. The earliest physical finding in hip OA is loss of internal rotation; with progressive disease, range of motion is limited further in all directions, the affected leg shortens, and significant functional limitation occurs, often necessitating surgery.

Foot

The first MTP joint is the primary foot joint involved in OA, with associated bony swelling and deformity (bunion). Significantly more common in women than men, these changes have been attributed to abnormal stresses imposed on the joint by footwear. In extreme cases, the joint space may be

destroyed, leading to a condition known as *hallux rigidus*, which may interfere with normal ambulation and necessitate surgical correction.

Spine

Technically, OA of the spine relates strictly to changes in synovium-lined joints (apophyseal and uncovertebral joints) that can lead to localized pain as well as irritation of adjacent nerve roots with referred pain in the form of radiculopathy. Nerve root compression resulting from apophyseal joint subluxation, prolapse of an intervertebral disc, or osteophytic spurring may occur, and the patient may present with muscle weakness, hyporeflexia, and paresthesia or hypesthesia. In the cervical region, spinal involvement can lead to cord impingement with long tract signs, or it may affect the vertebral artery, producing insufficiency of the posterior circulation with associated symptoms (Chapter 414). OA of the spine should be differentiated from diffuse skeletal hyperostosis, in which there is marked calcification of the paraspinous ligaments and sparing of the arthrodial spinal joints.

Primary Generalized Osteoarthritis

The pattern of involvement of three or more joints or joint groups with OA has been given the name *primary generalized osteoarthritis;* it is seen most commonly in older women. Typically, the DIP and PIP joints of the hand, the knees, and the spine are involved. Whether this represents a distinct subset of OA is not known but has been suggested.

DIAGNOSIS

Laboratory Findings

OA involves a pathologic process that appears largely limited to the joint and associated tissues, with no evidence of systemic involvement. Typically, the ESR is normal, and there is no elevation of acute phase reactants. The hemoglobin and leukocyte counts remain within normal limits. The synovial fluid itself demonstrates no evidence of an inflammatory reaction, with few leukocytes (typically fewer than 2000/mm^3) and good viscosity. Occasionally, fragments of cartilage and crystals of calcium hydroxyapatite or calcium pyrophosphate dihydrate are seen in the synovial fluid. Rheumatoid factor is absent in most patients with OA, but a significant number of older individuals exhibit low-titer elevations that are not diagnostic of rheumatoid arthritis but are a common accompaniment of aging.

Cartilage matrix components unique to the joints have been identified, and sensitive assays have been developed to detect these "biomarkers" in synovial fluid, serum, and urine. Further clinical correlations need to be performed to determine the relationship of these biomarkers to the disease process, activity, and state, and their possible use for earlier diagnosis and management of OA.

Radiology Findings

Pathognomonic findings of OA on plain radiography include the presence of osteophytes at the margins of involved joints, associated joint space narrowing representing areas of cartilage thinning or loss, and evidence of bony reaction marked by subchondral sclerosis and bone cysts in more progressive disease. Some patients may lack one or more of these findings.

Radiography has been shown to be insensitive to the pathologic processes occurring in the cartilage. Many patients exhibit normal radiographs with destructive cartilage changes documented by arthroscopy. However, performing a weight-bearing knee radiograph with the knee flexed to 20 degrees allows a more reliable assessment of joint space narrowing, and repeat radiographs in this view can be used to assess changes in joint space narrowing over time.

Imaging

Other techniques have been developed with greater potential sensitivity to detect cartilage and bone changes. In particular, MRI has the advantage of demonstrating cartilage as a positive image and has been used widely to document major cartilage injuries such as meniscal tears and to provide a quantitative estimate of cartilage volume. MRI has identified distinctive changes in bone, often adjacent to cartilage lesions, which are associated with pain, altered mechanical loading, and enhanced disease progression. Further refinement of this technology will be important in the future for assessing disease progression and the efficacy of therapeutic interventions.

Other technologies being developed to evaluate the OA joint include scintigraphy and ultrasonography.

TREATMENT Rx

People with OA seek pain relief and improved physical function. Because at this time there is no known therapy in humans that affects the basic disease process (i.e., to inhibit cartilage degradation or enhance synthesis), medical therapy has focused on providing symptomatic relief. Largely because of ease of administration and acceptance by patients, an unwarranted reliance has been placed on pharmacologic intervention, particularly nonsteroidal anti-inflammatory drugs (NSAIDs), as initial therapy, at the expense of physical measures that have less morbidity and may provide longer-term benefit. The American College of Rheumatology and the American Academy of Orthopedic Surgeons have formulated evidence-based guidelines for progressive, stepwise treatment of patients with knee and hip OA that incorporate this approach.

Physical Measures

Although often overlooked, physical therapy and exercise programs provide important benefit and should be prescribed as baseline therapy for all patients with OA. Muscle atrophy commonly accompanies OA. Because muscles serve to reduce load on cartilage, maintaining muscle function is crucial for cartilage integrity and pain reduction. Both muscle strength and range of motion can be improved with appropriate physical therapy. Isometric exercises are preferred to isotonic ones because they place less stress on the involved joint.

Heat and cold are both used, with varying effectiveness, to provide symptomatic relief to patients with OA and as an important adjunct to physical therapy regimens. Transcutaneous nerve stimulation, particularly to relieve back pain, and acupuncture are effective in some patients and sometimes may provide an alternative to pharmacologic intervention.

Periods of rest throughout the day may be an important adjunct in the routine of patients with OA. Reduction in joint loading, either by rest or by appropriate use of a cane, often permits increased periods of activity with reduced pain. Use of cushioned shoes (commercial running or walking shoes) also may ameliorate lower extremity joint symptoms. Back pain may be reduced by muscle-strengthening exercises and by a well-fitted brace. However, the fitted brace should be used only intermittently to prevent abdominal and paraspinal muscle atrophy.

Medical Therapy

Symptomatic relief of joint pain in patients with OA may be achieved with simple analgesic agents such as acetaminophen (Table 270-2). Particularly in elderly patients with decreased renal reserve and an increased incidence of upper gastrointestinal bleeding, acetaminophen and other simple analgesics should be the drugs of initial choice. If inflammation is present (erosive OA) or symptoms are not well controlled with simple analgesics, NSAIDs are generally more effective.■

A second class of NSAIDs, the cyclooxygenase-2 (COX2) inhibitors, inhibit inflammatory-mediated production of prostaglandins (COX2 mediated) but permit constitutive prostaglandin production (COX1 mediated) (Chapter 36). Although they produce less gastrointestinal toxicity than traditional nonselective NSAIDs, they have been associated with an increase in cardiovascular risk, a property that may be shared with nonselective NSAIDs as well.■ Therefore, only one selective COX2 inhibitor, celecoxib, is currently marketed in the United States. COX2 inhibitors may be preferred to nonselective NSAIDs, particularly in patients at high risk for gastrointestinal side effects, but each patient should be carefully informed of the cardiovascular risks associated with this class of medications.

Oral glucosamine and chondroitin are referred to as *nutriceuticals*; their use has been shown in some randomized clinical trials to reduce pain in subjects with knee OA but more recent, larger trials have been negative.■■ The time to onset of pain relief and the magnitude of this response have not been well characterized. Studies are still underway to determine whether these nutriceuticals alter the structural deterioration of the knee joint in OA.

Controlled studies of intra-articular steroid injections have demonstrated safety and benefit when injections were given every 3 months for up to 2 years at both the knee and the hip.■ Intra-articular injections of steroids should not be repeated more than three or four times per year in any given joint because of the possibility of potentiating cartilage breakdown. Systemic use of steroids has no place in the treatment of OA. Intra-articular hyaluronate can improve joint symptoms and appears to be effective in subgroups of subjects with knee OA. Topical treatment with capsaicin, a substance P inhibitor, has been shown to relieve localized pain in some patients with OA. The development of compounds that can stimulate cartilage synthesis or prevent degradation is actively being pursued as disease modifying agents, whereas a number of novel agents are currently in development for the treatment of pain from OA, including inhibitors of nerve growth factors.

Surgical Therapy

Joint replacement surgery has been the most important advance in the treatment of OA in the past half-century (Chapter 285). Patients for whom optimal medical management has failed, who continue to have pain that interferes with sleep or activity or have significant limitations of joint function,

TABLE 270-2 RECOMMENDATIONS FOR PHARMACOLOGIC MANAGEMENT OF OSTEOARTHRITIS OF THE HIP AND KNEE*

ORAL
Acetaminophen
Nonselective NSAID plus misoprostol or a proton pump inhibitor†
COX2-selective inhibitor
Nonacetylated salicylate
Other pure analgesics
Glucosamine and/or chondroitin sulfate
Tramadol
Opioids
INTRA-ARTICULAR
Glucocorticoids
Hyaluronan
TOPICAL
Capsaicin
Methylsalicylate

*The choice of pharmacologic therapy should be individualized for each patient.
†Misoprostol and proton pump inhibitors may be used in patients who are at increased risk for upper gastrointestinal adverse events.
COX2 = cyclooxygenase-2; NSAID = nonsteroidal anti-inflammatory drug.

are candidates for an operation. Those individuals with altered limb alignment and early OA of a hip or knee may benefit from osteotomy. Most patients have more advanced disease and require total joint replacement. Ideal candidates for total joint arthroplasty exhibit well-maintained muscle strength and should be older than 60 years of age. Younger patients are discouraged from undergoing joint replacement because of the small but real incidence of long-term failure of joint implants, mainly due to loosening. Revision arthroplasty is possible but has a higher failure rate and can be avoided by delaying the initial arthroplasty as long as possible and putting less load on the replaced joint.

Arthroscopic surgery is useful for removing loose bodies and repairing intrinsic defects of the knee, and in shoulder (rotator cuff) and ankle disease. In patients with knee OA without such findings, arthroscopy has not been shown to provide superior outcomes compared with medical management. Total shoulder arthroplasty appears to be preferred over alternative techniques in terms of shoulder function. Abrasion arthroplasty (chondroplasty) has been widely used in patients with knee OA, but no data exist to demonstrate its efficacy, and it cannot be recommended currently.

FUTURE DIRECTIONS

Novel agents to treat the pain of OA are actively being evaluated, including those acting at the level of the peripheral nervous system, such as inhibitors of nerve growth factor, and a number of centrally acting drugs thought to act at a supraspinal level to alter pain pathways and pain perception, such as serotonin and noradrenaline reuptake inhibitors. Potential disease-modifying agents under investigation include systemic agents inhibiting cartilage degradation (calcitonin, vitamin D, inhibitors of MMPs, inducible nitric oxide synthases, cathepsin K, IL-1β, and TNF-α), local intra-articular anticatabolic agents (lubricin, tissue inhibitor of metalloproteinase-3 inhibitors of IL-1β, TNF-α, and MMP-13), and potential anabolic agents administered through intra-articular injections (fibroblast growth factor-18, osteogenic protein-1, and mesenchymal stem cells). In addition, current research involves biosynthetic cartilage replacement and improved materials for total joint replacement. Therefore, the future holds promise not only to slow the joint degeneration in OA but possibly also to reverse it.

BURSITIS, TENDINITIS, AND OTHER PERIARTICULAR DISORDERS AND SPORTS MEDICINE

JOSEPH J. BIUNDO

DEFINITION

An entire array of painful and sometimes disabling musculoskeletal syndromes exist that are not articular in origin but arise from tendons and bursae. These conditions are referred to by various names, in addition to *tendinitis* and *bursitis*, including the terms *nonarticular rheumatism, soft tissue diseases, regional rheumatic pain syndromes, overuse syndromes*, and *repetitive use syndromes* (Tables 271-1 and 271-2). These entities are often ignored, misdiagnosed as arthritis, or attributed to the aging process; awareness of the existence of these conditions and knowledge of basic musculoskeletal anatomy (Figs. 271-1 and 271-2) are the fundamental requirements for diagnosis. This knowledge is coupled with brief but specific physical diagnosis techniques. The accurate diagnosis and successful treatment of these conditions is gratifying to the clinician because many people can be relieved of their chronic painful syndromes.

Various terms regarding tendon injuries are used and may be confusing. The main term used is *tendinitis. Tendinosis* has been proposed as the correct terminology because there are degenerative changes in the tendon but very few inflammatory cells. In addition, fatty mucoid degeneration and hyaline features occur in these tendon syndromes. These tendon conditions are described by some as a *tendinopathy* because use of this term avoids the need

TABLE 271-1 MUSCULOSKELETAL CONDITIONS BY ETIOLOGY

TENDINITIS	TENDON RUPTURE	BURSITIS
Rotator cuff	Rotator cuff	Subacromial
Bicipital	Bicipital	Olecranon
Volar flexor	Quadriceps	Trochanteric
de Quervain's	Patellar	Ischial
Patellar	Posterior tibialis	Iliopsoas
Posterior tibialis	Achilles	Pes anserine
Achilles		Prepatellar
Epicondylitis		Retrocalcaneal

to decide whether or not inflammation is a factor. Also, tendons may *rupture* or *tear,* partially or completely. The term *tendon insufficiency* is used when the tendon is stretched or is partially or even completely torn. The terms *tenosynovitis* and *peritendinitis* refer to an inflammatory response of the tenosynovium or peritendon, respectively.

Tendon syndromes are basically "overuse" injuries. Tendinitis may occur when the tendon repeatedly bears more load than it can withstand. This may result from excessively high loads across normal tendons or from normal loads across degenerated tendons. In addition to load and repetitiveness, tendon changes resulting from immobility and from aging may play a role, as may the use of certain medications such as floxins and corticosteroids.

Bursae are closed sacs that are lined by a synovial membrane and serve as a cushion. They are located between tendon and bone, tendon and tendon, or bone and skin and allow smooth gliding between these structures. A bursa, which normally has a small amount of bursal fluid, can become inflamed from trauma or overuse, or become infected, producing a bursitis. When this occurs, some swelling and pain of the bursa may be present.

TABLE 271-2 TENDINITIS AND BURSITIS CONDITIONS BY REGION

Posterior tibial tendon tear
Retrocalcaneal bursitis
Plantar fasciitis

EPIDEMIOLOGY

The incidence of the nonarticular syndromes of bursitis and tendinitis is high. They are more common than both rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). For example, the incidence of shoulder pain, largely due to rotator cuff tendinitis and rotator cuff tear, was about 20% in a population older than 70 years of age.

DIAGNOSIS

A precise history is needed to identify the conditions present, and more than one syndrome can occur concomitantly. A working knowledge of regional anatomy and an approach that uses a regional differential diagnosis will help in obtaining a specific diagnosis. A complete neuromusculoskeletal examination should be performed, emphasizing careful palpation, passive range of motion (ROM), and active ROM alone or sometimes with resistance. Systemic and infectious causes must be considered. Diagnostic ultrasonography and magnetic resonance imaging (MRI) are sometimes useful in confirming a diagnosis.

TREATMENT Rx

Treatment of tendinitis and bursitis includes use of nonsteroidal anti-inflammatory drugs (NSAIDs), relative rest of the injured site, stretching and strengthening exercises, friction massage, use of modalities (heat, ice, and ultrasound), splinting, corticosteroid injections, and surgery. A comprehensive management of these regional syndromes should be undertaken, rather than relying on oral medications alone. The causative aspects should be evaluated, and activity modification should be advised as needed. The goals of therapeutic exercise are to increase flexibility by stretching, increase muscle strength by resistive exercises, and improve muscle endurance by some repetitive regimen. Caution should be exerted in performing corticosteroid injections; the injections should not be placed into the tendon proper, but rather into the peritendinous sheath. The injection should be placed beneath the subcutaneous tissue, to avoid skin and subcutaneous fat atrophy, and injections should not be given too frequently, to avoid the possibility of weakening and rupture of the tendon. The accuracy of injections may be improved with concomitant use of diagnostic ultrasonography to assist with determining the correct needle site. Also, fluoroscopically guided injections can be used to increase accuracy.

SPORTS MEDICINE INJURIES

An overlap exists between commonly occurring conditions of tendinitis and bursitis and those attributed to sports injuries (Table 271-3). For example, lateral epicondylitis, frequently referred to as *tennis elbow*, occurs more commonly secondary to non–sports-related causes. In contradistinction, iliotibial band syndrome is usually related to sports. Other entities that occur more often in relation to sports include ligamentous knee injuries, patellar

Turf toe
Stress fracture

tendinitis, ankle sprains, turf toe, and acromioclavicular separations. It is important in both categories to know the anatomy and biomechanics of the condition, so as to better diagnose and treat the problem. Sports-related injuries are helped with the classic RICE treatment, consisting of *r*est, *i*ce, *c*ompression, and *e*levation. Often, anti-inflammatory and analgesic drugs are used. However, there is less use of corticosteroid injections in athletic injuries than in routine cases of tendinitis and bursitis.

DISORDERS OF THE SHOULDER REGION

Shoulder pain is one of the most common musculoskeletal complaints in people older than 40 years of age. In younger people, athletic injuries are a frequent source of such pain.

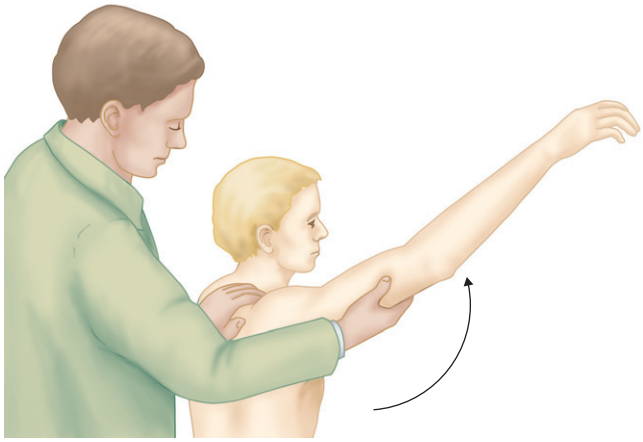

FIGURE 271-3. The impingement sign is elicited by forced forward elevation of the arm. Pain results as the greater tuberosity impinges on the acromion. The examiner's hand prevents scapular rotation. This maneuver may be positive in other periarticular disorders. (From Neer CS II. Impingement lesions. *Clin Orthop*. 1983;173:70-77.)

Rotator cuff tendinitis, or impingement syndrome, is the most common cause of shoulder pain. Tendinitis (and not bursitis) is the primary cause of pain, but secondary involvement of the subacromial bursa occurs in some cases. The condition may be acute or chronic and may or may not be associated with calcific deposits within the tendon. The key finding is pain in the rotator cuff on active abduction, especially between 60 and 120 degrees, and sometimes when lowering the arm. In more severe cases, pain may begin on initial abduction and continue throughout the ROM. Typically, chronic rotator cuff tendinitis manifests as an ache in the shoulder, usually over the lateral deltoid, and occurs with various movements, especially abduction and internal rotation. Other symptoms include difficulty in dressing oneself and night pain due to difficulty in positioning the shoulders. The physical findings include pain and loss of active abduction and internal rotation, less pain on passive motion, tenderness of the area of supraspinatus insertion, and a positive impingement sign (Fig. 271-3, Neer's sign), which is pain occurring in forced flexion. The causes of rotator cuff tendinitis are multifactorial, but relative overuse, especially from overhead activity causing impingement of the rotator cuff, is commonly implicated. Treatment consists of rest and modalities such as hot packs, ultrasound, or cold applications, with specific ROM exercises as soon as tolerated. NSAIDs are often beneficial, but the most frequent treatment is injection of a depot corticosteroid into the subacromial bursa, the floor of which is contiguous with the rotator cuff. Disodium EDTA administered by phonophoresis and mesotherapy to patients with calcific tendinitis of the shoulder has been found to be effective in pain reduction, improvement in shoulder function, and disappearance of calcifications.

In a rotator cuff tear, an acute tear after trauma is usually easily recognized. The trauma may be superimposed on an already degenerative and possibly

even partially torn cuff. In cases of trauma resulting in a ruptured cuff, fracture of the humeral head and dislocation of the joint should also be considered. However, most patients with a tear recall no trauma. In these cases, degeneration of the rotator cuff occurs gradually, resulting ultimately in a complete tear. Rotator cuff tears are classified as small (≤1 cm), medium (1 to 3 cm), large (3 to 5 cm), or massive (>5 cm). Shoulder pain, weakness on abduction, and loss of motion occur in varying degrees, ranging from severe pain and mild weakness to no pain and marked weakness. A positive drop-arm sign with inability to maintain actively 90 degrees of passive shoulder abduction may be present in patients with large or massive tears. Small complete tears and incomplete tears of the rotator cuff are treated conservatively with rest, physical therapy, and NSAIDs. Although its role has not yet been established by careful studies, a subacromial injection of a corticosteroid may relieve pain. Surgical repair is indicated in younger patients.

Bicipital tendinitis is manifested by pain, most often in the anterior region of the shoulder and occasionally more diffusely. The pain may be acute but is usually chronic and is related to impingement of the biceps tendon by the acromion. Tenosynovitis of the long head of the biceps is present, and the tendon may be frayed and fibrotic. Palpation over the bicipital groove reveals localized tenderness. The patient's response should be compared with the response to palpation of the opposite side (i.e., tendon with normal tenderness). Pain may be reproduced over the bicipital tendon in some cases by supination of the forearm against resistance (Yergason's sign), shoulder flexion against resistance (Speed's test), or extension of the shoulder. Treatment of bicipital tendinitis consists of rest, hot packs, ultrasound, and, as pain subsides, passive and then active ROM exercises. NSAIDs may be helpful, and occasionally a small amount of corticosteroid carefully injected into the tendon sheath may be of benefit. Rupture of the biceps tendon can occur at the superior edge of the bicipital groove, producing a characteristic bulbous enlargement of the lateral half of the muscle belly.

Adhesive capsulitis (frozen shoulder) is associated with generalized pain and tenderness and severe loss of active and passive motion in all planes. It is rare before 40 years of age but may occur secondary to any type of shoulder problem. However, not every stiff and painful shoulder is necessarily adhesive capsulitis. Inflammatory arthritis and diabetes can cause adhesive capsulitis. Additional factors such as immobility, low pain threshold, depression, and neglect or improper initial treatment also favor the development of a frozen shoulder. Many cases, however, are idiopathic. The joint capsule adheres to the anatomic neck, and the axillary fold binds to itself, causing restricted motion. The capsule becomes thickened and contracted. Arthrography can help confirm this diagnosis by showing a decrease in volume of the shoulder joint capsule. Oral steroids improve pain and range of motion in the short term, but a frozen shoulder is probably best treated with a comprehensive program involving NSAIDs and corticosteroid injections into the glenohumeral joint and the subacromial bursa. Physical therapy consists of ice packs, ultrasound, transcutaneous electrical nerve stimulation, and gentle ROM exercises, beginning with pendulum exercises and wall climbing with the fingers and progressing to active ROM and strengthening exercises.

DISORDERS OF THE ELBOW REGION

Olecranon bursitis occurs frequently and involves the subcutaneous olecranon bursa, either secondary to trauma or as an idiopathic condition. The bursa is characteristically swollen and tender on pressure, but pain may be minimal and usually no motion is lost. Aspiration may yield clear or blood-tinged fluid with a low viscosity, or grossly hemorrhagic fluid. Inflammatory olecranon bursitis may be caused by gout, RA, or calcium pyrophosphate deposition disease, and infection can also cause a bursitis. Aspiration alone and protection from trauma are usually sufficient to resolve the condition. A small dose of corticosteroid may be injected into the bursa. With septic olecranon bursitis, localized erythema is the major clue. Heat, pain, and a positive culture are also frequently present.

Lateral epicondylitis, or tennis elbow, is a common condition in those who overuse their arms. Localized tenderness directly over or slightly anterior to the lateral epicondyle is the hallmark of this disorder. Pain may occur during handshakes, while lifting a briefcase, or with other similar activities. Probably fewer than 10% of patients actually acquire lateral epicondylitis through playing tennis. Job and recreational activities, including gardening and athletics, are the usual causes. Pathologically, the condition consists of degeneration of the common extensor tendon, particularly of the extensor carpi radialis brevis tendon. Treatment is aimed at altering activities and preventing overuse of the forearm musculature. Ice packs, heat, and NSAIDs are of some benefit. A forearm brace can also be used. A local corticosteroid injection with a 25-gauge needle over the lateral epicondyle often produces satisfactory initial relief. Isometric strengthening is important as the initial part of a rehabilitation program.

Medial epicondylitis, or golfer's elbow, which mainly involves the flexor carpi radialis, is less common and less disabling than lateral epicondylitis. Local pain and tenderness over the medial epicondyle are present, and resistance to wrist flexion exacerbates the pain.

DISORDERS OF THE WRIST AND HAND

A ganglion is a cystic swelling that arises from a joint or tendon sheath and occurs most commonly over the dorsum of the wrist. It is synovial lined and contains thick, jelly-like fluid. Ganglia apparently develop secondary to trauma or prolonged wrist extension. Usually, the only symptom is swelling, but occasionally a large ganglion produces discomfort on wrist extension.

De Quervain's tenosynovitis may result from repetitive activity that involves pinching with the thumb while moving the wrist. The symptoms are pain, tenderness, and occasionally swelling over the radial styloid. Pathologic findings include inflammation and narrowing of the tendon sheath around the abductor pollicis longus and extensor pollicis brevis. A positive Finkelstein test result is usually seen: pain increases when the thumb is folded across the palm and the fingers are flexed over the thumb as the examiner passively deviates the wrist toward the ulnar side. However, this test may also be positive in patients with osteoarthritis (OA) of the first carpometacarpal (CMC) joint and must be differentiated from this common condition. Treatment involves splinting, local corticosteroid injection (Fig. 271-4), and NSAIDs as indicated. Rarely, surgical removal of the inflamed tenosynovium is needed.

Volar flexor tenosynovitis consists of inflammation of the tendon sheaths of the flexor digitorum superficialis and flexor digitorum profundus tendons in the palm. It is extremely common but often unrecognized. Pain in the palm is felt on finger flexion, but in some cases the pain radiates to the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints on the dorsal side, misleading the examiner. The diagnosis is made by palpation and identification of localized tenderness and swelling of the volar tendon sheaths. The middle and index fingers are most commonly involved, but the ring and little fingers can also be affected. Often a nodule composed of fibrous tissue can be palpated in the palm just proximal to the MCP joint on the volar side. The nodule interferes with the normal tendon gliding and can cause a triggering or locking, which may be intermittent and may produce an uncomfortable sensation. Similar involvement can occur at the flexor tendon of the thumb. The most common cause is overuse trauma of the hands from gripping with increased pull on the flexor tendons. It may be part of inflammatory conditions, such as RA, psoriatic arthritis, or apatite crystal deposition disease. It is seen frequently in conjunction with OA of the hands. Injection of a long-acting steroid into the tendon sheath usually relieves the problem, although surgery on the tendon sheath may be needed in unremitting cases.

Gamekeeper's thumb (skier's thumb) is caused by trauma to the thumb resulting in instability of the first MCP joint. This instability is due to laxity or rupture of the ulnar collateral ligament. It is treated by immobilization, but surgical repair may be necessary.

Avulsion of flexor digitorum profundus (jersey finger) may result from trauma, usually in football, when a player grabs onto a jersey. The distal phalanx, usually the fourth, is hyperextended while the digitorum profundus

FIGURE 271-4. Injection of de Quervain's tenosynovitis.

is contracting maximally. The avulsion of the tendon results in an inability to flex the distal phalanx of that digit. Surgery is required to correct the problem.

DISORDERS OF THE HIP REGION

Although trochanteric bursitis is common, it frequently goes undiagnosed. It occurs predominantly in middle-aged to elderly people, and somewhat more often in women than in men. The main symptom is aching over the trochanteric area and lateral thigh. Walking, various movements, and lying on the involved hip may intensify the pain. Onset may be acute, but more often it is gradual, with symptoms lasting for months. In chronic cases, the patient may fail to locate or describe the pain adequately, or the physician may fail to note the symptoms or interpret them correctly. Occasionally, the pain has a pseudoradiculopathic quality, radiating down the lateral aspect of the thigh. In a few cases, the pain is so severe that the patient cannot walk and complains of diffuse pain of the entire thigh. The best way to diagnose trochanteric bursitis is to palpate over the trochanteric area and elicit point tenderness. In addition to specific pain on deep pressure over the trochanter, other tender points may be noted throughout the lateral aspect of the thigh muscle. Pain may be worse with external rotation and abduction against resistance. Although bursitis is usually described as the principal problem, the condition may actually arise at the insertions of the gluteus maximus and gluteus medius tendons. Local trauma and degeneration play a role in the pathogenesis. Conditions that may contribute to trochanteric bursitis, apparently by adding stress to the area, include OA of the lumbar spine or of the hip, leg-length discrepancy, and scoliosis. Treatment consists of local injection of depot corticosteroid using a 22-gauge, 3.5-inch needle to ensure that the bursal area is reached (Fig. 271-5). NSAIDs, weight loss, and strengthening and stretching of the gluteus medius muscle and iliotibial band help in management.

Coccydynia is manifested by pain in the coccyx area when pressure is applied to the area. This most notably occurs on sitting. The patient squirms from buttock to buttock to relieve the pressure and consequent pain, and often chooses to sit on a cushion. The symptoms may be chronic and severe. The condition may relate to a fall on the coccyx, dropping to a hard chair when sitting, or some related trauma to the coccyx. However, at times no obvious cause can be detected. Women are much more frequently affected, perhaps because the lordosis that often occurs in women exposes the coccyx to more trauma. The diagnosis is confirmed by finding localized tenderness over the coccyx on palpation. A plain x-ray can be obtained to exclude a fracture or dislocation of the coccyx. Treatment with a local injection of 1 mL of a long-acting corticosteroid and 2 mL of a 2% lidocaine solution is usually very effective. The exact nature of the pathology of coccydynia has not been studied, but it is presumed to be a bone bruise.

In iliopsoas bursitis, groin and anterior thigh pain are present and worsen on passive hip hyperextension and sometimes on flexion, especially with resistance. Tenderness is palpable over an involved bursa. The patient may hold the hip in flexion and external rotation to eliminate pain and may limp to prevent hyperextension of the hip. The iliopsoas bursa lies behind the iliopsoas muscle, anterior to the hip joint and lateral to the femoral vessels. It communicates with the hip in 15% of cases. The diagnosis is more apparent if a cystic mass is seen (about 30% of the cases); however, other causes of cystic swelling in the femoral area must first be excluded. A bursal mass can cause femoral venous obstruction or femoral nerve compression. As with most cases of bursitis, acute or recurrent trauma and inflammatory conditions such as RA may lead to iliopsoas bursitis (also called *iliopectineal bursitis*). The diagnosis is confirmed by plain x-ray with injection of a contrast medium into the bursa, or by computed tomography or MRI. Iliopsoas bursitis usually responds to conservative treatment including corticosteroid injections. With recurrent involvement, excision of the bursa may be necessary.

FIGURE 271-5. Injection of trochanteric bursitis.

Ischial or ischiogluteal bursitis is caused by trauma or by prolonged sitting on hard surfaces, as evidenced by the name *weaver's bottom*. Pain is often exquisite when sitting or lying down. Because the ischiogluteal bursa is located superficial to the ischial tuberosity and separates the gluteus maximus from the tuberosity, the pain may radiate down the back of the thigh. Point tenderness over the ischial tuberosity is present. Use of cushions and local injection of a corticosteroid are helpful.

DISORDERS OF THE KNEE REGION

Anserine bursitis is seen predominantly in overweight, middle-aged to elderly women with large legs and OA of the knees. The symptoms are pain and tenderness over the medial aspect of the knee about 2 inches below the joint margin with the pain worsened by climbing stairs. The pes anserinus (Latin for "goose foot") is composed of the conjoined tendons of the sartorius, gracilis, and semitendinosus muscles. The bursa extends between the tendons and the tibial collateral ligament. The diagnosis is made by eliciting exquisite tenderness over the bursa. Anserine bursitis is often overlooked because it frequently occurs concomitantly with OA of the knee, which, when present, is the assumed cause of pain; however, in some cases of dual involvement, anserine bursitis is the principal source of pain. The treatment is rest, stretching of the adductor and quadriceps muscles, and a corticosteroid injection into the bursa.

Prepatellar bursitis is manifested as a swelling superficial to the kneecap and results from trauma such as frequent kneeling, leading to the name *housemaid's knee*. The prepatellar bursa lies anterior to the lower half of the patella and the upper half of the patellar ligament. The pain is generally slight unless pressure is applied directly over the bursa. The infrapatellar bursa, which lies between the patellar ligament and the tibia, is also subject to trauma and swelling. Chronic prepatellar bursitis can be treated by protecting the knee from the irritating trauma.

Patellar tendinitis (jumper's knee) is seen predominantly in athletes engaging in activities such as repetitive running, jumping, or kicking. Pain and tenderness are present over the patellar tendon.

Iliotibial band syndrome is manifested by lateral knee pain caused by friction between the iliotibial band and the lateral femoral condyle. It is an overuse injury and is seen in runners, cyclists, and other athletes performing repetitive knee flexion activities.

Popliteal cysts, also known as Baker's cysts, are not uncommon, and the clinician should be well aware of the possibility of their dissection or rupture. A cystic swelling behind the knee with mild or no discomfort can be the only initial finding. With further distention of the cyst, however, a greater awareness and discomfort are experienced, particularly on full flexion or extension. The cyst is best seen when the patient is standing and examined from behind. Any knee disease having a synovial effusion can develop into a popliteal cyst. Popliteal cysts are most common secondary to RA, OA, or internal derangements of the knee. There are a few reported cases secondary to gout and Reiter's syndrome. A syndrome of pseudothrombophlebitis may occur as a result of cyst dissection into the calf or actual rupture of the cyst. Findings include diffuse swelling of the calf, pain, and sometimes erythema and edema of the ankle. An ultrasound or arthrogram of the knee confirms both the cyst and the possible dissection or rupture. A cyst related to an inflammatory arthritis is treated by injection of a depot corticosteroid into the knee joint, and possibly into the cyst itself, which usually resolves the problem. If the cyst results from OA or an internal derangement of the knee, surgical repair of the underlying joint lesion is usually necessary to prevent a recurrence of the cyst.

In the knee area, tendon ruptures may occur, and quadriceps tendon rupture is involved about 50% of the time; otherwise, patellar tendon rupture occurs. Quadriceps tendon rupture is generally caused by sudden violent contractions of the quadriceps muscle when the knee is flexed. A hemarthrosis of the knee joint may follow. Patients with chronic renal failure, RA, hyperparathyroidism, or gout, and patients with SLE taking steroids have been reported to have spontaneous ruptures of the quadriceps tendon. The patient experiences a sudden sharp pain and cannot extend the leg.

Radiographic studies may show a high-riding patella. The tendon is usually found to be degenerated, and surgical repair is often indicated. Rupture of the patellar tendon has been associated with a specific episode of trauma, repetitive trauma from sporting activities, and systemic diseases.

DISORDERS OF THE ANKLE AND FOOT REGION

Achilles tendinitis usually results from trauma, athletic overactivity, or improperly fitting shoes with a stiff heel counter, but it can also be caused by inflammatory conditions such as ankylosing spondylitis, Reiter's syndrome, gout, RA, and calcium pyrophosphate dihydrate crystal deposition disease. Pain, swelling, and tenderness occur over the Achilles tendon at its attachment and in the area proximal to the attachment. Crepitus on motion and pain on dorsiflexion may be present. Management includes NSAIDs, rest, shoe corrections, heel lift, gentle stretching, and sometimes a splint with slight plantar flexion. Local injection of platelet-rich plasma (PRP) has become an increasingly used treatment for releasing growth factors into degenerative tendons; however, a randomized controlled trial for treatment of chronic Achilles tendinopathy was found to be ineffective in improving pain and activity.■ The Achilles tendon is vulnerable to rupture when involved with tendinitis, and treatment with a corticosteroid injection could increase this possibility.

Achilles tendon rupture is well known and occurs with a sudden onset of pain during forced dorsiflexion. An audible snap may be heard, followed by difficulty in walking and standing on toes. Swelling and edema over the area usually develop. Diagnosis can be made with the Thompson test, in which the patient kneels on a chair with the feet extending over the edge and the examiner squeezes the calf and pushes toward the knee. Normally this produces plantar flexion, but in a ruptured tendon, no plantar flexion occurs. Achilles tendon rupture usually occurs during athletic events or with trauma from jumps or falls. The tendon is more prone to tear in people with preexisting Achilles tendon disease and in those taking corticosteroids. Orthopedic consultation should be obtained, and immobilization or surgery may be selected, depending on the situation.

For acute, severe ankle sprain, a below-knee cast or Aircast produces a faster recovery than a tubular compression bandage, but there is no difference in outcomes at 9 months.■

Plantar fasciitis, which is seen primarily in persons between 40 and 60 years of age, is characterized by pain in the plantar area of the heel. The onset may be gradual, or it may occur with trauma or overuse from some activity, such as athletics, prolonged walking, using improper shoes, or striking the heel with some force. Plantar fasciitis may be idiopathic; it also is likely to be present in younger patients with spondyloarthritis (Chapter 273). The pain characteristically occurs in the morning on arising and is most severe for the first few steps. After an initial improvement, the pain may worsen later in the day, especially after prolonged standing or walking. The pain is burning, aching, and occasionally lancinating. Palpation typically reveals tenderness anteromedially on the medial calcaneal tubercle at the origin of the plantar fascia. Treatment includes relative rest with a reduction in stressful activities, NSAIDs, use of heel pad or heel cup orthosis, arch support, and stretching of the heel cord and plantar fascia. A local corticosteroid injection, using a 25-gauge needle, is often of help.

In posterior tibial tendinitis, pain and tenderness occur just posterior to the medial malleolus; it can be caused by trauma, excessive pronation, RA, or spondyloarthropathy. Extension and flexion may be normal, but pain is present on resisted inversion or passive eversion. The discomfort is usually worse after athletic activity, and swelling and localized tenderness may be present. Treatment usually includes rest, NSAIDs, and possibly a local injection of corticosteroid. Immobilization with a splint is sometimes needed.

Posterior tibialis tendon rupture, which is not commonly recognized, is a cause of progressive flat foot. It can result from trauma, chronic tendon degeneration, or RA. An insidious onset of pain and tenderness may be noted along the course of the tendon just distal to the medial malleolus, along with swelling medial to the hind foot. The unilateral deformity of hind foot valgus and forefoot abduction is an important finding. The forefoot abduction can best be seen from behind; more toes are seen from this position than would be seen normally. The result of the single heel rise test is positive when the patient is unable to rise onto the ball of the affected foot while the contralateral foot is off the floor. Treatment usually includes rest, NSAIDs, and possibly a local injection of corticosteroid. Immobilization with a splint is sometimes needed.

Manifestations of retrocalcaneal bursitis include pain at the back of the heel, tenderness of the area anterior to the Achilles tendon, and pain on dorsiflexion. Local swelling is present, with bulging on the medial and lateral aspects of the tendon. Retrocalcaneal bursitis, also called sub-Achilles bursitis, may coexist with Achilles tendinitis, and distinguishing the two is sometimes difficult. This condition may be secondary to RA, spondylitis, a reactive arthritis, gout, or trauma.

Turf toe is an injury of the big toe originally described during play on artificial turf. It results from hyperextension of the first metatarsophalangeal (MTP) joint when a fixed, dorsiflexed foot is forced into the ground. The plantar capsular ligament may be sprained or torn.

Stress fracture is also known as march fracture or fatigue fracture because it was associated with spontaneous fracture after long marches in army recruits. Pain, swelling, tenderness, and occasionally erythema develop over the metatarsal area, usually without any clear history of trauma. On questioning, however, the episode of spontaneous pain related to onset of the fracture can be identified in some cases. The neck of the second metatarsal bone is most frequently involved, but the third metatarsal is also a site of fracture. Aside from prolonged marching, other athletic events with overactivity, including jogging, are common causes. Stress fractures may be seen in patients with RA and in elderly people. The difficulty in diagnosing stress fractures is that the initial radiographs usually show no abnormalities or, at most, only a faint fracture line. A repeat radiograph several weeks later shows healing with callus formation. Bone scans aid the early diagnosis of stress fractures by showing an increase in uptake over the fracture site. Usually these fractures heal spontaneously, and rest and strapping of the foot are helpful. Occasionally, a cast is needed.

RHEUMATOID ARTHRITIS

JAMES R. O'DELL

DEFINITION

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disease of unknown etiology that primarily targets synovial tissues. It is relatively common, with a prevalence of slightly less than 1% in adults all over the world. RA shortens survival and significantly affects quality of life in most patients. Essentially all patients exhibit some systemic features such as fatigue, low-grade fevers, anemia, and elevations of acute phase reactants (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]). The primary target of RA is the synovium, and this is responsible for most of the protean clinical features. Synovial tissues proliferate in an uncontrolled fashion, resulting in excess fluid production, destruction of cartilage, erosion of marginal bone, and stretching and damage of the tendons and ligaments.

In the past decade, the landscape of treatment of RA has changed dramatically. Current therapies result in substantial clinical benefit for most patients, particularly with early diagnosis, and 50% of patients can achieve remissions

with treatment with an appropriate disease-modifying antirheumatic drug (DMARD).

EPIDEMIOLOGY

RA is present all over the world, with a remarkably consistent prevalence of 0.5 to 1% of adults, and with some differences in certain population groups. For reasons that are still unclear, the prevalence in women is two or three times greater than that in men. RA can occur at any age, but onset before the age of 45 years in men is uncommon. The relatively few well-done inception cohorts that are available suggest that the yearly incidence of RA is approximately 40 per 100,000 for women, and about half that for men. These figures vary significantly based on the age of the cohort. The best available data suggest that the incidence of RA in women increases with age until approximately 50 years of age and then reaches a plateau. The incidence rate is much lower in young men, approximately one third that in women, but increases steadily with age and approaches that of women older than 65 years. Because the incidence of RA increases or is stable with age and RA is a lifelong disease, the prevalence of RA increases with each decade. Recent data suggest that the incidence of RA, particularly rheumatoid factor (RF)-negative RA, may be decreasing. The reasons for this are unclear, but, if elucidated, they could provide valuable insights into the etiology and pathogenesis of RA and might allow the implementation of strategies to prevent clinical disease.

RA has a significant genetic component; therefore, it is not surprising that RA is reportedly very unusual in certain populations and more common in others. Most notably, cohorts have been described in rural Nigeria in which no individuals are affected with RA; in contrast, a prevalence of RA of 5% has been found in some studies of Chippewa, Yakima, and Inuit Native American tribes.

PATHOBIOLOGY

Genetics

Genetics plays a significant role in determining both the risk of developing RA and the severity of the disease. Twin studies reveal a concordance rate for RA that averages 15% for monozygotic twins and approximately 5% for dizygotic twins. These data in monozygotic twins simultaneously reveal both the significance of genetic factors and the fact that they are clearly not the only important factor, or else the concordance rate would approach unity.

It has now been clearly shown that RA is a multigene disease with important contributions from both human leukocyte antigen (HLA) and non-HLA genes. The association of certain HLA alleles, specifically HLA-DR4, with an increased risk of developing RA and of having more severe disease has long been recognized. This association is explained by a particular amino acid sequence in the third hypervariable region on the DRβ1 chain. HLA-DR molecules are present on the surface of antigen-presenting cells and allow T cells to recognize antigen in the context of DR. Hypervariable regions on the DR molecule are particularly important for antigen recognition. Table 272-1 details the amino acid sequence of several DRβ1 chains that are associated with RA and some that are not. The amino acid sequence associated with RA has been called the *shared epitope* or the *at-risk allele*. It has been shown by a number of investigators that patients with the shared epitope have more severe RA and more extra-articular manifestations than those who are negative for the shared epitope. Furthermore, individuals with two copies of the shared epitope, particularly those with HLA-DR4, have a further increased risk for the development of severe RA. This association with a particular antigen recognition site may ultimately aid understanding of the antigen or antigens that are important for triggering RA. Recently, proteins in which arginine has been converted to citrulline were shown to be bound with greater avidity by the shared epitope. The importance of certain DRβ1 alleles in RA supports the concept that T cells are integrally involved in the pathogenesis.

Population-based studies have suggested that only about one third of the genetic risk for RA is explained by genes located in the HLA region. A functional polymorphism for the gene that encodes intracellular protein tyrosine phosphatase nonreceptor 22 *(PTPN22)* has been reproducibly associated with RA and with a number of other autoimmune diseases, including type 1 diabetes, systemic lupus erythematosus, Graves' disease, and Hashimoto's thyroiditis. Recent genome-wide association studies (GWAS) have identified at least 20 other candidate genes that are associated with RA, including polymorphisms for signal transducer and activator of transcription (STAT4), tumor necrosis factor receptor–associated factor 1 (TRAF-1), and CD40.

The shared epitope is present in approximately 25 to 35% of the white population, but the chance of developing RA among individuals who carry this allele is only about 1 in 25. Therefore, despite identifying the most important genetic risk factor for RA, this test has little or no clinical utility. In addition to genetics, a number of other factors have been associated with the incidence, and in some cases the severity, of RA, including estrogen use (protective), smoking, and silica exposure.

ETIOLOGY

Clearly, other factors, in addition to genetics, are active in precipitating or triggering RA. RA appears to require the complex interaction of genetic and environmental factors with the immune system, and ultimately in the synovial tissues throughout the body (Fig. 272-1). Serum collected before the development of clinical RA show that immunologic changes predate clinical manifestations by years. Autoantibodies, particularly anti–citrullinated peptide antigen (ACPA) antibodies and RF, are present in the sera of many individuals 5 to 10 years before the clinical onset of disease. By following cohorts of people at high risk for RA, investigators are learning much about these early immunologic changes and ultimately about the triggers for the disease.

The use of oral contraceptives has been associated with a decrease in the incidence of RA; because the effect appears to be strongest for oral contraceptives that have high estrogen content, it is postulated that estrogen is

responsible for this protective effect. Studies that have tried to address the question of postmenopausal estrogen use and its effect on RA have yielded conflicting results.

Smoking has long been associated with a significant increase in the risk of developing RA but recently it has been shown that this is true only for ACPA-positive patients and is not associated with ACPA-negative disease. Furthermore, smoking appears to be a risk factor for RA only in those patients who are shared-epitope positive. Smoking has also been associated with poor responses to treatment. Purported triggers in addition to smoking have included bacteria *(Mycobacteria, Streptococcus, Mycoplasma, Escherichia coli, Helicobacter pylori),* viruses (rubella, Epstein-Barr virus, parvovirus), superantigens, and other undefined factors.

PATHOGENESIS

The pathogenesis of RA is complex, and there are almost certainly multiple triggering mechanisms including but not limited to smoking, infection, molecular mimicry, immune complexes, altered T-cell repertoire, and T-cell reactivity. Furthermore, it is likely that the triggers may be different based on the genetic background. As mentioned previously, smoking is a well-known trigger for some individuals but appears to be a risk factor only in those patients who possess the shared epitope.

Rheumatic fever, reactive arthritis (formerly known as *Reiter's syndrome*), and, more recently, Lyme arthritis are examples of arthritic syndromes for which infectious triggers have clearly been demonstrated, but these triggering agents are often difficult or impossible to isolate at the time when the arthritic syndromes occur. Many other examples exist in animal models of arthritis, including syndromes induced by mycobacteria and streptococci. Reactive arthritis has clearly been shown to occur when any one of a myriad of different but specific infectious triggers is presented to a specific location in the body (the gastrointestinal or genitourinary tract) of individuals with a certain genetic background, in most cases HLA-B27. Additionally, in this syndrome, the age and gender of the individual and hence the maturity of the immune system may be critical in the development of clinical disease, which occurs primarily between the ages of 15 and 40 years in males. Once unraveled, the pathophysiology of RA is likely to be similarly complex.

Despite the absence of clear evidence linking any infectious agent to RA, it is widely believed that ultimately an important triggering role will be elucidated for infectious or other environmental agents. Once triggers for RA are identified, strategies for prevention can be addressed, but this information may not help individuals with established disease. Possibly infections involving the innate immune system are causative in an early subclinical phase of the rheumatoid disease process, with the agents being absent once clinical disease develops.

The relative roles of the cellular versus the humoral immune system in the initiation and perpetuation of RA are much debated; both appear to be important. Most likely, the mechanisms of initiation of the disease process are different from those that perpetuate the chronic disease. T cells, particularly of the activated T_H1 and T_H17 types, appear to predominate in synovial tissues. These T cells, presumably activated by some as yet unknown antigen presented by macrophages, B cells, or synoviocytes in the context of HLA-DR, secrete cytokines that drive further synovial proliferation. It is believed by many that, although RA may initially be triggered by exogenous antigens, the process, once initiated, may be perpetuated by autoantigens. Macrophage-derived cytokines, particularly interleukin-1 (IL-1) and tumor necrosis factor-α (TNF-α), play central roles in this ongoing inflammatory process. As definitive proof, biologic products directed against these cytokines have shown significant efficacy in the treatment of RA.

The humoral immune system also plays a role. RF has long been a serologic marker of RA and is well known to correlate with more severe disease, including erosions of bone, and with the presence of extra-articular features. The reason that RF is produced in excess and the exact role that it plays remains elusive. RF production may increase complement activation and result in the release of lysosomal enzymes, kinins, and oxygen free radicals. ACPA antibodies exhibit a high specificity (95 to 99%) for RA, although their sensitivity for RA with currently available assays is only about 70%. Even though both RF and ACPA antibodies also correlate with more aggressive erosive disease, this link is strongest for ACPA antibodies.

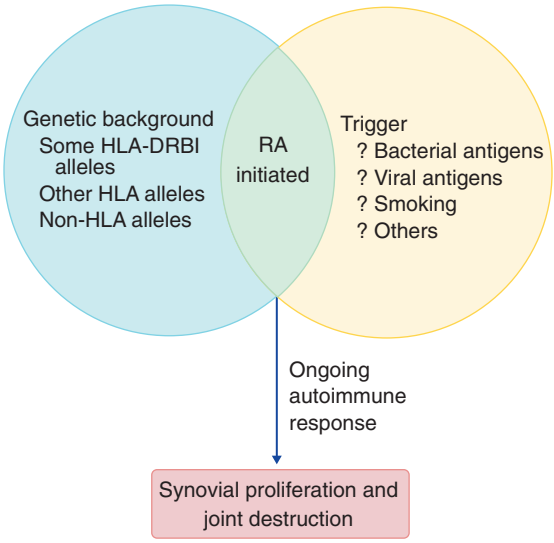

FIGURE 272-1. Initiation of rheumatoid arthritis (RA). HLA = human leukocyte antigen.

PATHOLOGY

The synovial tissues are the primary target of the autoimmune inflammatory process that is RA; the reason for this remains elusive. Once RA is initiated, the synovial tissues throughout the body become the site of a complex interaction of T cells, B cells, macrophages, and synovial cells (Fig. 272-2). The resultant proliferation of the synovial tissues (synovitis) causes the production of excessive amounts of synovial fluid and the infiltration of pannus into adjacent bone and cartilage. Synovitis results in the destruction of cartilage

and marginal bone and in the stretching or rupture of the joint capsule as well as tendons and ligaments. In patients, these effects are manifested by the deformities (Fig. 272-3 and E-Fig. 272-1) and disabilities that make up the clinical picture of RA.

CLINICAL MANIFESTATIONS

Articular Manifestations

RA can affect any of the synovial (diarthrodial) joints (Fig. 272-4). Most commonly, the disease starts in the metacarpophalangeal (MCP), proximal interphalangeal (PIP), and metatarsophalangeal (MTP) joints, followed by the wrists, knees, elbows, ankles, hips, and shoulders, in roughly that order. Early treatment helps limit the number of joints involved. Less commonly, and usually later, RA may involve the temporomandibular, cricoarytenoid, and sternoclavicular joints. RA may involve the upper part of the cervical spine, particularly the C1-C2 articulation, but, unlike the spondyloarthropathies, it does not involve the rest of the spine. However, RA patients are at an increased risk for osteoporosis, and this risk should be considered and dealt with early.

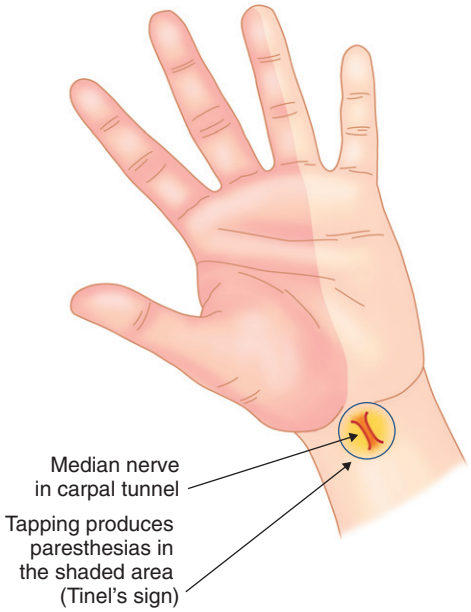

FIGURE 272-5. Carpal tunnel syndrome. Distribution of pain and/or paresthesias *(shaded area)* when the median nerve is compressed by swelling in the wrist (carpal tunnel).

Hands

The hands are a major site of involvement, and a significant portion of the disability that RA causes is because of damage and dysfunction of the hands. Typical early disease starts with swelling of the PIPs and MCPs. The distal interphalangeal (DIP) joints are rarely involved; significant involvement of the DIP joints should suggest the possibility of a different diagnosis (i.e., osteoarthritis or psoriatic arthritis). Figure 272-3 illustrates the classic ulnar deviation of the MCP joints and swan-neck deformities (hyperextension of the PIP joints) that are commonly seen in late, more established disease. Boutonniere (or buttonhole) deformities also occur as a result of hyperflexion of the PIP joints. If the clinical disease remains active, hand function deteriorates. Sudden loss of function of individual fingers may occur as a result of tendon rupture, which requires the expertise of a carefully selected hand surgeon to repair.

Feet

Feet, particularly the MTP joints, are involved early in most patients with RA. Radiographic erosions occur at least as early in the feet as in the hands. Subluxation of the toes is common and leads to the dual problem of breakdown of the skin and ulcers on the top of the toes. Painful ambulation may also develop owing to loss of the cushioning pads that usually protect the heads of the MTP joints.

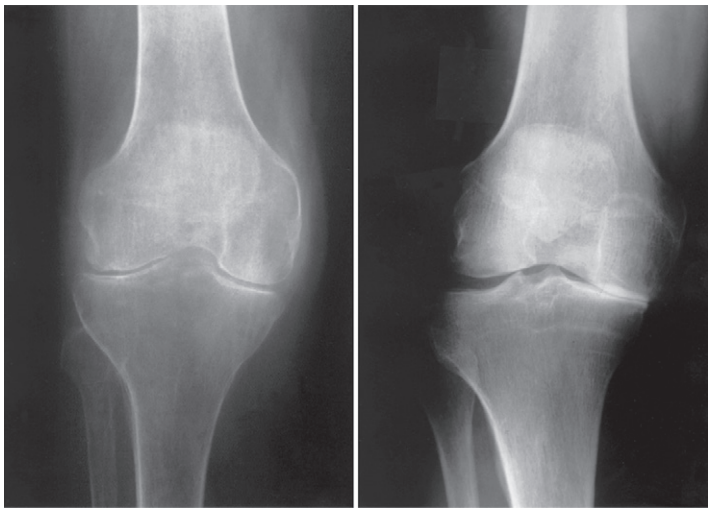
Wrists

The wrist joints are involved in most patients with RA; radial deviation is the rule, and patients with severe involvement may progress to volar subluxation. Even early in the course of the disease, synovial proliferation in and around the wrists may compress the median nerve, causing carpal tunnel syndrome (Fig. 272-5). Later, this synovial proliferation may invade tendons and lead to rupture of some extensor tendons.

Large Joints

Involvement of knees, ankles, elbows, hips, and shoulders is common. Characteristically, the whole joint surface is involved in a symmetrical fashion. Therefore, RA is symmetrical not only from one side of the body to the other but also within the individual joint. In the case of the knee (Fig. 272-6A), the medial and lateral compartments are both severely narrowed in RA; in contrast, in patients with osteoarthritis (see Fig. 272-6B), only one compartment of the knee may be involved.

Synovial cysts may occur around any of the joints (large or small), and they occasionally manifest as soft, fluctuant masses that present diagnostic challenges. Synovial cysts from the knee are perhaps the best examples of this phenomenon. When the knee produces excess synovial fluid, it may accumulate in the popliteal space (popliteal or Baker's cyst) (E-Fig. 272-2). These cysts can cause problems by pressing on the popliteal nerve, artery, or veins.



A B

FIGURE 272-6. Radiographs of the knees in the two most common forms of arthritis: rheumatoid arthritis and osteoarthritis. A, Severe involvement in rheumatoid arthritis, with almost complete symmetrical loss of joint space in both the medial and the lateral compartment, but with little subchondral sclerosis or osteophyte formation. **B,** Typical osteoarthritis, with severe, near-total loss of joint space of one compartment and a normal or actually increased joint space of the other compartment. Note also the significant subchondral sclerosis in the involved area, typical of osteoarthritis.

Baker's cysts may dissect into the tissues of the calf (usually posteriorly), or they may rupture into the upper calf. Dissection may produce only minor symptoms, such as a feeling of fullness; rupture of the cyst with extravasation of the inflammatory content produces significant pain and swelling and may be confused with thrombophlebitis, the so-called pseudothrombophlebitis syndrome. Ultrasonography of the popliteal fossa and calf is useful to establish the correct diagnosis and to rule out thrombophlebitis, which may be precipitated by popliteal cysts. Treatment of popliteal (Baker's) cysts should be directed at interrupting the inflammatory process through an intra-articular injection of corticosteroid into the knee.

Neck

Although most of the axial skeleton is spared in RA, the cervical spine is commonly involved, particularly the C1-C2 articulation. Bony erosions and ligament damage can occur in this area and may lead to subluxation (see E-Fig. 272-1). Most often, subluxation at C1-C2 is minor and without accompanying symptoms; patients and caregivers need only be cautious and avoid forcing the neck into positions of flexion. Occasionally, subluxation at C1-C2 is severe and leads to compromise of the cervical cord with symptoms and in some cases death.

Other Joints

Wherever synovial tissue exists, RA can cause problems. The temporomandibular, cricoarytenoid, and sternoclavicular joints are examples of other joints that may be involved in RA. The cricoarytenoid joint is responsible for abduction and adduction of the vocal cords. Involvement of this joint may lead to a feeling of fullness in the throat, to hoarseness, and, rarely, when the cords are essentially fused in a closed position, to a syndrome of acute respiratory distress with or without stridor. In this latter situation, emergent tracheotomy may be life-saving.

Extra-articular Manifestations

Systemic features of RA such as fatigue, weight loss, and low-grade fevers occur frequently. As with all the other extra-articular features, they are more common in those patients who possess RF or ACPA antibodies, or both (Table 272-2).

Skin

Subcutaneous nodules are seen in approximately one fourth of patients with RA, almost exclusively in those who are RF positive. Patients with nodules who are RF negative should be carefully scrutinized for a different diagnosis, such as chronic tophaceous gout. Nodules may occur almost anywhere (e.g., lungs, heart, eye), but most commonly they occur subcutaneously on extensor surfaces (particularly the forearms) (Fig. 272-7), over joints, or over pressure points. Rheumatoid nodules are firm on examination, usually are not tender, have a characteristic histologic picture, and are thought to be initiated by small vessel vasculitis. A syndrome of increased nodulosis, despite good control of the joint disease, has been described with methotrexate therapy (Fig. 272-8).

Small vessel vasculitis, manifested as digital infarcts or leukocytoclastic vasculitis, may occur in RA (Fig. 272-9) and should prompt more aggressive

FIGURE 272-7. Rheumatoid nodules. Large rheumatoid nodules are seen in a classic location along the extensor surface of the forearm and in the olecranon bursa.

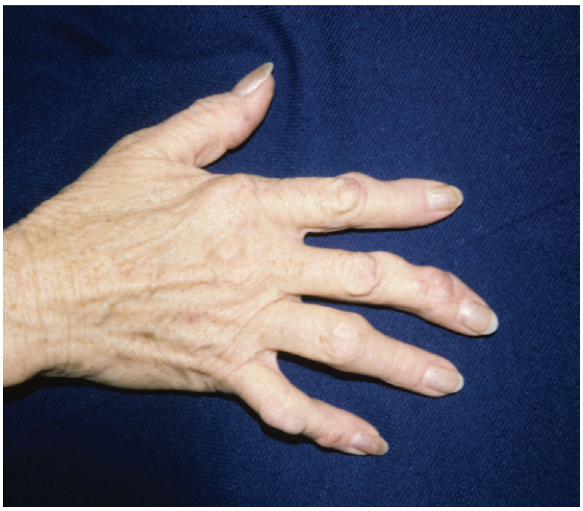


FIGURE 272-8. Rheumatoid nodulosis. In this patient, multiple rheumatoid nodules are present over joints. In some cases, nodules may dominate the clinical picture. Rarely, this may be seen as a side effect of methotrexate therapy.

TABLE 272-2 EXTRA-ARTICULAR MANIFESTATIONS OF RHEUMATOID ARTHRITIS

Skin	Nodules, fragility, vasculitis, pyoderma gangrenosum
Heart	Pericarditis, premature atherosclerosis, vasculitis, valve disease, and valve ring nodules
Lung	Pleural effusions, interstitial lung disease, bronchiolitis obliterans, rheumatoid nodules, vasculitis
Eye	Keratoconjunctivitis sicca, episcleritis, scleritis, scleromalacia perforans, peripheral ulcerative keratopathy
Neurologic	Entrapment neuropathy, cervical myelopathy, mononeuritis multiplex (vasculitis), peripheral neuropathy
Hematopoietic	Anemia, thrombocytosis, lymphadenopathy, Felty's syndrome
Kidney	Amyloidosis, vasculitis
Bone	Osteopenia

DMARD treatment. A vasculitis of small and medium arteries that is indistinguishable from polyarteritis nodosa also can be seen with RA and requires aggressive systemic therapy. Finally, pyoderma gangrenosum occurs with increased frequency in association with RA.

Cardiac Involvement

Cardiac involvement directly related to RA is uncommon; however, patients with RA have a significantly increased morbidity and mortality from coronary artery disease. The reasons are not clear, but chronic inflammation may be the major cause. Some of the medications used to treat RA and a sedentary lifestyle may be additional risk factors for the development of coronary artery disease. Pericardial effusions are common in RA (50% by echocardiography) but usually are asymptomatic. Rarely, long-standing pericardial disease may result in a fibrinous pericarditis, and patients may present clinically with constrictive pericarditis (Chapter 77). Uncommonly, rheumatoid nodules occur in the conduction system and cause heart block.

Pulmonary Manifestations

Pulmonary manifestations of RA include pleural effusions, rheumatoid nodules, and parenchymal lung disease (Chapters 84 and 92). Pleural effusions occur more commonly in men and are usually small and asymptomatic. Of interest, pleural fluid in RA is characterized by low levels of glucose and low pH and, therefore, may at times be confused with empyema. Rheumatoid nodules may occur in the lung, especially in men (Fig. 272-10); these are usually solid but may calcify, cavitate, or become infected. Rarely, pulmonary nodules rupture and produce a pneumothorax. If RA patients are exposed to coal dust, diffuse nodular densities may occur (Caplan's syndrome). Differentiating rheumatoid nodules from lung cancer can be problematic, particularly if the lesion is solitary. Therefore, the presence of pulmonary nodules in a patient with RA should precipitate an aggressive diagnostic evaluation.

Diffuse interstitial fibrosis occurs in RA and may progress to a honeycomb appearance on radiography with increasing dyspnea. Rarely, bronchiolitis obliterans can be seen with or without organizing pneumonia. Bronchiolitis obliterans carries a poor prognosis and may occur more often in association with D-penicillamine or gold therapy.

Ophthalmologic Manifestations

The most common manifestation of RA in the eye is keratoconjunctivitis sicca (dry eyes) from secondary Sjögren's syndrome. Patients may have associated xerostomia (dry mouth), parotid gland swelling, or, occasionally, lymphadenopathy. Scleritis can also occur and may be painful, with progression to thinning of the sclera (with deep pigment showing through on physical examination). Scleritis may progress to perforation of the orbit (scleromalacia perforans). Rarely, tendonitis of the superior oblique muscles can result in double vision (Brown's syndrome).

Neurologic Manifestations

Peripheral nerve entrapment syndromes, including carpal tunnel syndrome (median nerve at the wrist), and tarsal tunnel syndrome (anterior tibial nerve at the ankle), are common in RA. Vasculitis can lead to mononeuritis multiplex and a host of additional neurologic problems. Subluxations at C1-C2 may produce myelopathy (see E-Fig. 272-1). Rheumatoid nodules in the central nervous system have been described but are rare and usually asymptomatic.

Felty's Syndrome

Felty's syndrome is the triad of RA, splenomegaly, and neutropenia. This complication is seen in patients with severe, RF-positive disease and may be accompanied by hepatomegaly, thrombocytopenia, lymphadenopathy, and fevers. Most patients with Felty's syndrome do not require special therapy; instead, treatment should be directed toward their severe RA. If severe neutropenia (Chapter 170) exists (<500 cells/μL) and is accompanied by recurrent bacterial infections or chronic, nonhealing leg ulcers, splenectomy may be indicated.

Some patients with RA, who were previously thought to have Felty's syndrome, have peripheral white blood cell counts dominated by large granular lymphocytes with almost complete absence of neutrophils. This condition is known as the *large granular lymphocyte syndrome* and is thought to be a variant of T-cell leukemia. In the setting of RA, this syndrome has a good prognosis, with the neutropenia often responding dramatically to methotrexate therapy.

FIGURE 272-10. Rheumatoid nodules in the lung. Chest radiograph demonstrates discrete rheumatoid nodules in both right and left lower lobes. (Courtesy of Dr. Martin Lidsky, Houston, TX.)

Clinical Course

Although the presentation is variable, most patients with RA have an insidious onset of pain, stiffness, or swelling, or a combination of these, in multiple joints over the course of weeks to months. Systemic features such as fatigue, low-grade fevers, and weight loss may accompany the joint manifestations of RA. Less commonly, the onset can be fulminant, occurring almost overnight, or patients may exhibit persistent monoarthritis or oligoarthritis for prolonged periods before manifesting the more typical pattern of joint involvement. Rarely, some patients, particularly men, develop extra-articular features of RA before the joint problems appear.

The distribution of involved joints is a critical clue to the underlying diagnosis. The joints that are involved in patients with RA at presentation are also variable; typically, the symptoms start in the small joints of the hands (PIP and MCP joints) and in the toes (MTP joints). Importantly, RA usually spares the DIP joints and the small joints of the toes (see Fig. 272-4). Later, RA moves, or some would say "metastasizes," to larger joints: wrists, knees, elbows, ankles, hips, and shoulders (roughly in that order). Although the patient's history of joint symptoms (arthralgia) is important, the diagnosis of RA requires the presence of inflammation (swelling, warmth, or both) on examination of the joints.

Morning stiffness is a hallmark of inflammatory arthritis and is a prominent feature of RA. Patients with RA are characteristically at their worst in the morning or after prolonged periods of rest (called *gel phenomenon*). This stiffness in and around joints often lasts for hours, and quantifying it is one way to measure improvement. Stiffness is relieved by warmth and activity, and reducing or eliminating joint stiffness is a clear goal of therapy.

DIAGNOSIS

All current treatment paradigms for RA stress the early and aggressive use of DMARDs. Therefore, the importance of accurate early diagnosis of RA cannot be overemphasized. However, there is no one single finding on physical examination or laboratory testing that is pathognomonic of RA. Instead, the diagnosis of RA requires a collection of historical and physical features as well as an alert and informed clinician.

TABLE 272-3 CLASSIFICATION CRITERIA FOR RHEUMATOID ARTHRITIS*

Morning stiffness (≥1 hr)
Swelling (soft tissue) of three or more joints
Swelling (soft tissue) of hand joints (PIP, MCP, or wrist)
Symmetrical swelling (soft tissue)
Subcutaneous nodules
Serum rheumatoid factor
Erosions and/or periarticular osteopenia in hand or wrist joints seen on radiograph

*Criteria 1 through 4 must have been continuously present for 6 wk or longer, and criteria 2 through 5 must be observed by a physician. A classification of rheumatoid arthritis requires that four of the seven criteria be fulfilled.
MCP = metacarpophalangeal; PIP = proximal interphalangeal.

TABLE 272-4 DIFFERENTIAL DIAGNOSIS OF RHEUMATOID ARTHRITIS

DISORDER	SUBCUTANEOUS NODULES	RHEUMATOID FACTOR

– = Not present; + = frequently present; ± = occasionally present.

Classification

Table 272-3 lists the current classification criteria for RA; although they are not designed specifically for the purpose of diagnosis, these criteria are widely used as a diagnostic aid. The first five criteria are all clinical; in other words, they are established by physical examination or by talking with the patient. Only the last two criteria require laboratory tests or radiographs. The first four criteria must be present for at least 6 weeks before a diagnosis of RA can be made. This caveat is necessary because a host of conditions, including many virus-related syndromes, can cause self-limited polyarthritis syndromes that look identical to RA, including at times the presence of RF. Such conditions usually last only 2 to 3 weeks. Therefore, inflammatory arthritis that is present for at least 6 weeks should not be considered a postviral condition, except for parvovirus arthritis, and the diagnosis of RA should be strongly considered, with the early initiation of appropriate treatment. The goal for most RA patients should be to establish a diagnosis and to start DMARD therapy within 3 months of disease onset. The presence of ACPA antibodies, even in the first few weeks of disease, is strongly suggestive of ongoing aggressive RA. New classification criteria for RA have been developed and, once validated, may prove more useful in diagnosis.

Laboratory Findings

Historically, the most characteristic laboratory abnormality in RA is the presence of RF, which is found in approximately 80% of patients. RF was first described in the 1930s and is an antibody that recognizes the Fc portion of immunoglobulin G as its antigen. The presence of RF is strongly associated with more severe articular disease as well as with essentially all the extra-articular features previously discussed. Importantly, RF is seen in association with many diseases other than RA, particularly in disease processes that provide chronic stimulation of the immune system (Table 272-4). ACPA antibodies, found in approximately 70% of patients with RA, have a high specificity (93 to 98%), are often present before clinical disease is diagnosed, and are associated with aggressive erosive disease. RA is associated with many other autoantibodies, including antinuclear antibodies (~30%) and antineutrophil cytoplasmic antibodies, particularly of the perinuclear type (~30%).

Most patients with RA have an anemia of chronic disease. The degree of anemia is proportional to the activity of the disease, and therapy that controls the disease will normalize the hemoglobin levels. Other causes of anemia should also be considered in RA, particularly iron deficiency anemia from gastrointestinal blood loss. Thrombocytosis is common, with platelet counts returning to normal as the inflammation is controlled. Acute phase reactants and ESR and CRP levels also parallel the activity of the disease, and their persistent elevation portends a poor prognosis in terms of both joint destruction and mortality. White blood cell counts may be elevated, normal, or, in the case of Felty's syndrome, profoundly depressed. Eosinophilia is present in some patients with RA.

Synovial fluid in RA is characterized by white blood cell counts in the range of 5000 to 100,000/mm^3, with approximately two thirds of the cells being polymorphonuclear leukocytes. There are no synovial fluid findings that are pathognomonic of RA.

Differential Diagnosis

The accurate diagnosis of RA early in its course, although challenging, is critical if patients are to benefit maximally from therapeutic intervention. Once disease has been present and active for years and the characteristic deformities and radiographic changes have occurred, the diagnosis is all too obvious. Unfortunately, once RA has progressed to that point, many of the deformities no longer are amenable to medical therapy.

Many diseases can mimic RA (see Table 272-4). Early in the course of disease, self-limited viral syndromes need to be considered, especially hepatitis B and C, parvovirus, rubella (infection or vaccination), and Epstein-Barr virus. At any time, systemic lupus erythematosus, psoriatic arthritis, and reactive arthritis may present diagnostic challenges. In the case of these three mimics, a targeted history and examination to elucidate their associated clinical features, such as rashes, oral ulcers, nail changes, dactylitis, urethritis, and renal, pulmonary, gastrointestinal, or ophthalmologic problems, is critical. Especially in elderly patients with fulminant-onset RA, remitting RF-negative symmetrical synovitis with pitting edema (the so-called RS3PE syndrome) and paraneoplastic syndromes should be considered. Chronic tophaceous gout may also mimic severe nodular RA. Hypothyroidism not only causes many rheumatic manifestations but also occurs commonly in conjunction with RA and, therefore, should be kept in mind.

TREATMENT Rx

General Measures

RA is a lifelong disease process that has no known cure; the diagnosis is made based on clinical criteria, and many different options exist for treatment. All these factors magnify the importance of the patient-physician relationship and place a premium on the art rather than the science of medicine. Optimal care for patients with RA requires effective ongoing interactions between primary care physicians and rheumatologists, and, in some cases, physical therapists, occupational therapists, and orthopedic surgeons. Because of the serious nature of the disease, the rapid introduction of new treatments, and the need for expertise in monitoring these therapies, all patients with RA should be evaluated early by a rheumatologist and followed closely.

The goal of therapy is disease remission (Table 272-5). When RA is treated early, remission is possible in 40 to 50% of patients. However, remissions require the ongoing use of DMARDs and, even then, are not always durable. Essentially all RA patients should be treated with DMARDs. Some combination of nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and DMARDs is necessary in most patients. In many, or perhaps most, patients with RA, combinations of different DMARDs (conventional and biologic) are necessary for optimal control. Therapy should be escalated rapidly to ensure maximal suppression of disease while minimizing toxicity and expense. Patients with RA should be educated about their disease and its treatment. In most cases, patients should have an opportunity to spend time with physical therapists and occupational therapists to learn about range-of-motion exercises, joint protection, and assistive devices.

Medical Therapy

In the treatment of RA, three types of medical therapies are used: NSAIDs, glucocorticoids, and DMARDs (both conventional and biologic). Initial therapy should include at least one DMARD, whereas combinations of the three types of medications is the rule.■

TABLE 272-5 KEYS TO OPTIMIZE OUTCOME OF TREATMENT OF RHEUMATOID ARTHRITIS

Early, accurate diagnosis
Early DMARD therapy
Strive for remission in all patients
Monitor carefully for treatment toxicities
Consider and treat comorbid conditions*

*Important comorbid conditions include cardiovascular disease, increased susceptibility to infections, and osteoporosis.
DMARD = disease-modifying antirheumatic drug.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs are important for the symptomatic relief they provide to RA patients; however, they play only a minor role in altering the underlying disease process (Chapter 36). Therefore, NSAIDs should rarely, if ever, be used to treat RA without the concomitant use of DMARDs. Many clinicians waste valuable time switching from one NSAID to another before starting DMARD therapy.

Much has been written about the gastrointestinal toxicity of NSAIDs, and these concerns are particularly relevant to RA patients who often have significant risk factors, including age and concomitant steroid use. Therefore, cyclooxygenase-2 (COX2)–selective agents have been a popular choice for patients with RA. The recent evidence linking these agents to increased cardiovascular toxicity has been particularly troubling for patients with RA, who are already at high risk for myocardial infarction. Therefore, if COX2-selective agents are used, they should be kept at a low dose. Consideration should be given to low-dose aspirin prophylaxis in RA, but this may increase the gastrointestinal toxicity of NSAIDs. The use of concomitant misoprostol or proton pump inhibitors should be considered in all patients with RA who are taking NSAIDs. Additionally, the potential for NSAIDs to decrease renal blood flow and to increase blood pressure should be kept in mind.

Glucocorticoids

Glucocorticoids have had a significant role in the treatment of RA for more than half a century (Chapter 34). Indeed, RA was chosen as the first disease to be treated with this new therapy, partly because it was thought that RA was a disease of glucocorticoid deficiency (an issue that remains unresolved). As was the case with the first patient treated in 1948, glucocorticoids are dramatically and rapidly effective in patients with RA. Not only are glucocorticoids useful for symptomatic improvement, but they also significantly decrease the radiographic progression of RA. However, the toxicities of long-term therapy are extensive and potentially devastating. Therefore, the optimal use of these drugs requires an understanding of several principles (Table 272-6).

Glucocorticoids remain among the most potent anti-inflammatory treatments available; for this reason, and because of their rapid onset of action, they are ideally suited to help control the inflammation in RA while the much slower-acting DMARDs are starting to work. Prednisone, the most commonly used glucocorticoid, should rarely be used in doses higher than 10 mg/day to treat the stiffness and articular manifestations of RA. This dose should be slowly tapered to the lowest effective dose, and the concomitant DMARD therapy should be adjusted to make this possible. Glucocorticoids should rarely, if ever, be used to treat RA without concomitant DMARD therapy. The paradigm is to shut off inflammation rapidly with glucocorticoids and then to taper them as the DMARD is taking effect ("bridge therapy"). In all patients receiving glucocorticoids, strong measure should be taken to prevent osteoporosis. Bisphosphonates have been shown to be particularly effective in this regard. Higher doses of glucocorticoids may be necessary to treat extra-articular manifestations, especially vasculitis and scleritis.

Disease-Modifying Antirheumatic Drugs

DMARDs are a group of medications that have the ability to inhibit greatly the disease process in the synovium and to modify or change the disabling potential of RA. In most cases, these drugs have the ability to halt or slow the radiographic progression of RA.

Conventional DMARDs

Included in this group of medications are methotrexate, sulfasalazine (Azulfidine), gold, antimalarials (Plaquenil and others), leflunomide (Arava), azathioprine (Imuran), and minocycline. It is critically important that clinicians and patients understand that conventional DMARDs take 2 to 6 months to exert their maximal effect, and all require some monitoring (Table 272-7). Therefore, other measures, such as glucocorticoid therapy, may be needed to control the disease while these medications are starting to work.

All these DMARDs have been shown to be effective in treating both early and more advanced RA that remains active. Until additional research elucidates factors that allow selection of the best initial therapy for each patient, the choice will depend on patient and physician concerns about toxicity and monitoring issues, as well as the activity of disease and presence of comorbid conditions. The critical factor is not which DMARD to start first but rather getting the DMARD therapy started early in the disease process.

TABLE 272-6 GUIDELINES FOR USE OF GLUCOCORTICOIDS

Avoid use of glucocorticoids without DMARDs
Prednisone, >10 mg/day, is rarely indicated for articular disease
Taper to the lowest effective dose
Use as "bridge therapy" until DMARD therapy is effective
Remember prophylaxis against osteoporosis

DMARD = disease-modifying antirheumatic drug.

TABLE 272-7 CAVEATS FOR MONITORING DISEASE-MODIFYING ANTIRHEUMATIC DRUG THERAPIES*

MEDICATION	CAVEATS
Prednisone	Use as bridge to effective DMARD therapy. Prophylaxis for osteoporosis? (see Table 272-6)
Hydroxychloroquine	Keep dosage lower than 6.5 mg/kg/day. Yearly eye checkup by ophthalmologist
Sulfasalazine	CBC for neutropenia, initially every month, then every 6 mo
Methotrexate	CBC and SGOT/SGPT every 8-12 wk when dose is stable. Many toxicities respond to folic acid or small dose reduction. If pneumonitis, stop and do not restart. Decreasing renal function may precipitate toxicities. Absolute contraindication in pregnancy
Leflunomide	CBC and SGOT/SGPT every 4-8 wk; long half-life may require cholestyramine washout; absolute contraindication in pregnancy
TNF inhibitors	If fevers or infectious symptoms of any kind, stop until symptoms resolve; aggressively work up and treat possible infections. May precipitate congestive heart failure, demyelinating syndromes, or lupus-like syndromes

*Patients receiving DMARDs, both conventional and biologic, should be monitored by a rheumatologist.
CBC = compete blood count; DMARD = disease-modifying antirheumatic drug; SGOT = serum glutamate oxaloacetate transaminase (aspartate aminotransferase); SGPT = serum glutamate pyruvate transaminase (alanine aminotransferase); TNF = tumor necrosis factor.

Methotrexate

Methotrexate is the preferred DMARD of most rheumatologists, in part because patients have a more durable response, and because, with correct monitoring, serious toxicities are rare. Methotrexate is dramatically effective in slowing radiographic progression and is usually given orally in doses ranging from 5 to 25 mg/week as a single dose. This once-a-week administration is worthy of emphasis; prior experience with daily therapy in psoriasis has demonstrated the importance of allowing the liver time to recover between doses. Oral absorption of methotrexate is variable; subcutaneous injections of methotrexate may be effective if oral treatment is not. Side effects of methotrexate include oral ulcers, nausea, hepatotoxicity, bone marrow suppression, and pneumonitis. With the exception of pneumonitis, these toxicities respond to dose adjustments. Monitoring of blood counts and liver blood tests (albumin and aspartate aminotransaminase [SGOT] or alanine aminotransferase [SGPT]) should be done every 4 to 8 weeks initially and, when stable, every 3 months thereafter, with adjustments in the dose of methotrexate as needed. Renal function is critical for clearance of methotrexate; previously stable patients may experience severe toxicities when renal function deteriorates. Pneumonitis, although rare, is less predictable and can be fatal, particularly if the methotrexate is not stopped or is restarted. Folic acid, 1 to 4 mg/day, can significantly decrease most methotrexate toxicities without apparent loss of efficacy. If methotrexate alone does not sufficiently control disease, it is combined with other DMARDs. Methotrexate in combination with virtually any of the other DMARDs (conventional or biologic) has been shown to be more effective than either drug alone.■

Leflunomide

Leflunomide, a pyrimidine antagonist, has a very long half-life and is most commonly started at 10 to 20 mg/day orally. Diarrhea is the most common toxicity and responds to dose reduction, and doses of leflunomide of 10 to 20 mg three to five times per week are frequently used. Also, because of the long half-life and teratogenic potential of leflunomide, women wishing to become pregnant who have previously received leflunomide, even if therapy was stopped years ago, should have blood levels drawn. If toxicity occurs or if pregnancy is being considered, leflunomide can be rapidly eliminated from

the body by treatment with cholestyramine. Laboratory monitoring for hematologic and hepatic toxicity should be done during treatment with leflunomide, as recommended for methotrexate.

Antimalarial Drugs

The antimalarial drugs hydroxychloroquine (Plaquenil) and chloroquine are frequently used for the treatment of RA. They have the least toxicity of any of the DMARDs and do not require monitoring of blood tests. Yearly monitoring by an ophthalmologist is recommended to detect any signs of retinal toxicity (rare). Hydroxychloroquine is the most commonly used preparation and is given orally at 200 to 400 mg/day. These drugs are frequently used in combination with other DMARDs, particularly methotrexate.[2] Hydroxychloroquine has recently been shown to decrease the incidence of diabetes in patients with RA.

Sulfasalazine

Sulfasalazine is an effective treatment when given in doses of 1 to 3 g/day. Monitoring of blood counts, particularly white blood cell counts, in the first 6 months is recommended. Sulfasalazine and hydroxychloroquine are often combined with methotrexate,; this is referred to as triple therapy.

Minocycline

Minocycline, 100 mg twice daily, has been shown to be an effective treatment for RA, particularly when used in early, RF-positive disease. Chronic therapy (>2 years) with minocycline may lead to cutaneous hyperpigmentation. Minocycline has been associated with drug-induced lupus.

Gold

Gold, the oldest DMARD, when given intramuscularly remains an extremely effective therapy for a small percentage of patients. It is less commonly used because of its slow onset of action, need for intramuscular administration, frequent monitoring required (complete blood count and urinalysis), and frequent toxicities. Toxicities include skin rashes, bone marrow suppression, and proteinuria.

Biologic DMARDs

Recent research has continued to elucidate the central role that cytokines, most notably TNF-α and IL-1, play in the pathophysiology of RA (Chapter 35). This has led directly to the development and clinical use of biologic agents directed against TNF-α1 (etanercept[3] [Enbrel], infliximab[4] [Remicade], adalimumab[5] [Humira], golimumab [Simponi], and certolizumab [Cimzia]) and IL-1 (anakinra [Kineret]). Three new monoclonals have been approved for RA: an anti-CD20, rituximab (Rituxan); a T-cell agent, abatacept (Orencia); and an anti–IL-6 receptor antibody, tocilizumab (Actemra).[6–8] All RA patients receiving biologic therapies should be monitored by a rheumatologist, and their physicians should be aware of the risk for infections that are often atypical. Essentially all the biologicals, when combined with methotrexate, have been shown to decrease disease activity and slow radiographic progression in RA patients with active disease despite methotrexate. Currently, biologic agents should not be used in combination with each other because all studies to date have shown a significant increase in infections. See Chapter 35 for further details on the use of biologic agents in the treatment of RA.

Treatment of Underlying Conditions

Optimal care of patients with RA requires recognition of the associated comorbid conditions, including an increased risk of cardiovascular death, osteoporosis, infections (especially pneumonia), and certain cancers.

Cardiovascular Disease

Increasingly, cardiovascular disease is being recognized as the cause of much of the excess mortality in RA. A number of factors contribute to this mortality, including sedentary lifestyle, glucocorticoid therapy, and treatments that increase homocysteine levels, such as methotrexate and sulfasalazine. However, recently a strong association between chronic inflammation and cardiovascular disease was identified, and it is likely that this may be the most significant factor. Therapies that control RA earlier and better can be expected to decrease cardiovascular morbidity and mortality. Clinicians should consider RA a risk factor for cardiovascular disease and should aggressively address other cardiovascular risk factors (Chapter 51) in their rheumatoid patients.

Other Associated Diseases

Osteoporosis is common in patients with RA, and early treatment results in long-term dividends. Patients with RA are at an increased risk for infections, and some forms of treatment further increase this risk. Patients should be cautioned to seek medical attention early for even minor symptoms suggestive of infection, especially if receiving anti-TNF therapy. All patients with RA should receive a pneumococcal vaccine at appropriate intervals and yearly influenza vaccinations. Finally, patients with RA have an increased risk of lymphoma. Occasionally, B-cell lymphomas are associated with immunosuppression and regress after immunosuppression is discontinued. RA patients have significantly decreased risk (odds ratio, 0.2) of developing colon cancer. This is thought to be secondary to chronic inhibition of COX by NSAIDs.

PROGNOSIS

Until recently, RA was thought to be a relatively benign disease. It is now clear that, once established, RA is a lifelong progressive disease that produces significant morbidity in most patients and premature mortality in many. Long-term studies have found that 50% of patients with RA have had to stop working after 10 years (approximately 10 times the average rate). Patients who are RF or ACPA positive and those who are positive for the shared epitope have a worse prognosis, with more erosions and more extra-articular disease (see Table 272-2). Once deformities are found on examination or erosions on radiography, the damage is largely irreversible. It has been clearly shown that erosions occur in most patients in the first 1 to 2 years and that the rate of radiographic damage can be affected by early therapy. Therefore, early DMARD therapy is critical. Although limited long-term data are available, the current information strongly suggests that patients have the opportunity to benefit greatly if the newer principles of therapy are practiced.

FUTURE DIRECTIONS

Significant advances in the effective treatment of RA have come from an understanding of the cytokine imbalance that accompanies this disease. Much research is focused on the further development of biologic products to modulate this balance. Biologic therapies that modulate B-cell and T-cell function have been shown to be effective in the treatment of RA. There remains a critical need for a cytokine thermostat that would allow titration of the desired cytokine balance to control disease without altering critical immune functions.

Even with existing therapies, there are many different effective options for patients with RA. The challenge for the clinician is to pick the right option for each patient. Few data are currently available to aid in this choice, and the establishment of parameters, genetic or otherwise, that would allow selection of the best initial option for each patient would be a major breakthrough. Finally, elucidation of the trigger or triggers for RA may allow the development of strategies to prevent the onset of clinical disease.

THE SPONDYLOARTHROPATHIES

ROBERT D. INMAN

COMMON FEATURES OF THE SPONDYLOARTHROPATHIES

DEFINITION

The spondyloarthropathies (SpAs) encompass a group of clinical syndromes that are linked in terms of disease manifestations and genetic susceptibility. The clinical subsets most commonly recognized are ankylosing spondylitis (AS), reactive arthritis (ReA), psoriatic arthritis (PsA), and enteropathic arthritis (EA) (Fig. 273-1). In addition, a sizable number of patients do not fit into one of these distinct diagnostic categories but share some of the common clinical features described in this chapter. This syndrome is termed *undifferentiated spondyloarthropathy* (USpA); it may evolve over time into a classic pattern such as AS, or it may retain an undifferentiated pattern in long-term follow-up studies.

PATHOBIOLOGY

Family studies involving multiple individuals with SpA have emphasized some of the common features among the four distinct subsets. The impression from such studies is that there is a shared common path of immunogenetic susceptibility, with further genetic and environmental influences that lead to characteristic clinical subsets. Thus, EA may occur in one such family, but in another family the disease may be PsA. In this sense, the SpAs seem to "breed true." It should be recognized, however, that some distinct clinical features can be very similar in their manifestations (e.g., guttate psoriasis and keratoderma blennorrhagicum), making simple discrimination difficult.

CLINICAL MANIFESTATIONS

There are several common features in the family of SpAs that serve to both link them with and distinguish them from the other major contributor to chronic polyarthritis—rheumatoid arthritis (RA) (Chapter 272). The SpAs have a strong predilection for the spine, in particular the sacroiliac joints. There is a shared tendency for new bone formation at sites of chronic inflammation, with joint ankylosis as a consequence. When peripheral arthritis occurs, it is commonly in the lower extremity and asymmetrical. There is a predilection for sites of tendon insertion into bone (entheses), so enthesitis is one of the most specific clinical manifestations of the SpAs. Theories postulating the basis for this target organ involvement have invoked biomechanical factors, innervation, local vascularity, and bone marrow–derived inflammatory mediators, but the precise mechanism remains incompletely defined. Whatever the reason, inflammation in the enthesis and contiguous subchondral bone is a characteristic feature of this form of arthritis, and the appearance of this inflammation on magnetic resonance imaging (MRI) is distinct enough to lead some investigators to use MRI for diagnostic purposes.

A predilection for ocular inflammation, particularly acute anterior uveitis, is a common feature of all SpA subsets. Indeed, some investigators consider anterior uveitis to be a feature of SpA in its own right because it may occur in the same susceptible population of patients even in the absence of joint involvement, and it may have a unique genetic predisposition. Finally, all SpA subsets have an association with the class I human leukocyte antigen (HLA) allele B27, with the strength of the association varying somewhat among them.

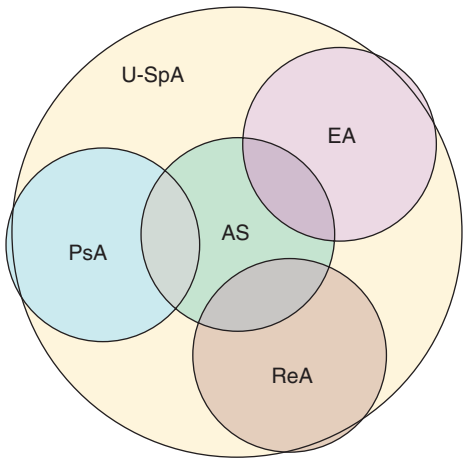

FIGURE 273-1. Schematic relationships among the different spondyloarthropathy (SpA) subsets. Ankylosing spondylitis (AS), considered the classic SpA, encompasses the essential features of this family of diseases. AS may overlap with psoriatic arthritis (PsA), enteropathic arthritis (EA), or reactive arthritis (ReA). Many patients have clinical features of SpA that do not meet the diagnostic criteria for any of the four defined subsets. Such cases are termed *undifferentiated SpA* (U-SpA).

DIAGNOSIS

Increasingly, diagnostic criteria (Table 273-1) are emphasizing the common clinical features—namely, inflammatory spinal pain or asymmetrical lower extremity synovitis. Several distinct features differentiate the SpAs from RA, the other main contributor to the differential diagnosis of chronic polyarthritis (Table 273-2). These features include sex predilection, HLA association, pattern of joint involvement, and presence of rheumatoid factor, which becomes the serologic distinction between seropositive disease (RA) and seronegative disease (SpAs).

At the level of joint histopathology, sites of chronic inflammation in RA are associated with erosions, but in the SpAs such sites are associated with new bone formation. This distinction suggests a fundamental difference in the cytokine profile in the microenvironment of the joint, but this issue has not been resolved, and the mediators of neo-ossification await identification. Dysregulation of the wnt/β-catenin pathway may play a key role in the ankylosing process. Synovial histopathology in SpA is characterized by abundant neutrophils, macrophages, and hypervascularity, whereas in RA the prominent features are lymphoid aggregates, dendritic cells, lining cell hyperplasia, and citrullinated proteins. These differences suggest that SpA reflects a fundamental alteration in innate immunity, whereas RA reflects dysregulation of adaptive immunity.

TREATMENT

General Measures

The SpAs necessitate a global approach to management in which education of patients is the cornerstone. Because the typical onset is during young adulthood, with a male preponderance, these patients may experience significant frustration or depression if their acute arthritis evolves into a chronic disease that significantly impairs their functional capabilities and quality of life. A clinician managing patients with SpA should be aware that these psychosocial aspects are an important part of the burden of illness. Similarly, there may be important implications for the workplace, particularly if a job demands significant bending or twisting. It is important to include the mechanical demands of the workplace in the global assessment of patients with SpAs.

Exercise is an important part of the treatment plan for patients with AS. Generally, high-impact sports should be avoided, whereas swimming is an

HLA = human leukocyte antigen.

ideal exercise. Stretching to maintain mobility and maintenance of posture should be emphasized, and an experienced physiotherapist can greatly assist in instructing patients in daily exercises. Long car trips and air travel should include periodic stretching. Sleep position should emphasize a straight back position rather than one curled on the side. Deep breathing exercises and avoidance of cigarettes should be stressed.

One key area of concern for patients is prognosis, because the SpAs, particularly ReA, often occur in young, active individuals for whom athletic activity is a priority. There is general recognition that ReA has a greater propensity for chronicity than was previously appreciated, and this should temper an overly optimistic projection of the disease's natural history. At the 5-year follow-up of a cohort of patients with *Salmonella*-induced ReA, two thirds continued to have subjective complaints, and one third demonstrated objective changes in their joints. The variability in prognosis for the large group of patients falling into the USpA group is perplexing. At present, there is a lack of reliable predictors of progression in patients with this heterogeneous cluster of articular and extra-articular features.

Medical Therapy

Nonsteroidal Anti-inflammatory Drugs

In general, joint inflammation in the SpAs improves significantly after the introduction of nonsteroidal anti-inflammatory drugs (NSAIDs). Indomethacin and diclofenac (up to 200 mg/day in divided doses) or naproxen (up to 1000 mg/day in divided doses) are generally well tolerated in this population. These agents have to be used with caution in EA because of concern about exacerbating the underlying inflammatory bowel disease. In the case of AS, the goal with anti-inflammatory treatment is to achieve sufficient relief of pain and stiffness to allow an active, sustained program of exercise and physical activity that maintains posture and improves quality of life. Whether NSAIDs have disease-modifying capability has not been definitively resolved.

Corticosteroids

The response to the intra-articular injection of steroids in the peripheral joints of patients with SpA is often neither as dramatic nor as sustained as in those with RA. Corticosteroid injection into the sacroiliac joints is usually performed under imaging guidance (fluoroscopy or computed tomography [CT]). One study found that such injections resulted in a good response in 79% of patients and that the improvement could persist for many months. Systemic corticosteroids (either orally or via an intravenous bolus protocol) have been used for severe symptomatic flares, but controlled trials to validate their effectiveness are lacking. The goal should be prompt tapering of the dose when symptomatic control is achieved. The recognition that osteoporosis (Chapter 251) is a significant problem in AS provides further impetus to use corticosteroids sparingly. Topical steroids are usually effective for the treatment of the mucous membrane and skin manifestations of ReA. For uveitis, topical corticosteroid eye drops are an integral component of management, and treatment should be monitored jointly with an ophthalmologist.

Sulfasalazine

Randomized, placebo-controlled trials have provided some support for the use of sulfasalazine (SSZ), particularly in PsA. Three 36-week, randomized, double-blind multicenter studies of patients with AS, PsA, and ReA, respectively, were undertaken to compare SSZ (2 g/day) with placebo in each case. The different response rates in the placebo arms of these trials highlight the variability in the clinical course of the SpAs. An analysis of these studies stratified the patients into those having axial disease and those having peripheral disease. In patients with only axial disease, response criteria were met equally in the SSZ group and the placebo group. In patients with peripheral arthritis, responses were seen in 59% of the SSZ group and 43% of the placebo group ($P < .0005$). These findings are useful in guiding the selection of patients for SSZ treatment.

Methotrexate

Concurrent with the widespread use of methotrexate (MTX) in patients with RA, there has been increasing use of MTX in patients with SpA. Generally, responses have been good, particularly for peripheral joint disease, but few controlled trials have been conducted to substantiate these clinical impressions. There is no evidence that MTX changes the course of axial diseases in AS. Experience with long-term MTX therapy in 38 patients with PsA has been reported, and despite an improvement in joint count, there was no evidence of a slowing of radiographic progression. Long-term follow-up may be required to resolve whether MTX has a joint-sparing effect in PsA.

Other Disease-Modifying Agents

There have been several therapeutic approaches to the control of PsA, including chloroquine, intramuscular gold, and cyclosporine, all of which show some clinical efficacy; however, long-term studies are needed to evaluate these drugs more comprehensively. The response of SpA patients to SSZ may be attributable to the antibiotic moiety of this compound (sulfapyridine) or to the anti-inflammatory moiety (5-aminosalicylic acid). An open study of intravenous pamidronate for refractory AS showed significant improvement in disease activity scores, but the current impression is that this agent is less effective than the anti–tumor necrosis factor agents (see later).

Antibiotic Therapy

The current concept of the pathogenesis of ReA postulates that a bacterial infection, usually gastrointestinal (GI) or genitourinary (GU), is the triggering event in an immunogenetically susceptible host. For the other SpAs, there is less compelling evidence that infection plays a causal role. It is sound clinical practice to treat any culture-proven chlamydial urethritis in conjunction with treatment of the sexual partner. For this indication, a single 1-g dose of azithromycin is as effective as doxycycline 100 mg twice a day for 7 days. The role of antibiotics in the management of SpA has been controversial. An earlier retrospective review concluded that 37% of episodes of urethritis not treated with anti-*Chlamydia* agents were associated with subsequent ReA, whereas only 10% of such episodes progressed to ReA when treated with tetracycline. In a 3-month, double-blind, placebo-controlled study of chronic ReA, lymecycline significantly decreased the duration of illness in patients with *Chlamydia*-induced ReA but not in patients with ReA triggered by enteric pathogens. Two controlled trials demonstrated no significant difference between ciprofloxacin and placebo in ReA and undifferentiated oligoarthritis. Ciprofloxacin was not effective in *Yersinia*- or *Salmonella*-induced ReA, but there was a trend toward a response in *Chlamydia*-induced ReA. A study examining azithromycin in the treatment of SpA found no convincing evidence of disease-modifying potential. A recent report compared rifampin/azithromycin, rifampin/doxycycline, and placebo for chronic *Chlamydia*-induced ReA and observed that tender and swollen joint counts responded more significantly to the combination antibiotics than to placebo. The precise role of antibiotic agents in this clinical situation has not yet been finalized.

Anti–Tumor Necrosis Factor Therapy

The role of immunomodulatory cytokines in the pathogenesis of SpA has been controversial. Some studies have implicated a genetic polymorphism associated with the relative impairment of tumor necrosis factor-α (TNF-α) production as an AS susceptibility marker, but not all studies have supported this notion. Biologic agents, such as monoclonal antibodies to TNF-α (infliximab, adalimumab, golimumab) or the soluble TNF receptor (etanercept), have been used in the treatment of SpA. So far, these four anti-TNF agents have been comparably effective in trials of AS and PsA and appear to be better than antibiotics. These studies generally reported a prompt response in clinical outcome measures and in laboratory indicators of inflammation, and MRI evaluations have shown improvement in local inflammation in the sacroiliac joints and spine. The anti-TNF treatments have been well tolerated, with no significant incidence of serious adverse events, but patients appear to relapse

when treatment is discontinued. Experience with longer-term treatment with anti-TNF agents (>2 years) has been encouraging with regard to the persistence of the therapeutic effect and the infrequency of late adverse events. These biologic agents have been shown to retard radiographic progression in PsA, but whether anti-TNF treatments can alter the progressive ankylosis of AS over the long term awaits further study. The objective improvements seen on MRI provide hope that these agents may alter the long-term outcomes of AS structurally as well as functionally.

GENETIC SUSCEPTIBILITY

DEFINITION

The major histocompatibility complex (MHC), on the short arm of chromosome 6 in humans, is one of the most polymorphic regions of the human genome (Chapter 45). This is particularly so for the B locus, which constitutes part of the class I MHC genes in this complex. More than 200 different alleles have been detected at this locus, of which B27 is just one. As with all HLA alleles, there is codominant expression of B locus genes, such that most individuals who are B27 positive are heterozygous for the B locus. There appears to be little clinical or prognostic significance associated with the less common homozygous B27 state. The conventional role of class I HLAs is to present a processed peptide to the T-cell receptor of a specific $CD8^+$ cytotoxic T cell, thereby initiating an immune response against the pathogen from which that peptide was derived by intracellular proteolysis and processing. This function gives the HLAs a critical role in host defense against pathogens, and the heterogeneity of cellular immune responses is alleged to be an advantage for a species (such as humans) with an extensive polymorphism region of the genome. This idea has led to the concept that infectious diseases have driven allelic polymorphisms in the MHC. Such a hypothesis postulates a selective advantage in the extensive peptide-binding capabilities conferred by different alleles of the B locus, but there may also be disadvantages.

Recent genome-wide association studies in AS have identified additional genetic markers of susceptibility for AS. Polymorphisms in the *IL-23R* gene are associated with AS, and these particular variants are the same as those seen in inflammatory bowel disease and psoriasis. Thus the clinical convergence of these different diseases, well known to clinicians, now appears to have a common genetic element. Polymorphisms in the endoplasmic reticulum aminopeptidase (ERAP) gene constitute the strongest genetic risk factor for AS after HLA-B27. ERAP plays a key role in trimming peptides in the endoplasmic reticulum before loading these peptide complexes onto a nascent class I MHC molecule. This finding continues to attribute a central role to MHC class I peptide presentation in the pathogenesis of AS.

EPIDEMIOLOGY

It is clear that HLA is strongly associated with the SpAs, yet the prevalence of HLA-B27 varies widely in different racial and ethnic clusters around the world. It is virtually absent in aboriginal populations in Australia, occurs in 1% of the population in Japan, in 7% in northern European countries, and in 50% in some of the native tribes in western Canada. The environmental-genetic interaction that may account for the expansion or restriction of this gene in human populations is unknown, but some evidence indicates that B27 may confer a more effective host response to some viruses. This variability has a practical impact for the clinician. Because the relative risk conferred by a gene reflects the prevalence of the gene in affected individuals versus its prevalence in the normal population, the relative risk for SpAs is higher in a population in which the gene is uncommon (e.g., Japan) than in a population in which B27 is more common (e.g., Scandinavia). In the North American white population, the prevalence of the gene is approximately 7%. Thus, there is a 7% "false-positive" rate if one is attempting to use the gene as a diagnostic marker to decipher the cause of chronic back pain in an unselected population of patients. In contrast, 90% of patients with AS are B27 positive, so there is a 10% "false-negative" rate when using the test diagnostically. The key factor is pretest probability. In a patient with chronic back pain that is clearly inflammatory in character, the addition of B27 positivity combines to strengthen the likelihood of AS accounting for the back problem. The presence of distinctive extra-articular features (e.g., uveitis) further increases this likelihood.

It is believed that the prevalence of AS in various parts of the world closely parallels the prevalence of B27 in that population, and in general, this pattern is valid. What introduces complexity into this concept is the recognition that there are more than 30 subtypes of B27. HLA-B2705 is regarded as the primordial subtype, with variability developing over time on the basis of alterations in genomic DNA. Some subtypes, notably B2706 and B2709, do not seem to confer increased susceptibility to the development of AS. This observation has led to a search for "arthritogenic peptides" that are presented by the disease-associated subtypes such as B2705 and B2704 but not by the non-disease-associated subtypes. To date, no simple peptide-susceptibility relationship has been demonstrated, but this is an important clue to the pathogenic role of B27, and studies are ongoing to explore this relationship.

Other steps have also been taken to define the mechanism whereby B27 confers disease susceptibility in addition to that of uniquely presenting an arthritogenic peptide to T cells. According to the theory of molecular mimicry, an autoimmune response can ensue after an infection if the immune response against the pathogen cross-reacts with host antigens. There is a degree of sequence homology between B27 and several candidate gram-negative enteric bacteria, and there is evidence for cross-reacting monoclonal antibodies, but the significance of such homology for disease pathogenesis remains unresolved. It has also been argued that B27 is distinctive in its propensity to misfold in the endoplasmic reticulum, which may induce a pro-inflammatory cascade called the *unfolded protein response*. Furthermore, B27 may have a distinct tendency to form heavy chain homodimers at the cell surface, and the possible consequences of this change for the immune response are under investigation. There has also been investigation into the alteration of primary host-pathogen interactions, such as modulation of pathogen invasion, intracellular replication, and clearance. However, no definitive allele-specific relationships have been demonstrated in these studies.

In B27 transgenic rats, the spontaneous development of pathology strikingly similar to human SpAs has supported the notion that B27 itself is the critical genetic factor in disease pathogenesis. These animals demonstrate pathology similar to that of Crohn's disease in the GI tract, spondylitis, peripheral arthritis, uveitis, and psoriasiform skin and nail changes. Of interest, if such animals are raised in a germ-free environment, there is a marked reduction in joint and gut disease, implying a dynamic interrelationship between microbial triggers and background host genes that seems to recapitulate the situation seen clinically.

Genome-wide screening studies of multiplex families with SpAs, particularly AS, are ongoing in several countries to identify other genes involved in the predisposition to these diseases. The strongest association of SpA to date remains with the HLA complex, so at least in familial AS, B27 may to a certain extent be necessary (but not sufficient) to confer disease susceptibility. MRI studies in asymptomatic B27-positive individuals indicate that there is a much higher prevalence of sacroiliitis than previously recognized, and studies are continuing to define that prevalence and indeed the prevalence of SpAs in the general population. Some investigators have concluded that SpAs are as common as RA.

CLINICAL SUBSETS OF THE SPONDYLOARTHROPATHIES

Ankylosing Spondylitis

EPIDEMIOLOGY

AS is the most common inflammatory disorder of the axial skeleton. The following is a useful rule of thumb: AS occurs in 0.2% of the general population, in 2% of the B27-positive population, and in 20% of B27-positive individuals with an affected family member. There is a male preponderance in the disease, with the male-to-female ratio ranging from 2.5 : 1 to 5 : 1; however, recent epidemiologic studies have found less female involvement than these estimates indicate. The basis for the gender bias has not been resolved. It is held, however, that AS is underrecognized in women, perhaps because of milder axial disease and a more delayed disease onset, but alternative diagnoses of pelvic and low back pain in women may hinder clinician awareness of the disease in female patients.

CLINICAL MANIFESTATIONS

AS typically begins in young adulthood, but symptoms may arise in adolescence or earlier. Up to 15% of children with juvenile chronic polyarthritis are classified as having juvenile AS. Such children may have a pauciarticular pattern, with a predilection for the tarsal joints and frequently minimal axial complaints. During the adolescent years there is an increasing prevalence of radiographic sacroiliitis, with a significant proportion of patients manifesting this feature by the end of the teenage years. At the other end of the age spectrum, a small number of patients with late-onset AS may have sacroiliitis and oligoarthritis. The axial involvement and asymmetrical lower extremity

TABLE 273-3 MODIFIED NEW YORK CRITERIA FOR ANKYLOSING SPONDYLITIS (1984)

CLINICAL CRITERIA
Low back pain and stiffness for >3 mo that improve with exercise but are not relieved by rest
Limitation of motion of the lumbar spine in both sagittal and frontal planes
Limitation of chest expansion
RADIOLOGIC CRITERIA
Sacroiliitis: grade ≥2 bilateral *or* grade 3 or 4 unilateral
GRADING
Definite AS if the radiologic criterion is associated with at least one clinical variable
Probable AS if:
The three clinical criteria are present
The radiologic criterion is present without the clinical criteria

AS = ankylosing spondylitis.

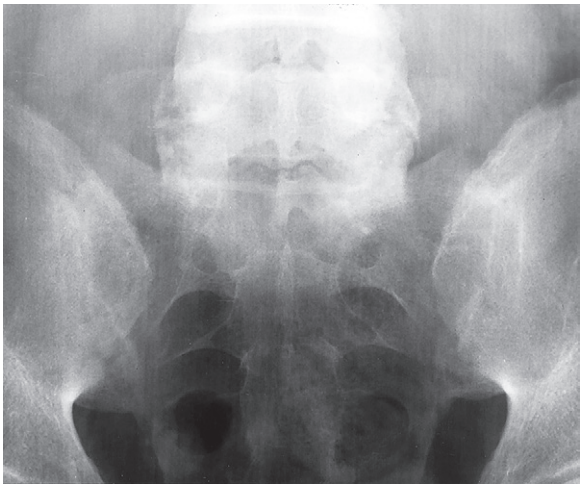

FIGURE 273-2. Bilaterally symmetrical sacroiliitis in ankylosing spondylitis.

involvement may serve to differentiate such patients from those with late-onset RA, although there may be overlapping clinical features. Recent studies indicate that the rate of radiographic progression may be less in juvenile-onset AS than in adult-onset AS.

The classic manifestation of AS is the onset of low back pain that persists for more than 3 months, is accompanied by early-morning stiffness, and is typically improved by exercise (Table 273-3). An extensive discussion of the differential diagnosis of low back pain is presented in Chapter 407. Some investigators would include a response to NSAID therapy as an additional feature differentiating AS from mechanical low back pain. Back pain that awakens the patient from sleep is often a clue to inflammatory back pain that may have been misdiagnosed as the pain of degenerative disc disease, the latter being a much more common cause of low back pain in the population at large. The pain typically occurs in the region of the sacroiliac joints, with or without slight radiation to the buttock area. Mid-thoracic pain and cervical pain, particularly at night, are less common but strongly suggest inflammatory back pain when they occur. Fatigue is also a suggestive symptom and is often highlighted by the typical young male patient, who sets a high functional norm in terms of sports and recreation. If the inflammation is inadequately controlled, there is increasing stiffness, which may persist most of the day, as well as progressive loss of mobility and flexibility.

Peripheral oligoarthritis is seen in up to 30% of patients with AS. Typically, it is an asymmetrical oligoarthritis with a predilection for the lower extremities. It is important to ask about concurrent or previous tendinitis (e.g., Achilles tendinitis) or heel pain (e.g., plantar fasciitis) because either may reflect an enthesitis that is part of the clinical picture. Involvement of the hip can occur at any point in the course of AS and can follow a course to joint destruction. A hip flexion contracture on this basis may contribute to increasing stoop on standing and walking, which may otherwise be attributed to spinal involvement in the disease.

Extra-articular features primarily involve the eye. Ocular involvement may occur in up to 40% of AS patients, most typically acute anterior uveitis (iritis). The uveitis often manifests as a slight impairment in visual acuity, with accompanying photophobia and eye pain. Typically, it is unilateral and recurrent. Inflammatory bowel disease and psoriasis occur in approximately 10% of AS cohorts. Less common manifestations include aortic insufficiency, cardiac conduction defects, and pulmonary fibrosis.

DIAGNOSIS

Physical Examination

Physical examination of the spine characteristically indicates restricted movement, which in the early stages may reflect paraspinal muscle spasm in part; late in the course it reflects ankylosis of the zygapophyseal joints and syndesmophyte bridging of the vertebral bodies. Forward flexion is restricted and can be monitored by measuring the finger to floor distance on bending forward. Schober's test is used to measure mobility in the lower part of the back: with the patient standing upright, a 10-cm span is marked from the fifth lumbar vertebra upward. On maximal forward flexion, the distance between the marks is remeasured. With normal spinal mobility, the flexed distance should register as 15 cm, or an increment of 5 cm. Thoracic involvement is measured in chest expansion, with the chest circumference at maximal inspiration being more than 5 cm greater than the circumference at maximal expiration. Changes in cervical mobility can be measured as the occiput to wall distance, with the patient's heels against the wall as the patient attempts to touch the back of the head to the wall. Restricted spinal mobility early in the course of the disease may best be detected by lateral spinal flexion, measured as the difference in the finger to floor distance when standing erect compared with maximal bending to the side. Inflammation in the sacroiliac joint may be reflected by joint line tenderness to direct pressure or by the fabere or Gaenslen maneuver. In the former, the patient lies supine while the examiner flexes and externally rotates the hip. In the latter, the examiner extends the hip by letting the leg dangle off the side of the examining table. In both cases, stress is placed on the sacroiliac joint and may reproduce the back pain if it derives from this site.

Laboratory Findings

Laboratory tests in the evaluation of inflammatory back pain are relatively nonspecific. The erythrocyte sedimentation rate and C-reactive protein are typically elevated, but normal levels do not exclude inflammatory back pain, and the degree of elevation is typically less than would be seen in acute RA. Anemia of chronic disease may be observed if the condition is long-standing. Serum immunoglobulin A levels may be elevated, but autoantibodies are notable for their absence. HLA-B27 is rarely the definitive factor for diagnosis, and the false-positive and false-negative rates have already been discussed; however, in the setting of characteristic back symptoms, the test has reasonably high sensitivity and specificity.

Imaging

Radiographic assessment is important for confirmation of disease, but early in the course there may be no radiographic changes in the sacroiliac joints. If the clinician has a high index of suspicion in such cases, MRI may improve the sensitivity of the plain radiograph because inflammatory changes on MRI predate radiographic changes. When ordering x-rays, specific views of the sacroiliac joints should be requested because the obliquity of the joint renders it difficult to assess on a routine anteroposterior pelvic radiograph. The classic findings are bilateral changes in the sacroiliac joints (Fig. 273-2). Abnormalities include erosions in the joint line, pseudowidening, subchondral sclerosis, and, finally, ankylosis, reflecting complete bony replacement of the sacroiliac joints.

Radiographs of the spine may reveal squaring of the vertebral bodies (loss of the normal anterior concavity of the lumbar vertebra) and "shiny corners" (subchondral sclerosis at the upper edge of the vertebral body), both of which are manifestations of enthesitis. Syndesmophytes, which represent marginal bridging of the vertebrae (Figs. 273-3 and 273-4), eventually develop and make the diagnosis clear. Because ankylosis of the apophyseal joints may occur without syndesmophyte formation, it is important to assess the posterior joints on the lateral lumbosacral spine views, as well as the anterior margin of the vertebrae. Eventually, the changes may result in a "bamboo spine," so called because the bridging syndesmophytes can mimic the appearance of bamboo. It is now appreciated that osteoporosis (Chapter 251) is a significant feature of AS, probably reflecting both the local chronic

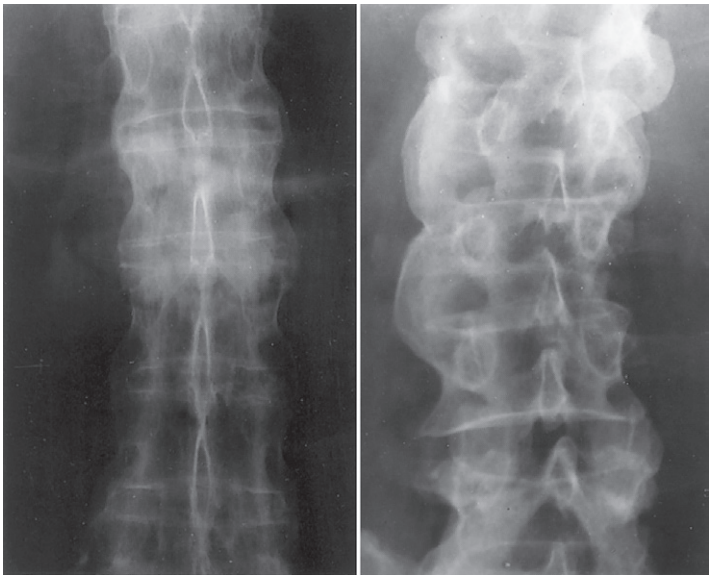

FIGURE 273-3. *Left,* Lumbar spondylitis in ankylosing spondylitis with symmetrical, marginal bridging syndesmophytes and calcification of the spinal ligament. *Right,* The bulky, nonmarginal, asymmetrical syndesmophytes of reactive arthritis with lumbar spondylitis.

FIGURE 273-4. A 34-year-old man who has had ankylosing spondylitis for 9 years and neck pain. Radiographs demonstrate narrowing of the C2-C3 apophyseal joints posteriorly and anterior bridging marginal syndesmophytes extending from C2 to C5.

inflammation and the abnormal biomechanical loading of the vertebrae as the disease progresses.

Differential Diagnosis

The differential diagnosis of AS includes the other SpAs; osteitis condensans ilii; diffuse idiopathic skeletal hyperostosis; the syndrome of synovitis, acne, pustulosis, hyperostosis, and osteomyelitis (SAPHO); and some induced hyperostotic states (vitamin A intoxication, fluorosis). New bone formation occurs in degenerative disc disease, but the bulky, horizontal appearance of osteophytes is easily distinguished from that of syndesmophytes, and narrowing of the disc space is not a feature of AS. Osteoarthritis of the sacroiliac joint has recently been recognized as having a higher prevalence than previously appreciated.

The clinical course and severity of AS are highly variable. Inflammatory back pain and stiffness dominate the picture in the early stages, whereas chronic pain and deformity may develop over time. In both early and late phases of the disease there may be a significant impact on work disability and quality of life. In only a minority of patients does the full-blown picture of a bamboo spine eventually develop, but there are few variables that can reliably aid in prognosticating the course. At present, the strongest predictor of new syndesmophyte formation is the presence of syndesmophytes at baseline. In AS patients in whom new, refractory spinal pain develops, an intervertebral fracture should be considered, which can occur after only minimal trauma.

Additional late complications may include cauda equina syndrome, osteoporotic compression fractures, spondylodiscitis, and restrictive lung disease.

Reactive Arthritis

DEFINITION

ReA is an aseptic arthritis that occurs subsequent to an extra-articular infection, most typically of the GI or GU tract. In the former, the key pathogens are *Salmonella typhimurium, Yersinia enterocolitica, Shigella flexneri,* and *Campylobacter jejuni.* In the latter, *Chlamydia trachomatis* is the most common offender.

EPIDEMIOLOGY

The true incidence and prevalence of ReA are not well defined. In epidemics involving *Salmonella* (Chapter 316) or *Yersinia* (Chapter 320), it is estimated that ReA develops in 2 to 7% of infected individuals but in as many as 20% of B27-positive infected individuals. In such epidemic studies, B27 confers risk not only for the onset of arthritis but also for axial involvement and chronicity. Genetic variants in Toll-like receptor 2 (TLR-2) are associated with acute ReA, thus implicating host innate immunity as central in ReA. The variability in the rate of ReA is determined by the heterogeneity of the cohorts reported, which introduces confounding variables of different genetic backgrounds in the population and different species of pathogens. Even in the setting of an epidemic point source outbreak, the inoculum varies widely among the exposed individuals, and the genetic makeup of the population at risk (e.g., the prevalence of B27) may differ greatly among different studies. Case ascertainment and relative risk are even more difficult to determine for post-*Chlamydia* ReA. Young adults in the United States have a high prevalence of asymptomatic *Chlamydia* carriage in the GU tract, and establishing a causal link between *Chlamydia* and synovitis can be difficult. Nevertheless, it is with *Chlamydia* that ReA has been most intensively studied.

PATHOBIOLOGY

Although immunofluorescence studies have identified bacterial antigens in the joints of patients with ReA after both GI and GU infections, it is primarily in post-*Chlamydia* ReA that results of polymerase chain reaction studies on synovial tissues have most consistently been positive, suggesting that viable *Chlamydia* may persist in the joints of such patients, albeit in a metabolically altered state.

Typically, the onset of arthritis occurs 1 to 3 weeks after the GI or GU infection, but the temporal details are often difficult to define precisely.

Although the definition of aseptic arthritis after an extra-articular infection may include a broader range of pathogens (e.g., *Chlamydia pneumoniae*), sites of infection (e.g., streptococcal pharyngitis), and types of infections (e.g., *Giardia* infections of the GI tract), these clinical scenarios have not generally been included in the category of ReA. They lack the other associated clinical features of the SpA group of diseases, and they lack an association with B27.

DIAGNOSIS

The pattern of joint involvement in ReA is one of asymmetrical oligoarthritis with a predilection for the lower extremity, a pattern shared by most SpA syndromes. Enthesitis may present as Achilles tendinitis or plantar fasciitis. Dactylitis, appearing as a sausage digit, may also be seen. Dactylitis is the net result of inflammatory changes affecting the joint capsule, entheses, periarticular structures, and periosteal bone. Sacroiliitis may be seen in the acute phase, but radiographic changes are seen largely in patients with a more chronic course.

When ReA is accompanied by certain extra-articular features such as urethritis, conjunctivitis, or mucocutaneous lesions, the term *Reiter's syndrome* has been applied historically, but it is no longer in common use. The urethritis may manifest as dysuria or discharge and the rash as circinate balanitis, which appears as vesicles or shallow ulcerations on the glans penis. Painless lingual or oral ulcerations may also be seen. The fact that the cervicitis may be less symptomatic could partially account for the underdiagnosis in women. The classic skin manifestation of ReA is keratoderma blennorrhagicum, a painless papulosquamous eruption on the palms or soles (Fig. 273-5). Occasionally,

nail dystrophy with pitting and onycholysis or subungual keratosis can be seen. The conjunctivitis can be bilateral and painful; in contrast, the acute anterior uveitis that can also be seen in this setting tends to be less painful and unilateral.

Radiographic changes of ReA can be seen in the involved peripheral joints, with early findings consisting of soft tissue swelling and juxta-articular osteopenia. Areas of periostitis and new bone formation may develop in peripheral joints. When changes in the sacroiliac joints are seen, they are typically asymmetrical (Fig. 273-6), in contrast to the symmetrical pattern seen in AS. In the chronic phase, syndesmophytes may develop, but they are described as bulky, nonmarginal, often asymmetrical formations that differ from the classic syndesmophytes of AS. The frequency with which ReA evolves into bona fide AS has not been determined definitively.

Differential Diagnosis

The most important differential diagnosis for such reactive arthropathies is septic arthritis. Both *Yersinia* and *Salmonella* can induce septic arthritis, so an appropriate culture of synovial fluid should precede the diagnosis of ReA whenever possible. The course of ReA is variable, and few prognostic markers are available for the clinician to predict the course in an individual case. The majority of patients have an initial episode lasting 2 to 3 months, but synovitis may persist for a year or longer. In one 5-year follow-up of a point source cohort of post-*Salmonella* ReA, 20% of patients had ongoing inflammatory joint disease, and some degree of functional disability was observed in 30% of patients 5 years after the onset of disease.

FIGURE 273-5. Keratoderma blennorrhagicum of the feet in reactive arthritis.

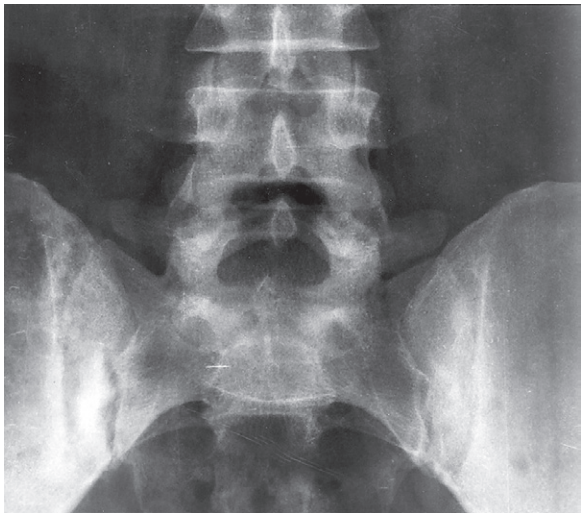

FIGURE 273-6. Bilaterally asymmetrical sacroiliitis in reactive arthritis. Erosions, pseudowidening, and ileal sclerosis are present.

REACTIVE ARTHRITIS AND HUMAN IMMUNODEFICIENCY VIRUS

An aggressive form of SpA may be seen in patients who are concomitantly infected with human immunodeficiency virus (HIV). There is no increased frequency of ReA in patients with HIV, but HIV may alter the course of these arthropathies, with a tendency for a more aggressive and more refractory joint disease. Aggressive skin and joint disease may be seen in patients in whom PsA develops in the setting of HIV infection. Most North American patients with the HIV-ReA constellation are B27 positive, but studies of comparable patients in Africa have found a sizable B27-negative component in such patients. The arthritis in these patients falls into two clinical patterns: (1) an additive, asymmetrical polyarthritis or (2) an intermittent oligoarthritis that most commonly affects the lower extremities. Enthesitis, fasciitis, conjunctivitis, and urethritis can all be seen in such patients. Sacroiliitis can occur, although extensive spinal syndesmophyte formation is not common.

Psoriatic Arthritis

EPIDEMIOLOGY

PsA develops in 5 to 7% of patients with psoriasis. Although most cases arise in patients with established cutaneous disease, some patients (particularly children) have arthritis that antedates the appearance of the skin lesions. Although the extent of psoriatic skin disease correlates poorly with the development of arthritis, the risk for PsA increases with a family history of SpA. The age at onset can range from 30 to 55 years, with an equal predilection for PsA in women and men. Psoriatic spondylitis has a slight male preponderance.

PATHOBIOLOGY

The genetic associations with PsA are complex. Psoriasis itself is associated with several HLA loci; some B alleles have been reported, but the dominant element is HLA-Cw6. HLA-B39 and HLA-B27 have been associated with sacroiliitis and axial involvement. No etiologic agent has been proved in PsA, although some investigators have proposed that the disease process represents ReA in response to cutaneous bacteria. The histopathology of the synovitis of PsA is comparable to that of the other SpAs, with the absence of the local production of immunoglobulin and rheumatoid factor differentiating this disease from RA. There is the potential for aggressive osteolysis, fibrous ankylosis, and heterotopic new bone formation to occur in PsA. As mentioned earlier, the coexistence of HIV and PsA seems to set the stage for an aggressive course of joint destruction in some patients.

DIAGNOSIS

PsA has a variable manifestation and disease course, but several clinical patterns have been identified in prospectively monitored cohorts of patients. The clinical subsets are not mutually exclusive, nor are they static over time. The most common form, which affects 30 to 50% of patients, is an asymmetrical oligoarthritis that may involve both large and small joints. Dactylitis, arising as sausage digits, can be seen in fingers and toes and actually represents an enthesitis. In the second subset there is selective targeting of the distal interphalangeal joints, seen in 10 to 15% of patients. These changes are strongly associated with nail dystrophy, of which the features are onycholysis, subungual keratosis, pitting, and oil drop–like staining (Fig. 273-7). The third

FIGURE 273-7. Nail pitting in psoriasis. The pits are more discrete and regular compared with pits affecting the nail plate in dermatitis.

subset (15 to 30% of patients) has a symmetrical polyarthritis that mimics RA in many ways, except for the absence of rheumatoid nodules and rheumatoid factor. The fourth clinical variant is psoriatic spondylitis, which occurs in 20% of patients; 50% of such patients are B27 positive. Finally, arthritis mutilans (5% of patients) is a destructive, erosive arthritis that affects large and small joints and can be associated with marked deformities and significant disability.

Radiographic changes in PsA involve soft tissue swelling (particularly in the case of dactylitis), erosions, and periostitis. Axial involvement may lead to the appearance of asymmetrical sacroiliitis with syndesmophytes that are bulky, asymmetrical, and nonmarginal. The classic "pencil-in-cup" deformity may be seen in patients with distal interphalangeal joint disease or arthritis mutilans. Acro-osteolysis is noted in a minority of patients and reflects an aggressive erosive process.

Differential Diagnosis

The diagnosis of PsA depends on finding the typical skin or nail changes in association with one of the articular variants described previously. The differential diagnosis for the skin lesions can include seborrheic dermatitis, dyshidrotic eczema, fungal infection, keratoderma blennorrhagicum, and palmoplantar pustulosis.

TREATMENT

Rx

Patients typically receive aggressive treatment for psoriasis (Chapter 446). The advent of biologic agents has had a major impact on the treatment of PsA. The anti-TNF agents have been studied most extensively, indicating the efficacy of infliximab, etanercept, adalimumab, and golimumab. In a study of patients with PsA, ustekinumab, a monoclonal antibody against interleukin-12/23, was well tolerated, reduced the extent and severity of psoriasis, and was safe.■

Enteropathic Arthritis

DEFINITION

EA refers to the arthritis associated with Crohn's disease (CD) or ulcerative colitis (UC) (Chapter 143; Table 273-4).

PATHOBIOLOGY

All extraenteric manifestations, including arthritis, occur more commonly in CD than in UC. Peripheral arthritis occurs in 10 to 20% of CD patients and in 2 to 7% of UC patients. This pattern of arthritis occurs more commonly in patients with other extraenteric features (e.g., erythema nodosum, iritis). It is typically an inflammatory, nonerosive polyarthritis, predominantly of large joints. In general, the clinical activity of the peripheral arthritis parallels the activity of the gut inflammation, and measures that control the GI disease usually control the joint disease as well. The peripheral arthritis of EA is not associated with B27. As mentioned earlier, both inflammatory bowel disease and AS share genetic susceptibility associated with genetic variants of *IL23-R*.

In contrast, the sacroiliitis or spondylitis of EA follows a pattern in which the joint inflammation waxes and wanes independently of the bowel inflammation. Axial disease occurs in 2 to 7% of both CD and UC patients. HLA-B27 is found in 50% of patients with axial arthritis. The course tends to be chronic, as opposed to the transient course of peripheral arthritis.

The association of bowel inflammation and arthritis is supported by ileocolonoscopic studies in which subclinical inflammation of the bowel has been demonstrated in diseases covering the entire spectrum of SpAs. Histologic evaluation demonstrates that changes of acute ileitis are seen in postdysenteric ReA, whereas chronic inflammatory changes are more likely to be seen in patients with AS. As mentioned earlier, the abnormalities in the bowel of B27 transgenic rats have strong similarity to the lesions of CD, and a germ-free environment minimizes inflammatory changes in both the gut and the joints. This finding argues that altered bowel permeability, with enhanced bacteremia or antigenemia, may provide the link in both cases.

DIAGNOSIS

It is important to recognize that the musculoskeletal features of EA may precede any GI symptoms or signs. Conversely, the diarrhea preceding the onset of peripheral or axial arthritis in a young patient could just as likely represent a food-borne pathogen (e.g., *Salmonella, Yersinia*), with secondary ReA as inflammatory bowel disease and accompanying EA. In the initial assessment of such a patient, it is important to carry out careful and complete stool cultures. If the GI symptoms persist, diagnostic colonoscopy is often required to resolve the issue.

TABLE 273-4 ENTEROPATHIC ARTHRITIS

FEATURE	PERIPHERAL ARTHRITIS	SACROILIITIS, SPONDYLITIS
CROHN'S DISEASE (CD)		
Frequency in CD	10–20%	2–7%
HLA-B27 associated	No	Yes
Pattern	Transient, symmetrical	Chronic
Course	Related to activity of CD	Unrelated to activity of CD
Effect of surgery	Remission of arthritis uncommon	No effect
Effect of anti-TNF therapy	Effective	Effective
ULCERATIVE COLITIS (UC)		
Frequency in UC	5–10%	2–7%
HLA-B27 associated	No	Yes
Pattern	Transient	Chronic
Course	More common in pancolitis than proctitis; related to activity of UC	Unrelated
Effect of surgery	Remission of arthritis	No effect

HLA = human leukocyte antigen; TNF = tumor necrosis factor.

Undifferentiated Spondyloarthropathy

Despite careful clinical and radiographic assessment, there are still a substantial number of patients who do not fall into one of the classic diagnostic subsets of SpA outlined previously. These patients are often defined as having USpA with peripheral enthesitis, asymmetrical arthritis or sacroiliitis, or iritis in the absence of identifiable antecedent infection or concurrent inflammatory bowel disease or psoriasis. The natural history of USpA has not been well defined, and case heterogeneity and diagnostic dilemmas plague a systematic or multicenter approach to the problem. When the clinical course is examined, a number of patients may finally meet the diagnostic criteria for AS, but many retain a distinct USpA pattern for prolonged periods.

SYSTEMIC LUPUS ERYTHEMATOSUS

MARY K. CROW

DEFINITION

Systemic lupus erythematosus (SLE) is a multisystemic autoimmune disease that results from immune system–mediated tissue damage. Manifestations of SLE can involve the skin, joints, kidney, central nervous system (CNS), cardiovascular system, serosal membranes, and the hematologic and immune systems. The disease is highly heterogeneous, with individual patients manifesting variable combinations of clinical features. In most patients with SLE, the disease is characterized by a waxing and waning clinical course, although some demonstrate a pattern of chronic activity. The molecular triggers of the disease are not known, but the pathogenesis is understood to involve the production of autoantibodies exhibiting multiple specificities, with reactivity with nucleic acid–binding proteins being a common feature. Immune complexes, along with immune system cells and soluble mediators, generate inflammation and tissue damage. Therapeutic approaches generally involve immunosuppression.

EPIDEMIOLOGY

A notable feature of SLE is that it occurs much more frequently in females than in males. Like Hashimoto's thyroiditis and Sjögren's syndrome, the female-to-male ratio is approximately 8 : 1 to 9 : 1 in adults, and most cases are diagnosed between the ages of 15 and 44 years. In children and women older than 55, the ratio is closer to 2 : 1. The prevalence of SLE is estimated to be approximately 124 per 100,000 in the United States, and the incidence of new cases is 1.8 to 7.6 per 100,000 per year. The prevalence, severity, and characteristics of disease differ in different ethnic groups, with SLE being three to four times more frequent in African Americans than in the white population. The severity of disease is also greater in Hispanics than in whites, although data for Hispanic populations are less abundant. Asians may also have a higher prevalence of disease than whites. Recent studies of lupus in minority populations indicate that socioeconomic factors are major contributors to the increased prevalence and severity of disease in African Americans and Hispanic Americans.

PATHOBIOLOGY

Current understanding of lupus pathogenesis incorporates roles for genetic susceptibility based on a threshold model involving multiple genes; environmental triggers, including microbial infection, sunlight, and certain drugs; and altered immune system function. Recent advances in immunology have focused attention on the mechanisms that account for innate immune system activation. At least some of the genetic and environmental contributions to lupus are likely to promote innate immune system activation and subsequent autoimmunity. Others may contribute to inflammation and tissue damage.

Murine models have proved useful in identifying genes that could contribute to lupus susceptibility or define patterns of disease. Production of autoantibodies characteristic of SLE and development of nephritis and accelerated death have been demonstrated in numerous murine strains in which immune system genes have been modified. In most cases, no alterations have been noted in the homologous human genes. The ease of induction of lupus-like disease in murine models suggests that there are numerous possible pathogenic paths that might lead to the clinical manifestations of lupus. It is not known which of these molecular pathways is responsible for human SLE.

Genetics

An important role for a genetic contribution to lupus susceptibility is suggested by the high concordance of disease in monozygotic twins (14 to 57%).

TABLE 274-1 GENES ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS

GENE*	PROTEIN
BANK1	B-cell scaffold protein with ankyrin repeats 1
BLK	B-lymphocyte–specific tyrosine kinase
C1QA, B, and *C*	Complement component C1q
C2	Complement component 2
C4A and *C4B*	Complement component C4
CRP	C-reactive protein
DRB11501	MHC class II (DR2)
DRB10301	MHC class II (DR3)
FCGR2A	Activating FcγRIIA
FCGR3A	Activating FcγRIIIA
IRF5	Interferon regulatory factor 5
ITGAM	Mac1/complement receptor 3
IRAK1	Interleukin-1 receptor–associated kinase 1
LYN	Lyn tyrosine kinase
PTPN22	Protein tyrosine phosphatase nonreceptor type 22
STAT4	Signal transducer and activator of transcription 4
TNFAIP3	A20
TNFSF4	Ox40 ligand
TREX1	DNase III

*Genes listed have an odds ratio of ≥1.3.
MHC = major histocompatibility complex.

Genes that might account for increased lupus susceptibility or severity include those encoding components of the complement pathway, including C1q, C2, and C4A (Table 274-1). Impaired production of these early complement components may decrease the clearance of apoptotic cells, thereby augmenting the pool of available autoantigens, or decrease the solubility of immune complexes. Polymorphic variants in components of the toll-like receptor (TLR) pathways that regulate type I interferon production, including interferon regulatory factor 5 *(IRF5)*, have been associated with a diagnosis of SLE and increased plasma interferon activity in some populations. Association of SLE with the major histocompatibility complex (MHC) class II alleles human leukocyte antigen (HLA)-DR2 and HLA-DR3 has been documented in many studies and is most striking in patients expressing particular autoantibody specificities. Polymorphisms in the Fc receptor genes *FCGR2A* and *FCGR3A* have been associated with SLE nephritis, possibly based on altered clearance of immune complexes. Variants of the *PTPN22* gene, which encodes a phosphatase that regulates T-cell activation, are also associated with SLE. Genome-wide association studies have expanded the list of lupus-associated gene variants to include regulators of innate immune system activation *(TNFAIP3, ITGAM, IRAK1)* and signaling molecules important in lymphocyte activation *(STAT4, BANK1, BLK,* and *LYN)*. Rare mutations in the *TREX1* gene, encoding a DNase, have been documented in some patients with lupus-like disease and high levels of interferon. The available data suggest a common theme: the genes that have been associated with lupus confer either increased activation or impaired regulation of the innate or adaptive immune responses, with increased type I interferon often observed in association with the risk genotype.

Environmental Triggers

Several classes of potential environmental triggers for lupus have been studied. Although the female preponderance of SLE implies a role for hormonal factors in the disease, recent concepts describe a possible contribution of epigenetic modification or dosage effects of the X chromosome as accounting for at least some of the sex skewing. A role for microbial triggers, particularly virus infection, has been postulated consistent with the constitutional symptoms that often characterize the earliest stage of the disease. Epstein-Barr virus has garnered particular interest among investigators because the frequency of previous infection in SLE patients is significantly higher than in the general population (99 vs. 94%). Evidence of exposure to other viruses, including cytomegalovirus, is equivalent between SLE patients and healthy

control subjects. Ultraviolet light exposure is a well-described trigger of lupus flares. Possible mechanisms include DNA damage and induction of apoptosis of skin cells, which result in concentration of nucleic acids and associated proteins in cell membrane blebs and increased processing by antigen-presenting cells. Data also support an association between current tobacco use and anti-double-stranded DNA antibodies and lupus disease activity. Certain drugs, including procainamide and hydralazine, can induce a lupus-like syndrome, but the symptoms usually abate after discontinuing use of the drug. These agents may promote demethylation of DNA, thereby increasing the availability of immunostimulatory DNA. Sulfa antibiotics have been reported to induce lupus flare in some patients. Administration of recombinant interferon-α to patients with hematologic malignancies or hepatitis C infection has been associated with induction of a lupus-like syndrome. In addition, anti–tumor necrosis factor agents have induced lupus autoantibodies and occasionally clinical lupus in patients with rheumatoid arthritis.

Immunologic Triggers

Genetic and environmental factors that increase the probability of development of SLE are likely to act on the immune system to induce autoimmunity and consequent tissue inflammation and damage. In addition to mechanisms that increase the availability of self-antigens, such as ultraviolet light, altered expression of gene products that mediate or regulate apoptosis, or impaired clearance of apoptotic debris, results in generalized activation of the immune system and contributes to autoimmunity in lupus. In parallel with the events that account for effective immune responses directed at exogenous microbes, the autoimmunity that occurs in SLE patients is likely to require activation of both innate and adaptive immune responses. The innate immune response is first activated by common molecular patterns expressed on the microbe and results in augmented antigen-presenting cell capacity and successful generation of an antigen-specific adaptive immune response. The characterization of the TLR family of pattern recognition receptors has provided new understanding of the mechanisms through which the innate immune system is activated by exogenous and endogenous stimuli, including nucleic acid–containing immune complexes, and promotes induction of a self-directed adaptive immune response.

Type I Interferon

Recent studies of gene expression in peripheral blood mononuclear cells of SLE patients using microarray technology have demonstrated that activation of genes regulated by type I interferon is a common feature in patients with active disease and may represent innate immune system activation. Interferon-α is gaining attention as a soluble mediator that may be responsible for many of the immunologic alterations that have been observed in SLE and is identified as a potential therapeutic target. Immune complexes containing DNA or RNA are postulated to contribute to the production of type I interferon in SLE. Demethylated CpG-rich DNA or RNA associated with nucleic acid–binding proteins can activate plasmacytoid dendritic cells and other immune system cells through TLRs and thereby result in the production of type I interferon (interferon-α or -β) and other proinflammatory cytokines (E-Fig. 274-1). Diverse effects of type I interferon on immune system function are consistent with the altered immune responses observed in SLE patients, including maturation of dendritic cells, increased immunoglobulin (Ig) class switching to mature immunoglobulin isotypes (IgG and IgA), and induction of soluble mediators that increase B-cell differentiation and inflammatory responses, such as B-lymphocyte stimulator (BLyS) and interferon-γ. Induction of an immunostimulatory microenvironment by interferon-α may support the development of a humoral immune response directed at self-antigens, particularly intracellular particles that contain nucleic acids and nucleic acid–binding proteins. It is not known why some individuals initiate immune system activation directed at self-antigens and others do not.

Autoantibodies

The most characteristic lupus autoantibodies target intracellular particles containing both nucleic acid and nucleic acid–binding proteins. Understanding the significance of induction of these particular autoantibody specificities may provide clues to the etiology of SLE. A recent analysis of the spectrum of autoantibodies present in the sera of individuals in whom SLE is later diagnosed has suggested that autoantibodies reactive with certain RNA-binding proteins, including the Ro protein, occur early in the preclinical stage of the disease, along with a positive antinuclear antibody (ANA) test. These are often followed by anti-DNA antibodies and, finally, by the development of antibodies specific for the spliceosomal proteins Smith (Sm) and ribonucleoprotein (RNP) at approximately the time of diagnosis (Fig. 274-1). These observations suggest that individuals who demonstrate progression from a narrow focus of humoral immunity to proteins associated with RNA to antibodies that bind DNA and other specificities are those in whom sufficient autoimmunity develops to manifest clinical symptoms. Approximately one third of SLE patients have autoantibodies reactive with phospholipids or the proteins associated with them, particularly β_2-glycoprotein I (β_2GPI). These autoantibody specificities can also be present independently of SLE in primary antiphospholipid antibody syndrome (Chapter 177).

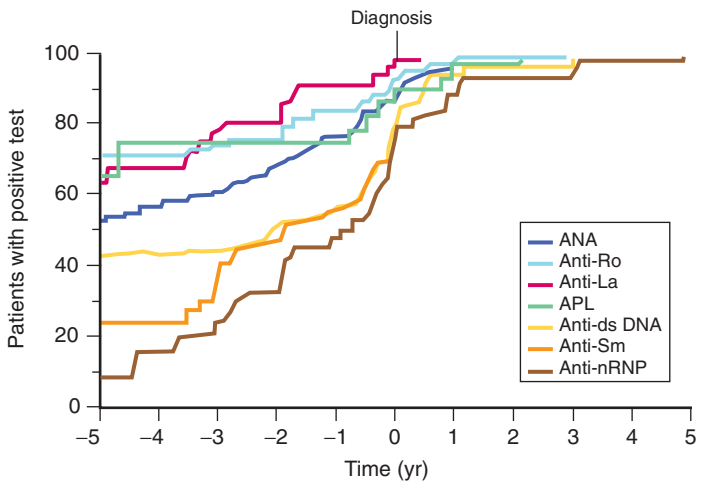

FIGURE 274-1. Proportion of patients with positive antibody tests relative to the time of diagnosis or appearance of the first clinical manifestation of systemic lupus erythematosus (SLE). For each autoantibody, the proportion of patients testing positive relative to the time of diagnosis or to the time of appearance of the first clinical criterion was assessed. In analyses of the time from antibody development to the diagnosis of SLE, antinuclear antibodies (ANAs) appeared significantly earlier than anti-Sm antibodies ($Z = 3.22$, $P < .001$) and antinuclear ribonucleoprotein (anti-nRNP) antibodies ($Z = 4.18$, $P < .001$), but not significantly earlier than anti-Ro, anti-La, antiphospholipid (APL), or anti-double-stranded DNA antibodies (anti-dsDNA). (From Arbuckle MR, McClain MT, Rubertone MV, et al. Development of autoantibodies before the clinical onset of systemic lupus erythematosus. *N Engl J Med.* 2003;349:16.)

Immune Complexes and Complement

Tissue and organ damage in SLE is mediated by the deposition or in situ formation of immune complexes and subsequent complement activation and inflammation. The complement system (Chapter 49), composed of more than 30 proteins that act in concert to protect the host against invading organisms, initiates inflammation and tissue injury. Complement activation promotes chemotaxis of inflammatory cells and generates proteolytic fragments that enhance phagocytosis by neutrophils and monocytes. The classic pathway is activated when antibodies bind to antigen and generate potent effectors. Alternative pathway activation mechanisms differ in that they are initiated by the binding of spontaneously activated complement components to the surfaces of pathogens or self-tissues. C3a, an anaphylatoxin that binds to receptors on leukocytes and other cells, causes activation and release of inflammatory mediators. C5a is a potent soluble inflammatory, anaphylatoxic, and chemotactic molecule that promotes recruitment and activation of neutrophils and monocytes and mediates endothelial cell activation through its receptor. The release of reactive oxygen and nitrogen intermediates is an additional mechanism that contributes to tissue damage.

Tissues targeted by immune system activity in lupus include the skin, where immune complexes and complement are deposited in a linear pattern (as demonstrated in the lupus band test, in which deposited antibodies are identified by a fluorescent tag), the glomeruli, and heart valves. Recent data also suggest that antibodies reactive with hippocampal neurons in the brain can mediate excitotoxic death. Immune and inflammatory mechanisms responsible for the vasculopathy of lupus are multifactorial and not clearly defined. Microvascular damage is observed in splenic arteries and is characterized by the typical onion-skin pattern of concentric connective tissue deposition. In addition to vascular damage mediated by inflammation, thrombosis, including microthrombi, contributes to ischemia and cell necrosis in the brain and other organs.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Constitutional Symptoms

SLE is a disease that involves virtually all components of the immune system and can be accompanied by constitutional symptoms similar to those seen in the setting of microbial infection. Fatigue, headaches, weight loss, and fevers are common, along with generalized arthralgias, myalgias, and lymphadenopathy. The level of activity of lupus typically follows a pattern of flares and remissions, although some patients sustain active disease for prolonged periods. Careful monitoring for the development of major organ system disease is important to ensure timely adjustments in medical therapy.

Cutaneous and Mucous Membranes

The skin and mucous membranes are affected in most lupus patients (Table 274-2). The erythematous facial rash with a butterfly distribution across the malar and nasal prominences and sparing of the nasolabial folds is the classic rash of SLE and is seen in 30 to 60% of patients (Fig. 274-2). The butterfly rash is often triggered by sun exposure, but photosensitivity can also be demonstrated diffusely in other areas of the body.

TABLE 274-2 CLINICAL MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

MANIFESTATION	APPROXIMATE FREQUENCY (%)
Cutaneous	88
Arthritis/arthralgias	76
Neuropsychiatric	66
Pleurisy/pericarditis	63
Anemia	57
Raynaud's phenomenon	44
Vasculitis	43
Atherosclerosis	37
Nephritis	31
Thrombocytopenia	30
Sensorimotor neuropathy	28
Cardiac valvar disease	18
Pulmonary alveolar hemorrhage	12
Pancreatitis	10
Myositis	5
Myocarditis	5

FIGURE 274-2. Malar rash in a patient with systemic lupus erythematosus. Note that the rash does not cross the nasolabial fold. (From Gladman DD, Urowitz MB. Systemic lupus erythematosus: clinical features. In: Klippel JH, Dieppe PA, eds. *Rheumatology*, 2nd ed. London: Mosby; 1998.)

The discoid skin lesions are erythematous plaques with central scarring and may be covered with scale. These lesions are seen in about 25% of patients, involve the scalp or the face and ears, and may be associated with alopecia. Discoid lesions can be present in the absence of systemic manifestations of SLE *(discoid lupus)*. In addition to the scarring alopecia of discoid lupus, more transient alopecia may be a clinical sign of increased disease activity and is associated with apoptosis of cells in the hair follicle.

Inflammation of the deep dermis and subcutaneous fat can result in lupus panniculitis, with firm painful nodules that sometimes adhere to the epidermis causing irregularities in the superficial skin. Subacute cutaneous lupus erythematosus is seen in sun-exposed areas and can involve erythematous plaques or psoriasiform lesions. It is associated with autoantibodies to the Ro (SSA) RNA-binding protein. Mucosal ulcerations, especially of the buccal mucosa and upper palate, result from mucositis and are typical of SLE. Manifestations of vasculopathy are also common in SLE, including arteriolar spasm or infarcts in the nail folds, a diffuse lacey pattern over the skin described as livedo reticularis, and petechial-purpuric or urticarial lesions on the extremities. Vasculopathy in SLE is often associated with the presence of antiphospholipid antibodies.

Musculoskeletal System

Arthralgias and nonerosive arthritis are among the most common clinical features of SLE and are experienced by more than 85% of patients. The proximal interphalangeal and metacarpophalangeal joints of the hand are most commonly symptomatic, along with the knees and wrists. In some patients (about 10%), deformities resulting from damage to periarticular tissue can occur, a condition termed *Jaccoud's arthropathy.* The heavy use of corticosteroids in many lupus patients can be accompanied by the development of osteoporosis, including osteoporotic fractures, or osteonecrosis, most commonly of the hips, although the underlying vasculopathy can also contribute to joint damage.

Inflammation of the muscles with elevated creatine phosphokinase can occur rarely in SLE, and myopathy may be observed as a consequence of corticosteroid therapy. Fibromyalgia, characterized by painful trigger points at characteristic locations, commonly accompanies SLE and can contribute to fatigue and depression.

Renal System

Kidney involvement in SLE is common, with 74% of patients being affected at some time in the course of disease, and is a poor prognostic indicator. Renal pathology is generally attributed to the deposition of circulating immune complexes or in situ formation of these complexes in glomeruli and results in the activation of complement and subsequent recruitment of inflammatory cells. In addition to glomerular inflammation, necrosis, and scarring, renal pathology is characterized by vascular lesions, including thrombotic microangiopathy and extraglomerular vasculitis, and tubulointerstitial disease, including tubular atrophy and interstitial fibrosis. Hypertension may be a consequence of significant renal involvement.

Most cases of lupus nephritis present a complex immunopathologic picture, but, in general, the pattern of renal disease reflects the site of deposition of immunoglobulins and the quality of the effector mechanisms they induce. Mesangial deposition of immunoglobulin induces mesangial cell proliferation and is associated with microscopic hematuria and mild proteinuria (Fig. 274-3). Subendothelial deposition of immune complexes results in proliferative and exudative inflammation, together with hematuria, mild to moderate proteinuria, and reduced glomerular filtration rate. Subepithelial deposition of immune complexes adjacent to podocytes and along the glomerular basement membrane can result in membranous nephritis with nephrotic-range proteinuria. In addition, antiphospholipid antibodies may support the development of thrombotic or inflammatory vascular lesions within or external to glomeruli.

A World Health Organization classification of lupus nephritis lesions was first published in 1975 with subsequent revisions. These classifications were reviewed and rigorously reexamined in the revised International Society of Nephrology and Renal Pathology Society classification criteria for lupus glomerulonephritis (GN) (Table 274-3). Class I and II GN involves mesangial deposition of immune complexes (class I without and class II with mesangial hypercellularity), class III describes focal GN involving less than 50% of total glomeruli, class IV includes diffuse GN involving 50% or more of glomeruli, class V designates membranous lupus nephritis, and class VI is characterized by advanced sclerotic lesions. Classes III and IV have subdivisions for active and sclerotic lesions, and class IV also has subdivisions for segmental and

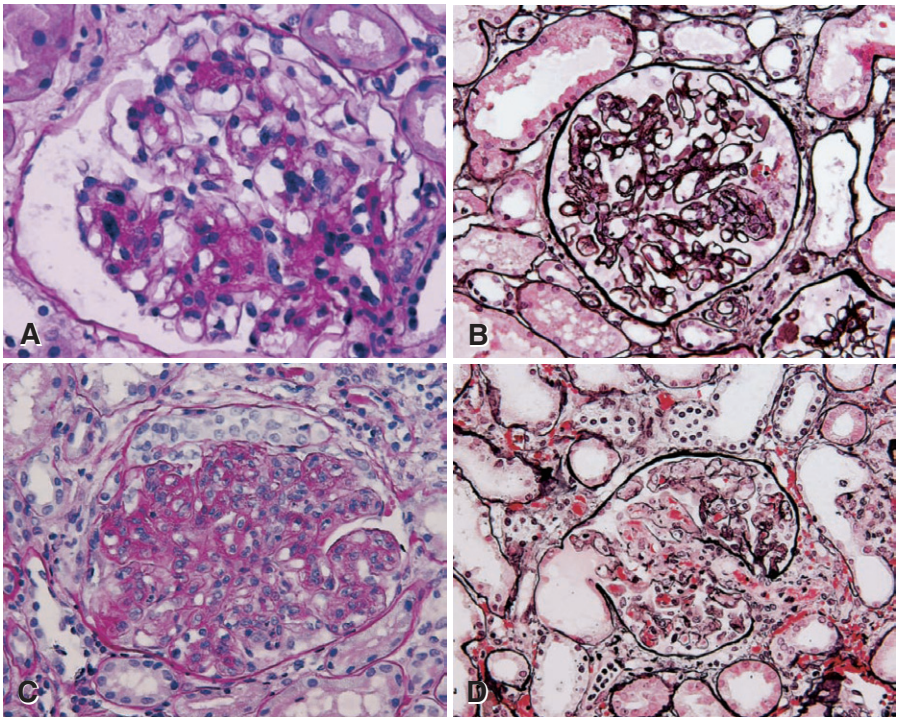

FIGURE 274-3. Histopathology of lupus nephritis. A, Lupus nephritis class II. A light micrograph of a glomerulus shows mild mesangial hypercellularity (periodic acid–Schiff). **B,** Lupus nephritis class III (A). Light micrograph showing a glomerulus with segmental endocapillary hypercellularity, mesangial hypercellularity, capillary wall thickening, and early segmental capillary necrosis (methenamine silver). **C,** Lupus nephritis class IV-G (A/C). A glomerulus manifests global endocapillary proliferation, leukocyte influx and apoptotic bodies, double contours, crescent formation with tubular transformation, early sclerosis, and disruption of Bowman's capsule (periodic acid–Schiff). **D,** Thrombotic microangiopathy in a patient with systemic lupus erythematosus and circulating anticoagulant. A glomerulus shows severe capillary and arteriolar thrombosis, endothelial cell swelling and necrosis, neutrophil influx, and stasis of erythrocytes. No signs of immune deposits were found (methenamine silver). (From Wenning JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol*. 2004;15:241.)

TABLE 274-3 INTERNATIONAL SOCIETY OF NEPHROLOGY/RENAL PATHOLOGY SOCIETY 2003 CLASSIFICATION OF LUPUS NEPHRITIS

Class I	**Minimal mesangial lupus nephritis** Normal glomeruli by light microscopy, but mesangial immune deposits by immunofluorescence
Class II	**Mesangial proliferative lupus nephritis** Purely mesangial hypercellularity of any degree or mesangial matrix expansion by light microscopy, with mesangial immune deposits. May be a few isolated subepithelial or subendothelial deposits visible by immunofluorescence or electron microscopy, but not by light microscopy
Class III	**Focal lupus nephritis*** Active or inactive focal, segmental, or global endocapillary or extracapillary glomerulonephritis involving <50% of all glomeruli, typically with focal subendothelial immune deposits, with or without mesangial alterations
Class III (A)	Active lesions: focal proliferative lupus nephritis
Class III (A/C)	Active and chronic lesions: focal proliferative and sclerosing lupus nephritis
Class III (C)	Chronic inactive lesions with glomerular scars: focal sclerosing lupus nephritis
Class IV	**Diffuse lupus nephritis**† Active or inactive diffuse, segmental or global endocapillary or extracapillary glomerulonephritis Involving ≥50% of all glomeruli, typically with diffuse subendothelial immune deposits, with or without mesangial alterations. This class is divided into diffuse segmental (IV-S) lupus nephritis when ≥50% of the involved glomeruli have segmental lesions and into diffuse global (IV-G) lupus nephritis when ≥50% of the involved glomeruli have global lesions. Segmental is defined as a glomerular lesion that involves less than half of the glomerular tuft. This class includes cases with diffuse wire loop deposits but with little or no glomerular proliferation.
Class IV-S (A)	Active lesions: diffuse segmental proliferative lupus nephritis
Class IV-G (A)	Active lesions: diffuse global proliferative lupus nephritis
Class IV-S (A/C)	Active and chronic lesions: diffuse segmental proliferative and sclerosing lupus nephritis Active and chronic lesions: diffuse global proliferative and sclerosing lupus nephritis
Class IV-S (C)	Chronic inactive lesions with scars: diffuse segmental sclerosing lupus nephritis
Class IV-G (C)	Chronic inactive lesions with scars: diffuse global sclerosing lupus nephritis
Class V	**Membranous lupus nephritis** Global or segmental subepithelial immune deposits or their morphologic sequelae by light microscopy and by immunofluorescence or electron microscopy, with or without mesangial alterations Class V lupus nephritis may occur in combination with class III or IV, in which case both will be diagnosed Class V lupus nephritis shows advanced sclerosis
Class VI	**Advanced sclerosis lupus nephritis** ≥90% of glomeruli globally sclerosed without residual activity

*Indicate the proportion of glomeruli with active and with sclerotic lesions.
†Indicate the proportion of glomeruli with fibrinoid necrosis and/or cellular crescents.
From Weening JJ, D'Agati VD, Schwartz MM, et al. The classification of glomerulonephritis in systemic lupus erythematosus revisited. *J Am Soc Nephrol*. 2004;15:241.

global involvement. Pathologic diagnosis should include descriptions of tubulointerstitial and vascular disease as well as glomerular involvement.

The prognosis of class I and class II disease is usually good, whereas class IV, the most common form of lupus nephritis, has the worst prognosis, particularly when the serum creatinine level is elevated at the time of diagnosis. Class V nephritis occurs in 10 to 20% of patients, and the implication for long-term outcome depends on the degree of proteinuria, with mild proteinuria having a good prognosis and nephrotic syndrome with chronic edema having a more negative prognosis. It should be noted that renal veins can occasionally become involved with thrombosis, which then

contributes to nephrotic syndrome. This complication can be evaluated by renal ultrasound.

Cardiovascular System

Pericarditis and valve nodules were among the first clinical manifestations described in SLE. It is only recently that the extent of premature atherosclerotic disease has been well documented. Pericarditis (Chapter 77) is the most common cardiac manifestation, but it is sometimes recognized only on imaging studies or at autopsy. It is a component of the generalized serositis that is often a feature of SLE and is associated with local autoantibodies and immune complexes. Pericarditis is usually manifested as substernal chest pain that is improved by bending forward and can be exacerbated by inspiration or coughing. The symptoms and effusions associated with pericarditis are quite responsive to moderate-dose (20 to 30 mg/day of prednisone) corticosteroid treatment.

Structural valve abnormalities in SLE range from sterile nodules originally described by Libman and Sacks to nonspecific valve thickening. The nodules are immobile and usually located on the atrial side of the mitral valve and sometimes on the arterial side of the aortic valve. Right-sided lesions are rare. These structural changes may in some cases result in valvular regurgitation. Although valve nodules are detected in most patients with SLE at autopsy, clinically significant valvular heart disease is much less common (1 to 18%). The verrucous valvular lesions of Libman and Sacks are most likely inflammatory in nature and may be associated with the presence of antiphospholipid antibodies.

Premature and accelerated atherosclerosis is increasingly recognized as being prevalent in lupus patients, and preclinical atherosclerotic carotid plaque has been documented in 37% of SLE patients as opposed to 15% of age- and sex-matched controls. Traditional cardiovascular risk factors apply, but the diagnosis of SLE is itself a significant risk factor for premature atherosclerosis. Although the lupus-specific mechanisms that confer additional risk for atherosclerosis have not been defined, it is likely that chronic inflammation associated with immune system activation contributes to the accumulation of vascular damage. Mortality from atherosclerosis may be up to 10 times greater in patients with SLE than in age- and sex-matched controls.

Although not specific to SLE, Raynaud's phenomenon (Chapter 80), characterized by episodic vasospasm and occlusion of the digital arteries in response to cold and emotional stress, is a feature in up to 60% of SLE patients and contributes to pain and sometimes necrosis of the distal ends of extremities. The character of the digits classically changes from pallor to cyanosis and then to rubor as vascular perfusion becomes impaired. In addition, small arteries, arterioles, and capillaries can be affected by vasculitis and fibrinoid necrosis with clinical manifestations that include periungual telangiectases, abdominal pain, and neuropsychiatric symptoms.

Pulmonary System

Pleuritis is the most frequent manifestation of pulmonary involvement in SLE and occurs in about 30% of patients at some point in their disease course. Pleuritis is characterized by pain on respiration and exudative effusions. Parenchymal disease is less common but may be based on several distinct mechanisms, including pneumonitis in the absence of documented infection and sometimes involving alveolar hemorrhage (in up to 12% of patients), pulmonary embolism secondary to peripheral thrombosis, or pulmonary hypertension with increased pulmonary resistance and impaired diffusing capacity.

Neuropsychiatric Involvement

Clinical features of SLE that involve the nervous system include both neurologic and psychiatric manifestations. The central and peripheral nervous systems can be affected by the disease. The American College of Rheumatology has identified 19 neuropsychiatric syndromes that can be associated with SLE, and validation of these neuropsychiatric findings has been substantiated in several independent studies (Table 274-4). The most common manifestations that are probably attributable to SLE cerebritis include cognitive dysfunction, present in 17 to 66% of SLE patients; psychosis or mood disorder, the former reported in up to 8% of patients; cerebrovascular disease in 5 to 18% of patients; and seizures, present in 6 to 51% of patients. Headaches are also common. Because none of these CNS manifestations are found exclusively in SLE, it can be difficult to be certain that a neuropsychiatric complaint or symptom can be attributed to SLE.

Evaluation of neuropsychiatric lupus depends on a careful clinical history and physical and laboratory examinations and, in some cases, imaging studies and analysis of cerebrospinal fluid to rule out infection. Magnetic resonance imaging is useful for detecting intracranial abnormalities, which are seen in 19 to 70% of patients and include white matter lesions, cerebral infarction, venous sinus thrombosis, and sometimes atrophy. More sophisticated imaging techniques such as magnetic resonance angiography and magnetic resonance spectroscopy can be used to assess cerebral blood flow or neuronal metabolism.

Cranial nerve and ocular involvement, most likely based on vasculopathy and focal ischemia, can sometimes affect vision. Ocular examination of the retina can reveal cotton-wool spots as a result of retinal ischemia or necrosis. Although rare, transverse myelopathy, frequently associated with antiphospholipid antibodies, can have devastating consequences, including paraplegia. Sensorimotor neuropathies, often asymmetrical, are more common (up to 28%) and are based on damage to small nerve fibers with vasculopathy in the small arteries that supply the nerve fibers.

As is the case with lupus nephritis, the pathophysiologic mechanisms that account for the neuropsychiatric manifestations of SLE are diverse and complex. Recent data suggest that autoantibodies cross-reactive with neuronal cell surface glutamate receptors and DNA may mediate excitotoxic death of neurons and are proposed to contribute to cognitive dysfunction. Antibodies directed against ribosomal P protein have also been associated with neuropsychiatric lupus, and antiphospholipid antibodies can contribute to a procoagulant state, vascular thrombosis, and cerebral ischemia. Cerebral vasculopathy has been clearly demonstrated by angiographic and pathologic studies. Noninflammatory small vessel vasculopathy is the most common lesion and can be associated with microinfarcts. Inflammatory mediators, including the cytokines interleukin-6 and interferon-α, and matrix metalloproteinases may also contribute to the neuropsychiatric manifestations of SLE.

Gastrointestinal System

Although uncommon, vasculitis of the gastrointestinal tract or mesentery can result in pain and bowel necrosis. Less common than pleuritis and pericarditis, peritonitis can manifest as peritoneal effusion and abdominal pain. Pancreatitis occurs in less than 10% of patients but may also be due to vascular pathology. Lupoid hepatitis, a syndrome that was named for the presence of positive ANAs in patients with chronic active hepatitis, is a misnomer because elevated transaminases are only rarely seen in lupus patients.

Lymphadenopathy

About one third of SLE patients demonstrate diffuse lymphadenopathy at some time during the course of their disease. The nodes are often nontender, and lymphoma is sometimes considered in the differential diagnosis. Biopsy usually reveals follicular hyperplasia, although some histopathologic findings

appear similar to the histiocytic necrotizing lymphadenitis that is a feature of Kikuchi's disease, a self-limited syndrome characterized by fever and lymphadenopathy. Recent multicenter studies have determined the frequency of malignancies in patients with SLE and have found a significant increase in hematologic malignancies, particularly non-Hodgkin's lymphoma. Splenomegaly is sometimes seen in SLE, and spleen pathology is characterized by a classic onion-skin histology that appears as concentric circles of collagen matrix surrounding splenic arteries and arterioles.

Hematologic System

In addition to autoantibody specificities that are fairly specific for SLE (anti-DNA, anti-Sm), antibodies that target each of the cellular blood elements are also common. Anemia is present in about 50% of patients and is multifactorial. It can be associated with a positive Coombs' test or microangiopathic hemolysis (Chapter 163) or reflect chronic disease (normochromic, normocytic) (Chapter 161). Leukopenia, particularly lymphopenia, is observed, with the lymphocyte count decreasing in the setting of increased disease activity. Antibodies that bind to lymphocytes and neutrophils have been described, and an increased tendency for lymphocytes to undergo spontaneous apoptosis may contribute to lymphopenia. Idiopathic thrombocytopenic purpura (Chapter 175) can be an early manifestation of SLE, and thrombocytopenia, induced by antiplatelet antibodies, can sometimes lead to a life-threatening risk for hemorrhage. Antibodies to clotting factors can also occur and contribute to impaired clot formation and hemorrhage.

Lupus Pregnancy and Neonatal Lupus

Whether pregnancy increases the likelihood of lupus exacerbation has been debated, with differences on this point presented by different investigators. However, abundant data indicate that patients with SLE have worse fetal outcomes than healthy individuals. Gestational hypertension, fetal growth restriction, and fetal distress are increased in patients with SLE and may lead to fetal loss or premature delivery. Preeclampsia can contribute to a poor outcome in both the mother and fetus and can be difficult to distinguish from a lupus flare associated with lupus nephritis.

Neonatal lupus is a distinct entity that can occur in infants of mothers with or without a diagnosis of SLE. The syndrome is characterized by cutaneous lesions and congenital heart block in the infant and the presence of antibodies to the Ro (SSA) or La (SSB) RNA-binding proteins (or both) in the mother. Mortality in babies with a congenital heart block is 15 to 31%. Deposition of anti-Ro IgG in the fetal heart, indicative of transplacental transfer of maternal autoantibody, and dense connective tissue encompassing the conduction system have been demonstrated in autopsy specimens. Prenatal testing of lupus mothers for the presence of anti-Ro and anti-La antibodies is appropriate, and careful monitoring with fetal echocardiography starting at week 16 of pregnancy can detect conduction defects. Fluorinated corticosteroids such as dexamethasone have been effective in reversing heart block in some cases.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibodies represent a distinct class of autoantibodies that are seen in about one third of SLE patients but can also be present in individuals who do not carry a diagnosis of SLE (Chapter 174). Although these antibodies were initially thought to be specific for phospholipids exposed in cell membranes, particularly after "flipping" of the membranes of apoptotic cells, extensive data support their primary reactivity with phospholipid-binding proteins, particularly β_2GPI. Whether in primary antiphospholipid syndrome or in SLE, antiphospholipid antibodies have been associated with venous and arterial thromboses. In addition to vascular thromboses, clinical manifestations of antiphospholipid syndrome include thrombotic microangiopathic glomerular disease, cardiac valve lesions, livedo reticularis, thrombocytopenia, hemolytic anemia, and CNS disease. Recent data indicate that these autoantibodies can contribute to fetal loss and growth restriction by binding to the placenta, activating the complement system, and inducing inflammation. Catastrophic antiphospholipid syndrome, triggered by the acute onset of multisystemic (three or more organs) thrombosis, is resistant to anticoagulation treatment and is fatal in approximately 50% of cases.

DIAGNOSIS

Classification

Criteria for the classification of patients with SLE for the purpose of clinical studies were developed by the American College of Rheumatology, with the most recent full revision published in 1982 and an update published in 1997 (Table 274-5). The criteria include 11 features that encompass manifestations of skin and mucosal involvement, arthritis, serositis, renal disorder, neurologic disorder, hematologic disorder, immunologic disorder, and an abnormal titer in the ANA test, with at least four criteria required for classification as SLE. ANA has low specificity but strengthens the sensitivity of the

TABLE 274-5 UPDATE OF THE 1982 REVISED CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

CRITERION*	DEFINITION
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences that tends to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Rash as a result of unusual reaction to sunlight, by history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving 2 or more peripheral joints and characterized by tenderness, swelling, or effusion
6. Serositis	A. Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion *or* B. Pericarditis—documented by electrocardiography, a rub, or evidence of pericardial effusion
7. Renal disorder	A. Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation is not performed *or* B. Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	A. Seizures—in the absence of offending drugs or known metabolic derangements; e.g., uremia, ketoacidosis, or electrolyte imbalance *or* B. Psychosis—in the absence of offending drugs or known metabolic derangements; e.g., uremia, ketoacidosis, or electrolyte imbalance
9. Hematologic disorder	A. Hemolytic anemia—with reticulocytosis *or* B. Leukopenia—less than 4000/mm^3 total on 2 or more occasions *or* C. Lymphopenia—less than 1500/mm^3 on 2 or more occasions *or* D. Thrombocytopenia—less than 100,000/mm^3 in the absence of offending drugs
10. Immunologic disorder	A. Deleted in 1997 update B. Anti-DNA: antibody to native DNA in abnormal titer *or* C. Anti-Sm: presence of antibody to Sm nuclear antigen *or* D. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or the fluorescent treponemal antibody absorption test (modified in the 1997 update)
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

*The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical studies, a person shall be said to have systemic lupus erythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

From Tan EM, Cohen AS, Fries JF, et al. The 1982 revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum.* 1982;25:1271.

criteria because it is positive in virtually all lupus patients. These criteria are not intended for use as diagnostic criteria because more than 50% of patients with SLE do not meet four criteria at any point in time, although all do meet these criteria at some point during the course of the disease. The criteria are useful in reminding the clinician of the most characteristic features of SLE, but a careful history with detailed review of systems and triggering factors, as well as a family history, is essential in raising suspicion for a diagnosis of SLE. Because drugs can trigger a lupus-like syndrome, a careful drug history should be taken. Procainamide and hydralazine present the greatest risk for development of lupus, with quinidine, isoniazid, minocycline, and recombinant interferon-α presenting a lower risk. At the onset of clinical symptoms, the diagnosis of SLE can be uncertain because many of the systemic manifestations of lupus can mimic other conditions, particularly viral infections or malignancy, and only some of the typical clinical symptoms may be expressed at any one point in time. Important features of SLE are its multisystemic nature and characteristic serology. The differential diagnosis of SLE includes other rheumatic disorders, such as rheumatoid arthritis and vasculitis; infections, including gonococcal arthritis, parvovirus B19, and mononucleosis; inflammatory bowel disease; thrombotic thrombocytopenic purpura; drug reactions; and malignancies, particularly lymphoma.

Laboratory Findings

Laboratory tests can be very helpful in supporting the diagnosis of SLE. All cellular elements of blood can be affected in lupus, so the complete blood count is an essential test that aids in diagnosis and management. A prolonged activated partial thromboplastin time (aPTT) can indicate the presence of pathogenic antiphospholipid antibodies (Chapter 174). These antibodies are also associated with a false-positive result in the serologic test for syphilis, an observation that is mainly of historical interest.

Evaluation of renal disease in SLE includes urinalysis with microscopic analysis of urine sediment, serum blood urea nitrogen and creatinine, and 24-hour urine collection for protein and creatinine clearance. Low serum albumin would be consistent with persistent proteinuria and membranous GN, whereas red and white blood cell casts in the urinary sediment suggest proliferative GN. Although a renal biopsy is usually performed only when the result may influence therapeutic decisions, pathologic classification of the features of renal disease can provide prognostic information.

The erythrocyte sedimentation rate (ESR), although a very nonspecific indicator of systemic inflammation, is often monitored and in many patients can provide an indication of disease activity. Interestingly, C-reactive protein, an acute phase reactant, is relatively uninformative in SLE because it is often low in comparison to an ESR performed on the same occasion.

Assaying and monitoring characteristic lupus serologic tests can strongly support the diagnosis of SLE and, in some cases, can assist in the assessment of disease activity. The ANA test is positive in virtually all patients and does not need to be repeated once it has been documented to be positive (Table 274-6). Anti-double-stranded DNA antibodies are common in SLE, and some studies have found that monitoring their titer can be useful in assessing the activity of lupus nephritis. Autoantibodies specific for proteins that associate with nucleic acids in intracellular particles are present in many patients and can provide support for a diagnosis of SLE. Anti-Sm antibodies are highly specific for SLE and, along with anti-RNP antibodies, react with the spliceosome particle. Anti-Ro (SSA) and anti-La (SSB) antibodies are specific for proteins in an RNA-containing particle and are common in patients with Sjögren's syndrome and in mothers of babies with neonatal lupus, as well as being a feature of SLE. It is useful to document the presence of anti-Sm, anti-RNP, anti-Ro, and anti-La antibodies when the diagnosis of SLE is being made, but the titers of these autoantibodies are not helpful in monitoring disease activity.

Proteins of the complement system are activated by immune complexes, such as those that form in patients with SLE. The activation products that result from enzymatic cleavage of the complement components promote inflammation directly, by binding to cell surface receptors on mononuclear phagocytes, and indirectly, by acting as chemotactic agents to recruit inflammatory cells. Decreased levels of two of the more stable complement components, C3 and C4, are typically measured in serum, and decreased C3 and C4 levels are often indicators of enhanced consumption and increased disease activity. Some laboratories also use a functional measure of total hemolytic complement activity (CH_{50}).

It is the global picture provided by a careful history, physical examination, and blood, urine, and serologic data that supports a diagnosis of SLE. It should be recognized that there is considerable heterogeneity among patients and that different combinations of clinical features will characterize any one individual. As is the case with many systemic diseases, infection and some malignancies may have a similar picture and should be included in the differential until the diagnosis of SLE is secure.

TABLE 274-6 AUTOANTIBODIES ASSOCIATED WITH SYSTEMIC LUPUS ERYTHEMATOSUS

TARGET ANTIGEN	APPROXIMATE FREQUENCY
Nuclear antigens	99
dsDNA	70
Sm	38
RNP (U1-RNP)	33
Ro (SSA)	49
La (SSB)	35
Phospholipids	21
Ribosomal P	10

TREATMENT

Although current knowledge of genetic risk factors for SLE is not sufficient to predict those in whom the disease will develop, once the diagnosis has been made, regular counseling and education are fundamental to the treatment of SLE patients. Patients should be advised to avoid known triggers of disease exacerbation, such as ultraviolet light, and should be instructed regarding the need for adequate rest. Pregnancy should be undertaken with caution and with careful monitoring. Lupus patients can be informed that data indicate that oral contraceptive agents[1] and estrogen replacement therapy[2] do not contribute to disease exacerbations.

Conventional Medical Therapy

Clinical manifestations of lupus that do not involve major organ systems can often be managed with nonsteroidal anti-inflammatory drugs, low-dose corticosteroids, and antimalarials. Corticosteroids are immunosuppressive agents that modulate many functions of lymphocytes and monocytes, including the production of proinflammatory cytokines. Oral prednisone in doses ranging from 5 to 30 mg daily is effective in treating constitutional symptoms, arthralgias, pericarditis and pleuritis, and skin disease. Topical corticosteroids are sometimes applied to cutaneous lesions. For more serious disease, particularly active nephritis, CNS disease, or systemic vasculitis, prednisone at 60 mg daily or 1 g of intravenous methylprednisolone administered daily for 3 days can often gain control of disease activity. Although effective, corticosteroids also have toxicities that add to the morbidity associated with lupus. The broad immunosuppression mediated by these drugs contributes to the susceptibility to infection that is an inherent feature of SLE. Osteonecrosis, osteoporotic fractures, posterior subcapsular cataracts, diabetes, myopathy, hypertension, hypoadrenalism, and emotional disturbance are additional deleterious effects of corticosteroids.

Antimalarial agents, most commonly hydroxychloroquine administered at 200 to 400 mg/day, have long been used to control skin involvement and arthralgias and are now routinely used in most lupus patients. An important Canadian study demonstrating an increased frequency of disease flare in patients who discontinued hydroxychloroquine contributed to its recent use in lupus for a broader range of clinical manifestations. Hydroxychloroquine has been associated with a decreased incidence of thrombosis, a mechanism that could affect vasculopathy and end-organ damage. An additional potential mechanism of action implicates the TLR pathway, which is responsible for activation of the innate immune response. The effects of antimalarial agents on acidification of the intracellular vesicles where TLRs associate with their ligands may inhibit immune cell activation mediated by stimulatory nucleic acids. Antimalarials are well tolerated. Because they can rarely cause eye toxicity, ophthalmologic examinations should precede initiation of therapy and take place every 6 to 12 months.

In addition to controlling autoimmunity and inflammation in SLE, it is essential to control hypertension adequately when it occurs. In patients with a history of thrombosis, who will usually have antiphospholipid antibodies, warfarin is recommended.

Immunosuppressive Agents

Alkylating Agents

Approximately 33% of lupus patients receive cytotoxic therapy during the course of their disease. Cyclophosphamide is a cytotoxic agent that has been one of the more reliable and studied treatments for severe organ system manifestations of lupus, particularly lupus nephritis and CNS involvement.

Studies performed at the National Institutes of Health in the 1980s led to recommendations of a standard regimen of cyclophosphamide, 0.5 to 1.0 g/m^2 body surface area administered intravenously monthly for 6 months, followed by quarterly doses through 2 years. Cyclophosphamide is usually given with oral prednisone in tapering doses or sometimes with pulse methylprednisolone. Although this regimen is often effective in controlling GN, overall patient survival has not been demonstrated to be increased, and cyclophosphamide is associated with significant toxicity, including cytopenia, infection, gonadal failure, and malignancy. Recent clinical studies have included modified immunosuppressive regimens, such as a 6-month induction followed by maintenance with less toxic immunosuppressive agents, including azathioprine■ or mycophenolate mofetil (MMF). Cyclophosphamide is relatively contraindicated in pregnant women.

Purine Synthesis Inhibitors

Azathioprine has been used for the treatment of lupus nephritis and as a steroid-sparing agent in SLE for many years. Azathioprine inhibits DNA synthesis and inhibits key signaling pathways in T lymphocytes. Azathioprine is commonly dosed at 2 to 3 mg/kg/day administered as a tablet. Toxicities of azathioprine target the bone marrow and result in cytopenias, as well as the liver, occasionally resulting in transaminitis. Its use is rarely associated with non-Hodgkin's lymphoma (Chapter 191). It has been used safely in pregnant women.

MMF is an inhibitor that binds to the isoform of inosine monophosphate dehydrogenase that mediates purine synthesis in activated lymphocytes. It has a good track record of utility in inhibiting allograft rejection. Recent clinical trials have compared MMF with intravenous cyclophosphamide for induction therapy in lupus nephritis; the results demonstrated equivalence of MMF and cyclophosphamide in patients with lupus nephritis.■ As noted, MMF may also be useful for maintenance treatment of lupus nephritis after induction with cyclophosphamide.

Methotrexate

Methotrexate is a folate antagonist that is commonly used in rheumatoid arthritis. A double-blind, randomized, placebo-controlled trial of oral methotrexate (15 to 25 mg/week for 6 months) in SLE controlled disease and allowed tapering of prednisone. The most responsive clinical manifestations were cutaneous and articular.

Ancillary and Other Therapies

Intravenous Gamma Globulin

Although positive data from controlled trials of intravenous gamma globulin are not available, case reports and clinical experience indicate that administration of pooled IgG fractions can sometimes be efficacious in gaining control of lupus disease activity that is refractory to other therapies. A common regimen is 2 g/kg in divided doses over a 3- to 5-day period. Several mechanisms have been proposed for this therapy, including blockade of Fc receptors, modulation of lymphocyte function through Fc receptors, increased catabolism of pathogenic immunoglobulin, and actions of the anti-idiotype antibody that is a component of the administered IgG.

Plasmapheresis

Removal of pathogenic antibodies and immune complexes is the goal of plasmapheresis, but there are scant data supporting the utility of this therapy. Nonetheless, plasmapheresis has been occasionally useful in lupus patients with life-threatening complications in which the clinical manifestations can be clearly attributed to pathogenic autoantibodies. In particular, plasmapheresis has been effective in cases of thrombotic thrombocytopenic purpura associated with SLE (Chapter 175).

Biologic Therapies

Biologic therapies (Chapter 35) are being actively investigated in clinical trials, but only one agent has been successful as yet in phase III studies. Belimumab, a monoclonal antibody, blocks a B-cell survival and differentiation signal. At a dose of 1 to 10 mg intravenously on days 1 and 28 and then every 28 days for 48 weeks, belimumab reduces disease activity by both validated measures and physician global assessment, and decreases autoantibody levels.■ The clinical settings that are most appropriate for the use of belimumab, which was recently approved by the U.S. Food and Drug Administration, will be determined by future clinical trials and clinical experience. Additional agents under investigation target B cells, T-cell activation, and cytokines. Rituximab, a monoclonal antibody specific for the cell surface B-cell molecule CD20, is approved for use in B-cell lymphomas and has been used in some patients with SLE who are poorly responsive to other therapies. Rituximab depletes B cells, often for many months, and may limit T-cell activation by eliminating activated B cells that can serve as antigen-presenting cells. However, controlled clinical trials of rituximab in lupus have not shown efficacy. Other agents that block B-cell survival and differentiation factors or target B-cell surface molecules are under study. T-cell targets include CD28 and inducible costimulator (ICOS), a T-cell surface molecule in the same molecular family as CD28 and CTLA4. Blockade of T-cell activation by CTLA4-Ig, a soluble inhibitor of CD28 ligation, or inhibition of ICOS-ICOS ligand interaction might inhibit B-cell differentiation in the germinal center. Monoclonal antibodies specific for most isoforms of interferon-α are under study and represent a rational approach in view of the increased interferon in many SLE patients. IL-6 and interferon-γ represent additional cytokine targets under study.

Future Directions

Recent advances in basic immunology, together with detailed molecular and clinical characterization of cohorts of SLE patients, have directed attention to the role that adjuvant-like factors play in activating the innate immune response through TLRs. The primary triggers of that response are not known, but abundant data support production of type I interferon as an important consequence of immune activation that has an impact on many aspects of lymphocyte function, probably including induction of self-antigen-specific immune responses. In addition to the biologic therapies currently under study that target T and B lymphocytes, future therapies may be designed that can inhibit TLR activation, signaling components downstream from TLRs, or type I interferon itself. Recognition that the complement system is an essential contributor to inflammation triggered by antiphospholipid antibodies, as well as by immune complexes, provides additional targets that might be inhibited therapeutically and limit tissue damage. Continued investigation of the genetic and environmental factors that contribute to disease susceptibility may permit identification of individuals at risk for the development of SLE and may elucidate the primary stimuli that lead to autoimmunity. Identification of informative biomarkers that reflect or even predict disease flares would improve medical management of lupus patients.

PROGNOSIS

Although survival of patients with a diagnosis of SLE is good, lupus remains a disease that is potentially fatal. SLE demonstrates a bimodal pattern of death, with deaths within the first year attributable to active lupus and infection and late deaths attributable to atherosclerotic cardiovascular disease. Recent cohort studies have estimated 5-year survival rates greater than 90%, with improvement in medical management probably contributing to improved outcomes as opposed to earlier studies, and 85% survival rates at 10 years. However, once a diagnosis of SLE has been made, prolonged remission is rare. Of 702 patients registered in a lupus clinic in Canada, 6.5% achieved complete remission (score of 0 on the SLE Disease Activity Index), and only 1.7% maintained remission for at least 5 years with no treatment. The presence of any permanent organ damage within the first year after a diagnosis of SLE is associated with poorer survival at 10 years (a 75 vs. 95% rate in those without permanent organ damage). Regarding renal outcome, an elevated level of serum creatinine at the time of diagnosis has been correlated with an adverse outcome.

Recent studies of minority populations in the United States have indicated that predictors of high lupus disease activity include Hispanic Texan and African American ethnicities, lack of health insurance, and poor social support. African admixture and anti-double-stranded DNA antibodies also predicted high levels of disease activity, as did previous disease activity.

Data from a multicenter study of nearly 10,000 patients has supported an increased risk for hematologic malignancies in SLE patients, particularly non-Hodgkin's lymphoma. Prognostic factors for an adverse fetal outcome in pregnant lupus mothers are maternal renal disease and hypertension.

275 SYSTEMIC SCLEROSIS (SCLERODERMA)

JOHN VARGA

DEFINITION

Systemic sclerosis (SSc) is an acquired rheumatic disease of unknown cause. It most commonly affects middle-aged women and is associated with considerable morbidity and mortality. Systemic sclerosis has protean clinical manifestations and follows a chronic and often progressive course. The hallmark of SSc is thickening and hardening of the skin (scleroderma), but most patients also manifest characteristic abnormalities in the lungs, gastrointestinal tract, kidneys, and heart. In its earliest stages, SSc is associated with prominent autoimmune and inflammatory features and altered vascular function. Over time, structural alterations in small blood vessels and progressive fibrosis in multiple organs ensue and cause organ failure. Although there is no cure for SSc, current treatment strategies can effectively control symptoms, slow disease progression, and improve quality of life. The presence of scleroderma (hard skin) distinguishes SSc from other autoimmune and rheumatic diseases, but skin induration is also a prominent feature of localized forms of scleroderma and multiple unrelated conditions (Table 275-1).

Classification

Systemic Sclerosis

Systemic sclerosis is commonly classified into two principal subsets: diffuse cutaneous SSc (dcSSc) and limited cutaneous SSc (lcSSc). These disease subsets are defined by the pattern of skin involvement and are associated with distinct clinical and laboratory manifestations (Table 275-2). In lcSSc, skin involvement is restricted to the fingers, toes, distal extremities, and face, and the trunk is spared. Diffuse cutaneous SSc is characterized by involvement of the skin proximal to the elbows and knees, including the trunk, as well as distal extremities. Diffuse cutaneous SSc is generally rapidly progressive with early pulmonary fibrosis and acute renal failure. In contrast, patients with lcSSc develop Raynaud's phenomenon long before other manifestations appear. A subset of patients with lcSSc have a constellation of calcinosis cutis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly (scleroderma of the fingers), and telangiectasia, which is termed *CREST syndrome*. Patients with the CREST syndrome generally have an indolent course and a good prognosis. In some patients, Raynaud's phenomenon and other characteristic clinical and laboratory findings of SSc occur in the absence of obvious skin thickening. This entity is designated *SSc sine scleroderma*.

Mixed Connective Tissue Disorder

Mixed connective tissue disorder (MCTD) is an overlap syndrome first described in 1971 that is characterized by features of systemic lupus erythematosus (SLE), SSc, and myositis, all occurring in the same patient. In the early phase, most patients have Raynaud's phenomenon in association with edema of the hands and evidence of inflammatory muscle disease. Over time, these patients sequentially manifest other features of connective tissue diseases, including pericarditis, esophageal dysmotility, sclerodactyly, neuropathy, and pulmonary arterial hypertension. Erosive arthritis does not occur. On the other hand, some patients develop acute renal involvement similar to scleroderma renal crisis. In the early stage of this disorder, it is often difficult to predict whether the patient will progress to develop a distinct connective tissue disease such as SSc or SLE, or will be ultimately diagnosed with MCTD. A diagnostic hallmark of MCTD is the presence in the serum of a highly characteristic autoantibody specificity against U1-ribonuclear protein (U1-RNP). Most MCTD patients have a very high titer (often greater than 1 : 1,000) of anti-U1-RNP autoantibody. Some of the features of MCTD might respond to corticosteroid therapy. Overall, patients with MCTD generally have a better prognosis than those with SSc.

Localized Scleroderma

Localized scleroderma refers to a family of generally benign skin conditions primarily affecting children. These conditions are characterized by discreet areas of skin induration in the absence of Raynaud's phenomenon or systemic involvement. Lesional skin is discolored and indurated and histologically may be indistinguishable from SSc. Localized scleroderma may occur as single or multiple solitary patches of induration (morphea) or as a coalescence of multiple patches (generalized morphea). The lesions are generally asymmetrical in distribution and spare the digits. Some individuals have extensive and disabling induration (pansclerotic morphea). Induration of the skin may follow in a linear distribution, most commonly on the lower extremities (linear scleroderma). In children, linear scleroderma can be complicated by growth retardation and joint contractures.

EPIDEMIOLOGY

SSc occurs as a sporadic disease with a worldwide distribution and affects all races. The incidence is 9 to 19 cases per million per year, with an estimated 100,000 cases in the United States. Studies from several countries suggest that the incidence of SSc is increasing, particularly among women. Like other connective tissue diseases, SSc shows a marked female predominance in the childbearing years and declines after menopause. The most common age of

TABLE 275-2 CLASSIFICATION OF SYSTEMIC SCLEROSIS

FEATURES	LIMITED CUTANEOUS SYSTEMIC SCLEROSIS	DIFFUSE CUTANEOUS SYSTEMIC SCLEROSIS
Skin induration	Limited to fingers, distal to elbows, face; slow progression	Diffuse: fingers, extremities, face, trunk; rapid progression; tendon rubs
Raynaud's phenomenon	Precedes skin involvement; associated with critical ischemia	Onset may be coincident with or subsequent to skin changes
Pulmonary fibrosis	Occasional, moderate	Frequent, early and severe
Pulmonary arterial hypertension	Frequent, late, may be isolated	May occur, often in association with pulmonary fibrosis
Scleroderma renal crisis	Very rare	Occurs in 15%; early
Calcinosis cutis	Frequent, prominent	Infrequent
Characteristic autoantibodies	Anticentromere	Antitopoisomerase I (Scl-70), anti-RNA polymerase III

onset is 30 to 50 years for both the limited and diffuse cutaneous forms. African Americans have a higher incidence than whites and an earlier age of onset, and are more likely to exhibit the diffuse cutaneous form of SSc associated with interstitial lung involvement and a worse prognosis.

Etiology and Environmental and Occupational Exposures

Although the cause of SSc is unknown, the onset is commonly ascribed to an interplay between environmental factors and genetic susceptibility. Suspected environmental triggers include infectious agents and occupational, dietary, medical, and lifestyle exposures. Patients with SSc possess elevated serum levels of antibodies to cytomegalovirus and parvovirus B19. Because some SSc autoantibodies cross-react with certain virus-associated epitopes, molecular mimicry has been considered a possible pathogenetic link between viral infection and SSc.

Epidemic outbreaks of SSc-like syndromes have been linked with specific toxic exposures. An outbreak of toxic oil syndrome in the 1980s affected more than 20,000 individuals in Spain. The syndrome was characterized by chronic skin induration and neuropathy, and the outbreak was linked to ingestion of contaminated rapeseed oils used for cooking. An outbreak of eosinophilia-myalgia syndrome (EMS) a decade later was linked to ingestion of over-the-counter L-tryptophan dietary supplements used for insomnia, weight loss, and other indications. The syndrome was characterized by peripheral blood eosinophilia and severe myalgia in the acute stage, followed by intractable scleroderma-like diffuse skin induration. Neither toxic oil syndrome nor EMS was associated with Raynaud's phenomenon or SSc-specific autoantibodies.

Occupational exposures tentatively linked with SSc include silica (in miners), polyvinyl chloride, epoxy resins, and aromatic hydrocarbons including toluene and trichloroethylene. Certain drugs, including bleomycin, pentazocine, hormone replacement therapy, cocaine, and appetite suppressants, have been linked with SSc or pulmonary arterial hypertension. Although earlier studies implied a possible association of SSc with silicone breast implants, large-scale epidemiologic investigations failed to establish an increased risk.

Genetic Factors

A genetic contribution to SSc susceptibility is indicated by the fact that 1.6% of patients have a first-degree relative with SSc, a prevalence rate substantially higher than in the general population (0.026). Indeed, a family history is the strongest identified risk factor for SSc. The risk for other autoimmune diseases is also increased among relatives of SSc patients. Genetic investigations in SSc to date have used the candidate gene approach. Case-control studies of genes for autoimmune susceptibility have indicated an association of SSc with *STAT4, IRF4, PTPN22,* and *BANK1,* and with the genes from human leukocyte antigen (HLA) class II, angiotensin-converting enzyme (ACE), endothelin-1, growth factors and their receptors, and extracellular matrix proteins. These findings suggest that SSc is a complex polygenic disease in which multiple genetic loci exert minor individual effects on disease susceptibility. A recent genomewide association study (GWAS) in a population of European ancestry identified multiple susceptibility loci associated with SSc. One of these is CD247, a component of the T-cell receptor-CD3 complex that has previously been associated with susceptibility to SLE. Additional SSc susceptibility loci confirmed in this GWAS included *MHC, IRF5,* and *STAT4,* each of which is involved in immune regulation, highlighting the role of autoimmunity in the pathogenesis of SSc.

PATHOBIOLOGY

The protean clinical and pathologic manifestations of SSc reflect a highly complex pathobiology encompassing three cardinal processes: autoimmunity and inflammation, vascular injury and obliteration, and fibrosis and matrix deposition in multiple organs (Fig. 275-1). This triad of distinct yet

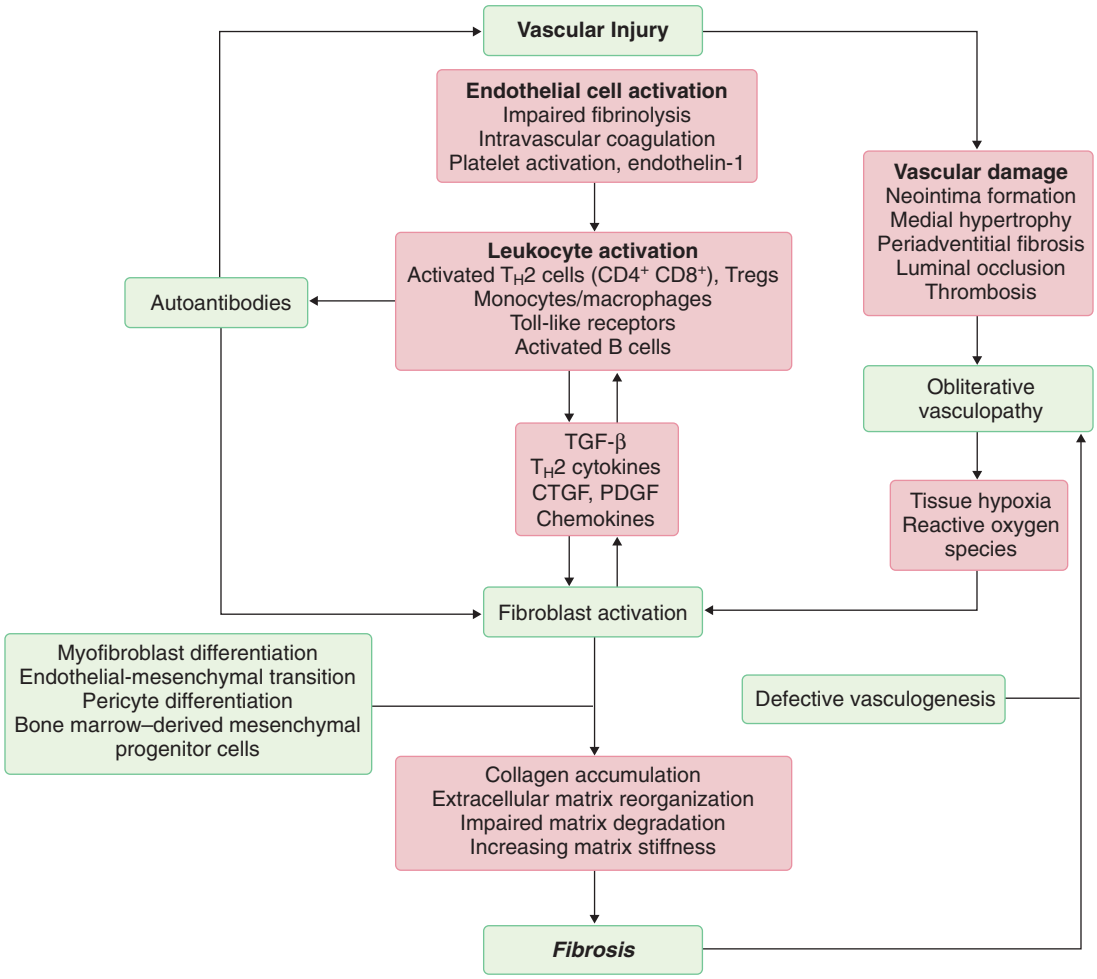

FIGURE 275-1. The pathogenetic triad of systemic sclerosis: vasculopathy, autoimmunity, fibrosis. Initial endothelial injury in a genetically susceptible individual leads to vascular damage, inflammation, and autoimmunity. The inflammatory and immune responses initiate fibroblast activation, resulting in intractable fibrosis. Vasculopathy, loss of microvasculature and reduced blood flow result in ischemia and generation of reactive oxygen species that contribute to, and further aggravate, tissue fibrosis and atrophy. CTGF = connective tissue growth factor; PDGF = platelet-derived growth factor; TGF-β = transforming growth factor-β.

interrelated processes is operative to a greater or lesser extent in every patient, and their variable relative contributions to the individual clinical phenotype account for the observed disease heterogeneity.

PATHOLOGY

The distinguishing pathologic hallmark of SSc is the constellation of capillary loss and obliterative vasculopathy coexisting with acellular fibrosis in the skin and internal organs. In early disease, perivascular inflammation can be detected in multiple organs before the appearance of fibrosis. The vascular lesion is characterized by intimal proliferation in the small and medium-sized arteries, resulting in luminal narrowing and obliteration. In later-stage SSc, fibrosis is prominent in the skin, lungs, gastrointestinal tract, heart, tendon sheath, perifascicular tissue surrounding skeletal muscle, and some endocrine organs. Accumulation of connective tissue rich in collagens, fibronectin, cartilage oligomeric matrix protein, and proteoglycans disrupts normal architecture, resulting in functional impairment of affected organs.

In the dermis, collagen deposition causes obliteration of the hair follicles, sweat glands, and other appendages as well as invasion of the subjacent adipose layer with entrapment of fat cells. The epidermis is atrophic, and the rete pegs are effaced. In late-stage disease, there is a paucity of vascular and lymphatic endothelium, and there is capillary rarefaction in the skin. In the lungs, the interstitium and alveolar spaces are infiltrated with inflammatory cells in early disease. With progression, interstitial fibrosis and vascular damage, often coexisting within the same lesions, dominate the pathologic picture. The most common histologic pattern in SSc lung is nonspecific interstitial pneumonitis. Progressive thickening of the alveolar septae results in obliteration of the air spaces, honeycombing, and loss of pulmonary blood vessels. Intimal thickening of the pulmonary arteries, best seen with elastin stain, underlies pulmonary hypertension. The lesions resemble those of, but are distinct from, idiopathic pulmonary arterial hypertension, with frequent vascular fibrosis but an absence of plexiform lesions. Pathologic changes in the gastrointestinal tract can be found at any level from the mouth to the rectum. Fibrosis of the lamina propria and submucosa with atrophy of the muscular layers are prominent changes in the lower esophagus, whereas striated muscle in the upper third of the esophagus is generally spared. Replacement of the normal intestinal tract architecture leads to disordered peristaltic activity with gastroesophageal reflux and dysmotility, gastroparesis, and small bowel obstruction. Chronic reflux is associated with esophageal inflammation, ulcerations, stricture formation, and Barrett's metaplasia.

Pathologic changes are common in the heart in SSc, with involvement of the myocardium and pericardium. Characteristic microvascular lesions are seen with concentric intimal hypertrophy and luminal narrowing, but not affecting epicardial coronary arteries. Contraction band necrosis reflecting ischemia-reperfusion injury in the myocardium is prominent and may be accompanied by patchy myocardial fibrosis. In the kidneys, noninflammatory lesions occur in the interlobular arteries. Scleroderma renal crisis is associated with striking changes in small renal arteries with reduplication of elastic lamina, marked intimal proliferation, and concentric narrowing of the lumen (onion-skin appearance), frequently accompanied by thrombosis and microangiopathic hemolysis (Fig. 275-2).

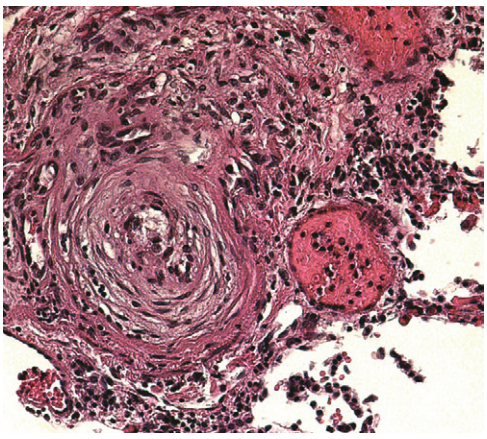

FIGURE 275-2. Pulmonary arterial obliterative vasculopathy. Striking intimal hyperplasia and narrowing of the lumen of a small pulmonary artery, coexisting with interstitial pulmonary fibrosis, in a patient with diffuse cutaneous systemic sclerosis.

Animal Models of Disease

Although no single animal model fully recapitulates the tripartite pathobiology of SSc, certain models exhibit particular disease features and are useful in investigating pathogenesis and therapy. The tight-skin mouse (Tsk1) spontaneously develops diffuse skin thickening and fibrosis. This phenotype is due to a duplication mutation in the gene for fibrillin-1, a component of extracellular microfibrils that provides a scaffold for elastin fibers but is also involved in the storage and regulation of transforming growth factor-β (TGF-β) and other growth factors. Different mutations in the fibrillin-1 gene cause Marfan syndrome, but such mutations have not been described in SSc. Scleroderma-like skin changes and fibrosis of the lungs and kidneys can be induced in mice by subcutaneous injection of bleomycin, or by transplantation of HLA-mismatched bone marrow or spleen cells. Increasingly, targeted genetic modifications such as deletion or transgenesis are used to create novel animal models for dissecting the interaction of molecules and pathways in fibrosis and for preclinical evaluation of novel therapies. For instance, mice transgenic for transcription factors Egr-1 and Fra-2, or for certain growth factors (TGF-β, connective tissue growth factor [CTGF], platelet-derived growth factor [PDGF], or Wnt10), spontaneously develop scleroderma-like features, whereas genetic targeting of Smad3 yields mice that are resistant to bleomycin-induced scleroderma.

Pathophysiologic Triad: Vasculopathy, Autoimmunity, and Fibrosis

Vasculopathy

Vasculopathy occurs early in SSc, involves multiple vascular beds, and accounts for major clinical complications. The process affects primarily the small and medium-sized arteries and arterioles and over time causes their obliteration. Factors thought to be responsible for triggering the initial vascular injury include viruses, oxygen radicals, circulating cytotoxic factors, complement activation, and autoantibodies. Endothelial cell injury and activation result in altered production of endothelium-derived vasodilatory (nitric oxide and prostacyclin) and vasoconstricting (endothelin-1) substances. Dysfunctional endothelium causes enhanced vascular permeability, upregulation of adhesion molecules with transendothelial leukocyte diapedesis, platelet aggregation, activation of intravascular coagulation, and defective fibrinolysis. Small blood vessels show intimal hyperplasia with thickening and reduplication of the basement membrane. In the vascular media, myointimal cells proliferate, whereas fibrosis develops in the adventitial layers; the net result is progressive narrowing and obliteration of capillaries, arterioles, and even large vessels. Impaired blood flow results in widespread tissue ischemia. Recurrent ischemia-reperfusion is associated with the generation of reactive oxygen species that further damage the endothelium. Paradoxically, despite the presence of tissue hypoxia and sometimes dramatically elevated levels of angiogenic factors, compensatory vasculogenesis is impaired. The combination of widespread capillary loss, obliterative vasculopathy of small and medium-sized arteries, and failure to regenerate damaged vessels are hallmarks of SSc.

Raynaud's Phenomenon

The earliest vascular complication of SSc, Raynaud's phenomenon, can precede other disease manifestations by years. Raynaud's phenomenon in SSc is characterized by an initially reversible altered blood flow response to cold challenge and is associated with autonomic and peripheral nervous system changes leading to impaired production of calcitonin gene–related peptide from sensory afferent nerves and heightened sensitivity of α_2-adrenergic receptors on vascular smooth muscle cells. In contrast to primary Raynaud's phenomenon, a common and relatively benign condition, Raynaud's phenomenon in SSc is generally progressive and complicated by irreversible structural changes in the blood vessels with tissue damage due to recurrent ischemia-reperfusion.

Inflammation and Autoimmunity

Cellular Immunity

Evidence of inflammation and autoimmunity is an invariable feature that SSc shares with other rheumatic diseases such as systemic lupus erythematosus and rheumatoid arthritis. The association of SSc with autoimmunity genes such as *IRF5* and *STAT4* provides strong support for the autoimmune basis of the disease. In early SSc, activated T cells and monocyte-macrophages accumulate in the skin, lungs, and other affected organs. Infiltrating T cells display restricted receptor signatures indicative of oligoclonal expansion in

TABLE 275-3 CHARACTERISTIC AUTOANTIBODIES IN SYSTEMIC SCLEROSIS

AUTOANTIBODY	SYSTEMIC SCLEROSIS SUBSET	CLINICAL ASSOCIATION
Topoisomerase-I	Diffuse cutaneous	Tendon friction rubs, ILD, cardiac involvement, scleroderma renal crisis
Centromere	Limited cutaneous	Digital ischemia, calcinosis, isolated PAH; scleroderma renal crisis rare
RNA polymerase III	Diffuse cutaneous	Extensive skin involvement; tendon friction rubs, scleroderma renal crisis
U3-RNP0	Diffuse cutaneous	PAH, ILD, scleroderma renal crisis, myositis
Th/T0	Limited cutaneous	ILD, PAH
PM/Scl	Limited cutaneous	Calcinosis, myositis
U1-RNP	MCTD	PAH

ILD = interstitial lung disease; MCTD = mixed connective tissue disease; PAH = pulmonary arterial hypertension.

response to unknown antigens and show T_H2 polarization with secretion of interleukin-4 (IL-4) and IL-13. T_H2 cytokines induce TGF-β and promote the synthesis of collagen and other extracellular matrix molecules. The frequency of circulating regulatory T cells is elevated, but their immunosuppressive function is defective. Macrophages show evidence of alternative activation associated with pathologic fibrogenesis. A role is emerging for innate immunity through toll-like receptors, which could provide a link of environmental triggers to the disease.

Humoral Autoimmunity and B Lymphocytes

Although autoantibodies have well-established clinical utility as diagnostic and prognostic markers in SSc, their role in pathogenesis and tissue damage remains speculative. In addition to antinuclear antibodies (ANAs), a number of highly disease-specific and mutually exclusive autoantibodies occur (Table 275-3). Some autoantibodies are directed against intracellular proteins (topoisomerase-I, centromere, and the RNA polymerases I and III), whereas others are directed against cell surface antigens (platelet-derived growth factor receptor) or secreted proteins (fibrillin-1 and matrix metalloproteases) and may directly contribute to vascular injury or fibrosis. B cells are implicated in both the autoimmune and fibrotic responses in SSc. In addition to their role in antibody production, B cells also present antigen, produce profibrotic cytokines such as IL-6 and TGF-β, and modulate the function of T cells and dendritic cells. In SSc, B cells show elevated CD19 expression, and the numbers of memory B cells and early plasma cells are reduced. Gene expression profiling has identified messenger RNA expression signatures characteristic of B-cell activation in the lesional skin.

Fibrosis

Fibrosis of the skin and multiple internal organs is the distinguishing feature of SSc. It characteristically follows, and is thought to be a consequence of, inflammation and vascular injury. Fibrosis is characterized by progressive replacement of normal tissue architecture with an acellular collagen-rich extracellular matrix secreted and remodeled by resident fibroblasts. Under physiologic conditions, fibroblasts that are activated by TGF-β and related factors can proliferate, migrate, elaborate collagens and extracellular matrix, and transdifferentiate into contractile myofibroblasts, enabling them to execute prompt repair of damaged tissue. When this highly regulated and self-limited physiologic repair program becomes sustained and amplified, excessive intractable scar tissue formation ensues.

Effector Cells in Fibrosis

Myofibroblasts are contractile connective tissue cells that display smooth muscle cell–like features and contribute to scar formation through production of collagen and TGF-β and contraction of the surrounding extracellular matrix. In SSc, activated myofibroblasts appear in tissue due to in situ activation of quiescent resident fibroblasts, through transdifferentiation from damaged epithelial cells, endothelial cells, or pericytes, or by migration and terminal differentiation of bone marrow-derived mesenchymal progenitor cells. Fibroblasts explanted from patients with SSc display cell-intrinsic abnormalities that persist during in vitro passage. For instance, cultured SSc fibroblasts exhibit increased rates of collagen gene transcription, secretion of cytokines and growth factors, expression of cell surface adhesion molecules, and evidence of constitutive autocrine TGF-β signaling.

CLINICAL MANIFESTATIONS

Overview

Multiple organs are affected in SSc, but the frequency, tempo, and severity of their involvement show substantial patient-to-patient variability. Patients with dcSSc characteristically develop extensive skin induration and early progressive internal organ involvement. Patients with lcSSc commonly present with long-standing Raynaud's phenomenon, modest skin changes, and indolent internal organ disease. However, many patients with SSc defy easy subclassification, and others show an overlap of typical SSc features coexisting with clinical and laboratory evidence of another autoimmune disease such as polymyositis, Sjögren's syndrome, polyarthritis, or systemic lupus erythematosus.

Initial Clinical Presentation

Diffuse Cutaneous Systemic Sclerosis

Patients with dcSSc typically present with soft tissue swelling, erythema, and pruritus, often accompanied by fatigue, stiffness, and malaise. Although arthralgia, muscle weakness, and carpal tunnel syndrome are common, Raynaud's phenomenon may not be present until later in the disease. In the ensuing weeks to months, the inflammatory edematous phase evolves into a chronic "fibrotic" phase with skin induration accompanied by hyperpigmentation, loss of body hair, and impaired sweating. The wrists, elbows, shoulders, knees, and ankles become stiff owing to fibrosis of the joint structures. Advancing skin changes are commonly accompanied by onset of internal organ involvement that is most rapidly progressive during the initial 4 years from disease onset. The risk for new organ involvement declines thereafter.

Limited Cutaneous Systemic Sclerosis

In lcSSc, the diagnosis is generally made at a more advanced stage of the disease. These patients give a history of long-standing Raynaud's phenomenon, sometimes complicated by ischemic ulcerations. The course of disease is indolent, with delayed onset and slow progression of gastroesophageal reflux, telangiectasia, or cutaneous calcinosis. Vascular manifestations tend to be more pronounced compared with dcSSc, and digital ischemia, cutaneous telangiectasia, and progressive pulmonary artery hypertension (PAH) are frequent late manifestations. In contrast, scleroderma renal crisis is uncommon in lcSSc.

Organ Involvement

Skin

Skin thickening, the distinguishing hallmark of SSc, is symmetrical and bilateral. It typically starts in the fingers and advances from distal to proximal extremities. The skin generally becomes hyperpigmented, but dark-skinned individuals may develop vitiligo-like hypopigmentation or "salt-and-pepper" changes most prominently on the upper back and chest. Obliteration of sweat glands and sebaceous glands results in decreased sweating and dry skin. The face gradually assumes a characteristic appearance with a beaklike nose, thinning and retraction of the lips, fine wrinkles (radial furrowing) around the mouth, and occasionally a masklike facies due to reduced mobility of the eyelids, cheeks, and mouth (Fig. 275-3). Decreased oral aperture (microstomia) interferes with eating and oral hygiene.

In patients with established SSc, the skin is atrophic and tethered to the subcutaneous tissue. Telangiectasia, similar to the skin lesions of hereditary hemorrhagic telangiectasia, is prominent on the face, hands, lips, and oral mucosa. Breakdown of atrophic skin leads to painful ulcerations at the extensor surfaces of the interphalangeal joints, fingertips, and bony prominences such as the elbows and malleoli. Ulcers may become secondarily infected, resulting in osteomyelitis. Ischemic fingertip ulcerations show slow healing that results in characteristic digital "pits." Ischemic loss of soft tissue at the fingertips is associated with resorption of the terminal phalanges (acroosteolysis) (Fig. 275-4).

Calcium deposits varying in size from tiny punctate lesions to large conglomerate masses develop in the skin and soft tissues. They are composed of calcium hydroxyapatite crystals and can be readily visualized on plain radiographs. Frequent locations include the finger pads, extensor surfaces of the forearms, and olecranon and prepatellar bursae. Calcific deposits can ulcerate

through the overlying skin, producing drainage of chalky white material, pain, and local inflammation.

Raynaud's Phenomenon

Raynaud's phenomenon (Chapter 80) is an episodic vasoconstriction in the digits that occurs in virtually all patients with SSc. Typical attacks start with pallor (vasoconstriction), followed by cyanosis (ischemia) and erythema (reperfusion). Attacks are commonly triggered by exposure to cold or emotional stress. Primary Raynaud's phenomenon, a benign condition representing an exaggerated physiologic response to cold, occurs in 3 to 5% of the population and is more frequent in women. Secondary Raynaud's phenomenon occurs not only in SSc but also in other connective tissue diseases, hematologic and endocrine conditions, and occupational disorders, and with the use of β-blockers and anticancer drugs such as cisplatin and bleomycin.

Distinguishing primary from secondary Raynaud's phenomenon can present a challenge. Secondary Raynaud's phenomenon typically develops at an older age (>30 years), tends to be more severe, and is frequently complicated by critical ischemia. Nailfold capillaroscopy allows cutaneous capillaries to be viewed under a drop of immersion oil using an ophthalmoscope. Patients with primary Raynaud's phenomenon have normal nailfold capillaries that appear as regularly spaced parallel vascular loops, whereas in SSc, capillaries are distorted with widened and irregular loops, dilated lumen, and areas of vascular "dropout."

Gastrointestinal Involvement

The gastrointestinal tract is commonly affected in both limited and diffuse cutaneous forms of SSc. A pathologic picture of smooth muscle atrophy and fibrosis and obliterative small vessel vasculopathy is seen throughout the length of the gastrointestinal tract.

Upper Gastrointestinal Tract

Oropharyngeal manifestations of SSc include xerostomia, reduced oral aperture, periodontal disease, and resorption of the mandibular condyles. The frenulum of the tongue may be shortened. Gastroesophageal reflux disease (GERD) with heartburn, regurgitation, and dysphagia is very common (Chapter 140). Reduced lower esophageal sphincter pressure resulting in gastroesophageal reflux frequently coexists with impaired esophageal clearance of refluxed gastric contents due to diminished motility in the distal two thirds of the esophagus. Delayed gastric emptying further aggravates the problem. On chest computed tomography scans, the esophagus is dilated with intraluminal air. Severe erosive esophagitis may be found on endoscopy in patients with minimal GERD symptoms. Esophageal strictures and Barrett's esophagus (Chapter 140) complicate chronic GERD. Because Barrett's esophagus is associated with an increased risk for adenocarcinoma, SSc patients require periodic endoscopy with mucosal biopsy. Hoarseness and chronic cough may be extraesophageal manifestations of GERD. Aspiration pneumonitis may aggravate underlying interstitial lung disease.

Stomach

Gastroparesis contributes to delayed gastric emptying with early satiety, abdominal distention, and aggravated reflux symptoms. Gastric vascular ectasia (GAVE) develops in 5% of patients, and is equally prevalent in limited and diffuse cutaneous disease. On endoscopy, parallel longitudinal mucosal folds resembling the stripes of a watermelon are seen in the antrum. The histologic features of dilated mucosal capillaries and fibromuscular dysplasia of the lamina propria reflect the diffuse small vessel vasculopathy of SSc. Patients with GAVE may develop recurrent gastrointestinal bleeding and typically present with unexplained anemia.

Lower Gastrointestinal Tract

Impaired small bowel motility in SSc can cause chronic diarrhea due to bacterial overgrowth. Fat and protein malabsorption, vitamin B_{12} and D deficiency, and occasionally severe malnutrition may ensue. Disturbed intestinal motor function can also cause recurrent episodes of intestinal pseudo-obstruction with acute abdominal pain, nausea, and vomiting. Differentiating pseudo-obstruction, which responds to supportive care and intravenous nutritional supplementation, from mechanical bowel obstruction, is a diagnostic challenge. Colonic involvement can cause constipation, rectal prolapse, and fecal incontinence. In late-stage SSc, wide-mouth colonic sacculations can occur and cause perforation and bleeding. An occasional radiologic finding is pneumatosis cystoides intestinalis due to air trapping in the bowel wall. These lesions can rupture and cause pneumoperitoneum. The liver is rarely affected in SSc. However, primary biliary cirrhosis associated with antimitochondrial antibodies may occur.

Lung Involvement

The two principal types of pulmonary diseases are interstitial lung disease and PAH. Many patients develop some degree of both complications. Less frequent pulmonary manifestations include aspiration pneumonitis complicating gastroesophageal reflux, pulmonary hemorrhage, obliterative bronchiolitis, pleural reactions, restrictive ventilatory disease due to chest wall fibrosis, spontaneous pneumothorax, and drug-induced lung toxicity. The

incidence of lung cancer, particularly bronchoalveolar carcinoma (Chapter 197), is increased.

Interstitial Lung Disease and Pulmonary Fibrosis

Interstitial lung disease (Chapter 92) in SSc can remain asymptomatic until quite advanced. The most frequent presenting symptoms are exertional dyspnea, fatigue, and reduced exercise tolerance. A chronic dry cough may be present. Physical examination may reveal "Velcro" crackles at the lung bases. Pulmonary function testing (Chapter 85) is a sensitive method for detecting early interstitial lung disease. The most common abnormalities are reductions in forced vital capacity (FVC) or single breath diffusing capacity (DLCO). However, a reduction in DLCO that is significantly out of proportion to the reduction in FVC (FVC/DLCO ratio >1.6) suggests pulmonary vascular disease.

Evidence of interstitial lung disease can be found in almost all patients and is clinically significant in up to 50%. Risk factors for interstitial lung disease include male gender, African American race, diffuse skin involvement, severe gastroesophageal reflux, and the presence of topoisomerase-I autoantibodies. The most rapid progression in interstitial lung disease occurs within the first 3 years of the disease.

Chest radiography is useful for ruling out infection and other causes of pulmonary involvement but is relatively insensitive for detection of early interstitial lung disease. In contrast, high-resolution computed tomography (HRCT) is highly sensitive (Chapter 84). Prominent HRCT features include reticular linear interstitial opacities, predominantly in the lower lobes. These may occur in isolation or in combination with ground-glass opacification. Additional findings include mediastinal lymphadenopathy and, rarely, honeycombing. The extent of lung disease on HRCT at initial evaluation correlates with progression and prognosis. Bronchoalveolar lavage (Chapter 85) can be useful for ruling out occult infection. Lung biopsy is only rarely indicated.

Pulmonary Arterial Hypertension

PAH is defined as a mean pulmonary arterial pressure of more than 25 mm Hg with a pulmonary capillary wedge pressure of less than 15 mm Hg (Chapter 68). Approximately 15% of SSc patients develop PAH, which can occur as an isolated abnormality or coexist with interstitial lung disease. The natural history of SSc-associated PAH is variable. However, many patients follow a downhill course with development of right heart failure and increased mortality. Risk factors for PAH in SSc include limited cutaneous disease, late age of disease onset, large number of cutaneous telangiectasias, and the presence of anticentromere autoantibodies, or antibodies to U1-RNP, U3-RNP (fibrillarin), B23, and β_2-glycoprotein I.

Early PAH is often clinically silent. The initial symptoms are exertional dyspnea and reduced exercise capacity. With progression, angina, syncope, and symptoms and signs of right-sided heart failure may appear. Physical examination shows tachypnea, a prominent pulmonic S_2 heart sound, palpable right ventricular heave, elevated jugular venous pressure, and dependent edema. Pulmonary arterial systolic pressures exceeding 40 mm Hg determined by Doppler echocardiography suggest the presence of PAH, as does an FVC/DLCO ratio of more than 1.6 on pulmonary function testing. Right heart catheterization is typically required for confirming the diagnosis of PAH, assessing its severity, and evaluating ventricular function. The serum levels of *N*-terminal brain natriuretic peptide (pro-BNP) are elevated and correlate with the severity of PAH and with survival.

Kidney Involvement

The kidneys are frequently involved in SSc. Scleroderma renal crisis is an uncommon but life-threatening acute complication, but chronic and indolent kidney disease also occurs.

Scleroderma Renal Crisis

Scleroderma renal crisis, the most dreaded complication of SSc, develops in 10 to 15% of patients, and almost always occurs within 4 years of the onset of SSc. Before the advent of ACE inhibiting drugs in the 1980s, scleroderma renal crisis was invariably fatal, with most patients dying within weeks. The pathogenesis involves obliterative vasculopathy and luminal narrowing of the renal arcuate arteries. Progressive reduction in renal blood flow, aggravated by vasospasm, leads to juxtaglomerular hyperplasia and increased renin secretion, with further renal vasoconstriction resulting in a vicious cycle that culminates in malignant hypertension (Chapters 67 and 127).

Scleroderma renal crisis is a medical emergency. Although most patients present with abrupt onset of hypertension and progressive renal insufficiency, in some, the blood pressure remains normal or only modestly elevated. Normotensive renal crisis is associated with a poor outcome. Hypertensive encephalopathy and retinopathy, pericarditis, and arrhythmias may occur. Urinalysis shows mild proteinuria, granular casts, and microscopic hematuria. When thrombocytopenia and microangiopathic hemolysis with fragmented red blood cells is detected, the diagnosis of thrombotic thrombocytopenic purpura (Chapter 175) is sometimes entertained. In many patients, oliguric renal failure develops over a period of weeks. Kidney biopsy can be useful for diagnosis and prognosis, but the characteristic lesions of intimal and medial proliferation and luminal narrowing are indistinguishable from the changes of accelerated hypertension.

Risk factors for scleroderma renal crisis include rapidly progressive skin involvement and the presence of tendon rubs, African American race, male gender, and autoantibodies to RNA polymerases I and III. In contrast, the presence of anticentromere antibodies is associated with a low risk for scleroderma renal crisis. Pericardial effusion, new-onset anemia, and thrombocytopenia may be harbingers of impending scleroderma renal crisis, and a history of recent corticosteroid use is associated with a more than ten-fold increased risk. Accordingly, SSc patients with early and progressive cutaneous disease should be counseled to determine their blood pressure daily. In these patients, corticosteroids should be used only when absolutely required, and at low doses.

Once scleroderma renal crisis occurs, prompt hospitalization and treatment with short-acting ACE inhibitors is essential. The goal is adequate blood pressure control before the onset of renal failure. Despite appropriate timely intervention, more than half of patients with scleroderma renal crisis require hemodialysis, although many recover sufficient renal function to discontinue hemodialysis. Oliguria or a serum creatinine level higher than 3 mg/dL at presentation predict poor outcome. The "prophylactic" use of ACE inhibitors to prevent scleroderma renal crisis is associated with a worse outcome and is not recommended.

Chronic Kidney Disease

Kidney biopsy specimens from SSc patients who have not developed scleroderma renal crisis commonly show chronic lesions such as reduplication of elastic fibers, sclerosed glomeruli, tubular atrophy, and interstitial fibrosis. In one study, evidence of abnormal renal function or proteinuria was found in more than one third of patients, but none progressed to end-stage renal disease. Patients with SSc may rarely develop glomerulonephritis associated with lupus serologies or antineutrophil cytoplasmic antibody–positive renal vasculitis.

Cardiac Involvement

Primary cardiac involvement is frequently detected using sensitive diagnostic tools but can be clinically silent. Cardiac involvement occurs more frequently in dcSSc and generally develops early in the disease. Clinically evident cardiac involvement is a poor prognostic factor. The endocardium, myocardium, and pericardium may be affected separately or together. Clinical manifestations include tachycardias, conduction abnormalities, valvular regurgitation, diastolic heart failure, and pericardial effusion. Systemic and pulmonary arterial hypertension and lung and renal involvement also affect the heart. Conventional echocardiography has a low sensitivity for detecting SSc heart involvement. Newer modalities such as tissue Doppler echocardiography, single-photon emission computed tomography, and especially cardiac magnetic resonance imaging (MRI) reveal a high prevalence of myocardial abnormalities such as abnormal ventricular relaxation and reversible perfusion defects (Chapter 56). Elevated serum level of NT-pro-BNP is a sensitive marker for increased pulmonary artery pressure but may also indicate primary cardiac involvement. Myocarditis can develop in association with muscle inflammation. Pericardial effusion occurs in more than 15% of SSc patients but is rarely significant.

Musculoskeletal Complications

Carpal tunnel syndrome (Chapter 428) occurs frequently and may be a presenting manifestation of SSc. Joint mobility is progressively impaired, especially in the hands. Large joint contractures can be accompanied by tendon friction rubs that can be heard or palpated on passive movement. Tendon rubs are due to extensive fibrosis and adhesion of the tendon sheaths and fascial planes at the affected joint. Joint inflammation is uncommon in SSc; however, erosive polyarthritis in the hands can occur. Muscle weakness may be a sign of deconditioning, disuse atrophy, and malnutrition. Less commonly, inflammatory myositis indistinguishable from idiopathic

polymyositis (Chapter 277) occurs in early disease. A noninflammatory myopathy characterized by atrophy and fibrosis in the absence of elevated muscle enzyme levels may occur in late disease. Bone resorption can affect the distal tufts of terminal phalanges (acro-osteolysis), mandibular condyles, ribs, and distal clavicles.

Other Manifestations of Systemic Sclerosis

Many SSc patients develop dry eyes and dry mouth, but in contrast to Sjögren's syndrome (Chapter 276), salivary gland biopsy shows fibrosis rather than focal lymphocytic infiltration. Hypothyroidism due to thyroid fibrosis is common and may be associated with antithyroid autoantibodies. The central nervous system is generally spared in SSc. However, a primarily sensory neuropathy of the trigeminal nerve due to fibrosis or vasculopathy can occur. Pregnancy in SSc is associated with an increased rate of adverse fetal outcomes. Furthermore, cardiopulmonary involvement may worsen, and scleroderma renal crisis can occur with pregnancy. Inability to attain or maintain penile erection is due to vascular insufficiency and fibrosis is frequent and may be the presenting disease manifestation. Cancer of the lung, tongue, and breast occur more frequently in patients with SSc. Barrett's esophagus is associated with increased risk for adenocarcinoma.

Laboratory Features

Anemia is common in SSc and may reflect chronic inflammation, gastrointestinal bleeding caused by GAVE or chronic esophagitis, or a maturation disorder caused by folate and vitamin B_{12} deficiency due to small bowel bacterial overgrowth and malabsorption. Microangiopathic hemolytic anemia (Chapter 163) caused by mechanical trauma and red blood cell fragmentation is a hallmark of scleroderma renal crisis. In contrast to other connective tissue diseases, the erythrocyte sedimentation rate and C-reactive protein are generally not elevated.

Antinuclear autoantibodies (ANAs) are present in virtually all patients with SSc at disease onset. Characteristic autoantibodies in SSc are described in Table 275-3. Autoantibodies against topoisomerase-I (Scl-70) are detected in 31% of patients with dcSSc but in only 13% of patients with lcSSc; conversely, anticentromere antibodies are detected in 38% of patients with lcSSc but in less than 2% of patients with dcSSc. Anticentromere antibodies are associated with PAH but are rarely seen with cardiac involvement, significant pulmonary fibrosis, or scleroderma renal crisis. Topoisomerase-I antibody–positive patients have reduced survival compared with those without this antibody, whereas anticentromere antibody–positive patients have improved survival compared with those without this antibody. Antibodies to RNA polymerase III (often recognized based on a speckled pattern of immunofluorescence) are associated with increased risk for scleroderma renal crisis. Antibodies to β_2-glycoprotein I are not specific but in SSc identify increased risk for critical ischemia.

DIAGNOSIS

Skin induration and Raynaud's phenomenon associated with typical visceral organ manifestations are sufficient to establish the diagnosis of SSc. Occasionally, full-thickness skin biopsy may be required for diagnosing scleroderma mimics such as scleredema, scleromyxedema, or nephrogenic systemic fibrosis (see Table 275-1). Primary Raynaud's phenomenon is differentiated from SSc by nailfold capillaroscopy and by testing for autoantibodies. Making the diagnosis of SSc can be difficult in early disease because initial symptoms are often nonspecific and can be mistaken for rheumatoid arthritis, systemic lupus erythematosus, myositis, or undifferentiated connective tissue disease. Rarely, SSc may present with accelerated hypertension or gastrointestinal bleeding caused by watermelon stomach as the initial manifestation. Laboratory features, including autoantibodies, are discussed in the previous section.

TREATMENT AND PREVENTION Rx

With the exception of ACE inhibitors for scleroderma renal crisis, no therapy has been shown to alter significantly the natural history of SSc. In contrast, effective treatments are available for alleviating symptoms of SSc and for slowing the progression of the cumulative organ damage. A significant reduction in disease-related mortality has occurred during the past 25 years. Because of the marked heterogeneity in clinical presentation, a thorough and individualized evaluation at baseline is indicated. Treatment must be tailored to each patient's unique needs. Optimal management incorporates prompt diagnosis, accurate classification and risk stratification, early recognition of organ-based complications, and regular monitoring for assessing progression, disease activity, and response to therapy. Management of complications should be proactive, with regular screening and initiation of appropriate intervention at the earliest possible opportunity. Given the multisystemic nature of SSc, an integrated team-based management approach is optimal. The team should incorporate appropriate medical specialists. Patients are empowered by learning about potential complications, therapeutic options, and natural history of their disease.

Disease-Modifying Therapy

Immunosuppressive Agents

Immunosuppressive agents effective in the treatment of other connective tissue diseases have generally shown modest or no benefit in SSc. Corticosteroids may alleviate stiffness and aching in early-stage dcSSc but do not slow the progression of skin or internal organ involvement and are associated with an increased risk for scleroderma renal crisis. Therefore, corticosteroids should be avoided if possible; when absolutely necessary, they should be given at the lowest dose possible and for brief periods only.

The use of cyclophosphamide in SSc has been evaluated in retrospective and controlled clinical trials.[1,2] Cyclophosphamide was shown to reduce the progression of symptomatic interstitial lung disease in early SSc. Compared with placebo, patients treated with cyclophosphamide showed stabilization and, rarely, modest improvement in respiratory symptoms, pulmonary function, and abnormalities on chest HRCT after 1 year of treatment.[■] The beneficial effect of oral cyclophosphamide on lung function was short-lived. Its use in SSc needs to be balanced against its potential for side effects, including bone marrow suppression, opportunistic infections, hemorrhagic cystitis, bladder cancer, and premature ovarian failure.

In small clinical trials, methotrexate and mycophenolate mofetil treatment were associated with a modest improvement in skin involvement. These drugs are generally well tolerated in SSc. There is some support in the literature for the use of immunomodulatory agents and interventions such as cyclosporine, azathioprine, intravenous immunoglobulin, and extracorporeal photophoresis for the treatment of SSc. Recent reports suggest that rituximab might be effective in ameliorating skin and lung involvement. Immune ablation using high-dose chemotherapy, with or without irradiation, followed by autologous stem cell reconstitution, has been reported to induce dramatic and durable remission in some patients with SSc and is currently being evaluated in randomized clinical trials. In light of its potential morbidity and mortality and its substantial cost, autologous stem cell transplantation is presently considered an experimental therapy in SSc.

Antifibrotic Therapy

Because tissue fibrosis causes progressive organ damage and contributes to the mortality of SSc, drugs that block the fibrotic process represent a rational approach to therapy. D-Penicillamine has been extensively used as an antifibrotic agent. In retrospective studies, D-penicillamine stabilized and improved skin induration, prevented new internal organ involvement, and improved survival of SSc. However, in a randomized controlled clinical trial of early active SSc, there was no difference in the extent of skin involvement between patients treated with standard-dose (750 mg/day) or very low-dose (125 mg every other day) D-penicillamine. Minocycline, bosentan, recombinant relaxin, interferon-γ, and inhibitors of tumor necrosis factor are putative antifibrotic agents that have failed to show meaningful benefit in SSc clinical trials. Small-molecule inhibitors of protein tyrosine kinases used successfully for the treatment of malignancies, such as imatinib, nilotinib, and dasatinib, block signaling by TGF-β and PDGF and thereby prevent fibrotic responses in vitro and in vivo. These agents are currently in clinical trials for the treatment of SSc.

Treatment of Organ-Specific Complications

Gastrointestinal Complications

Because significant gastroesophageal reflux may occur in the absence of symptoms, all patients with SSc should be treated for this complication. Proton pump inhibitors may need to be given in relatively high doses, and patients should be instructed to elevate the head of the bed and eat frequent small meals. Recurrent gastrointestinal bleeding from GAVE can be successfully treated with laser photocoagulation. Bacterial overgrowth due to small bowel hypomotility causes bloating and diarrhea and may lead to malabsorption, weight loss, and malnutrition. Treatment with short courses of rotating broad-spectrum antibiotics such as metronidazole, erythromycin, and tetracycline can eradicate bacterial overgrowth. Parenteral hyperalimentation may be indicated. Chronic hypomotility of the small bowel may respond to octreotide injections.

Vascular Therapy and the Treatment of Raynaud's Phenomenon

The goal of therapy is to reduce the frequency and duration of vasospastic episodes, prevent ischemic complications and enhance their healing, and slow the progression of obliterative vasculopathy. Patients should dress warmly, minimize cold exposure, and avoid drugs that could precipitate or exacerbate vasospastic episodes. The calcium-channel blockers nifedipine and diltiazem are commonly used but show only moderate benefit, and their use is often

limited by side effects (palpitations, dependent edema, light-headedness). ACE inhibitors do not reduce the frequency or severity of episodes, but angiotensin II receptor blockers such as losartan are effective and generally well tolerated. Some patients with Raynaud's phenomenon might require α1-adrenergic receptor blockers (e.g., prazosin), 5-phosphodiesterase inhibitors (e.g., sildenafil), topical nitroglycerine, or intravenous prostaglandins. Low-dose aspirin and dipyridamole prevent platelet aggregation and may have a role as adjunctive agents. The endothelin-1 receptor antagonist bosentan reduces development of new ischemic ulcers. Intravenous prostacyclin infusion and digital sympathectomy are options for some patients with severe Raynaud's phenomenon associated with digital ischemia. Empirical long-term therapy with statins and antioxidants may delay the progression of vascular damage.

Pulmonary Arterial Hypertension

Patients with SSc should be screened for PAH at initial evaluation and, for high-risk patients, on a yearly basis. When symptomatic PAH is detected, treatment should be started with an endothelin-1 receptor antagonist or a 5-phosphodiesterase inhibitor. Diuretics, oral anticoagulation, and digoxin may be used when appropriate. If hypoxemia is documented, supplemental oxygen should be given. If clinical response is inadequate, 5-phosphodiesterase inhibitors may be used in combination with endothelin-1 receptor antagonists. Prostacyclin analogues can be administered intravenously, by continuous subcutaneous infusion, or by frequent inhalations. Lung transplantation remains an option for selected SSc patients with PAH who fail medical therapy.

Treatment and Prevention of Scleroderma Renal Crisis

Prompt recognition of impending or early scleroderma renal crisis is essential. Because patients with early-stage SSc and progressive skin involvement are at highest risk, they should monitor their blood pressure daily and report significant alterations immediately. Corticosteroids should be used at the lowest possible doses and only when absolutely necessary. When scleroderma renal crisis occurs, patients should be hospitalized and treatment with short-acting ACE inhibitors started immediately to achieve prompt blood pressure normalization. There is no evidence that "prophylactic" use of ACE inhibitors can prevent the development of scleroderma renal crisis or ameliorate its severity. Although up to two thirds of patients who develop renal crisis require dialysis, delayed recovery of renal function can occur. Kidney transplantation is appropriate for patients unable to discontinue dialysis after 2 years. Survival with renal transplantation in SSc is comparable to that in other connective tissue diseases, and recurrence of scleroderma renal crisis is rare.

Skin Care

Skin involvement in early SSc is inflammatory and can be controlled with systemic antihistamines or short-term low-dose corticosteroids. Because of the increased risk for scleroderma renal crisis, blood pressure should be carefully monitored. Cyclophosphamide, methotrexate, D-penicillamine, and mycophenolate have been associated with modest improvement in skin induration in early-stage SSc. Skin dryness can be managed with the use of hydrophilic ointments and emollient bath oils. Fingertip ulcerations should be protected by occlusive dressing to promote healing and prevent infection. Infected skin ulcers are treated with topical or oral antibiotics and may necessitate surgical débridement. No medical therapy has been shown to be effective in preventing soft tissue calcification or in promoting its dissolution, and surgical therapy is only occasionally effective.

PROGNOSIS AND NATURAL HISTORY

Compared with patients with lcSSc, patients with dcSSc have a more rapidly progressive disease, greater internal organ involvement, and worse prognosis. However, the course of the disease is difficult to predict in early stages when the specific SSc subset—diffuse or limited cutaneous—is not clear.

Early inflammatory symptoms of dcSSc such as fatigue, edema, arthralgia, and pruritus subside after 2 to 4 years, and skin thickening reaches a plateau. Subsequently, the skin changes generally show slow regression, which characteristically occurs in an order that is the reverse of initial involvement, with softening on the trunk followed by proximal and finally the distal extremities. Sclerodactyly and finger contractures generally persist. Relapse or recurrence of skin thickening is rare. Visceral organ involvement develops and shows most rapid progression during the initial 2 to 4 years of the disease, and new organ involvement is rare after the skin involvement has reached a plateau. Scleroderma renal crisis almost invariably occurs within the first 4 years of disease. In patients with lcSSc, Raynaud's phenomenon typically precedes other manifestations by years or even decades, whereas visceral organ involvement such as PAH and GERD generally occurs late in the course of the disease.

Age- and gender-adjusted mortality rates in patients with SSc are more than five-fold higher than in the general population. The ten-year survival rate of patients with dcSSc is 55%, and 75% with lcSSc. Survival correlates with the extent of skin involvement, which represents a surrogate for visceral organ involvement. The leading causes of death are pulmonary fibrosis, PAH, gastrointestinal involvement, and cardiac disease. Markers of poor prognosis include male gender, African American race, older age of disease onset, a low body mass index, extensive skin thickening with truncal involvement, evidence of significant or progressive visceral organ involvement, the presence of antibodies to topoisomerase-I or RNA polymerase III, or the absence of anticentromere antibodies. In one study, SSc patients who had extensive skin involvement, vital capacity less than 55% of predicted, significant gastrointestinal involvement, and clinically evident cardiac involvement or scleroderma renal crisis had a less than 40% 10-year survival rate. The severity of PAH is correlated with mortality, and SSc patients who demonstrated a mean pulmonary arterial pressure of 45 mm Hg or greater had a 33% 3-year survival rate. Therapy with ACE inhibitors has had a dramatic affect on survival in scleroderma renal crisis, increasing from less than 10% at 1 year in the pre-ACE inhibitor era to a more than 70% 3-year survival rate at the present time.

NEPHROGENIC SYSTEMIC FIBROSIS

Nephrogenic systemic fibrosis (NSF) is a novel complication of renal insufficiency with certain clinical features resembling systemic sclerosis. The condition was initially described in 2000 and is now recognized as an emerging problem in patients with chronic renal failure. It is estimated that 2% of patients on long-term hemodialysis might develop NSF. Originally considered a purely dermatologic scleromyxedema-like condition and termed *nephrogenic fibrosing dermatopathy*, NSF is now recognized to be associated with visceral organ involvement and is therefore more accurately termed *nephrogenic systemic fibrosis*. The cutaneous manifestations of NSF share histopathologic and clinical features with other scleroderma-spectrum disorders, notably fasciitis and scleromyxedema. In most patients with NSF, the condition develops while undergoing long-term dialysis. However, no association with a particular route or type of renal replacement therapy has been demonstrated. Furthermore, NSF has also been described in patients who have never received dialysis. Histologic hallmarks include cutaneous fibrosis with mucin deposition and accumulation of spindle-shaped cells, including numerous CD34-positive cells, in the lesional skin.

The clinical hallmark of NSF is thickening and "woody" tightness of skin over the lower and, less commonly, upper extremities and contractures at large joints. Raynaud's phenomenon and hallmark SSc autoantibodies do not occur. A link between NFS and exposure to gadolinium-containing MRI contrast agents was suggested in 2006, leading to a warning by the U.S. Food and Drug Administration regarding the use of these agents in patients with renal insufficiency. This was followed by a substantial decline in the incidence of NSF. The pathogenesis of the syndrome remains unknown, but several studies described the detection of gadolinium in tissues from patients with NFS. Other studies report increased expression of fibrogenic cytokines, including TGF-β and CTGF, and evidence of activated TGF-β signaling in lesional NFS tissues. Of note, it has been observed that hemodialysis patients without NFS also had elevated levels of these cytokines in the skin. The course of NFS is generally progressive, and the prognosis is poor. Some patients show improvement with adjustment to renal replacement therapy, and others respond to renal transplantation. Anecdotal reports describe treatment with phototherapy, imatinib mesylate, and immunosuppressive agents. However, in most patients with NSF, the induration is resistant to therapy and leads to progressive induration, joint contractures, and reduced mobility. Many patients become wheelchair dependent.

276 SJÖGREN'S SYNDROME

STANLEY NAGUWA AND M. ERIC GERSHWIN

DEFINITION

Sjögren's syndrome (SS) is an autoimmune disease characterized by the immune-mediated destruction of exocrine glands, particularly salivary and lacrimal glands, with secondary development of keratoconjunctivitis and xerostomia. Primary and secondary forms of SS have been defined. Primary SS occurs in the absence of a connective tissue disease; secondary SS occurs most commonly in association with a systemic connective tissue disorder, particularly rheumatoid arthritis but also systemic sclerosis, systemic lupus erythematosus, and polymyositis.

EPIDEMIOLOGY

SS was first described in detail in 1933, but there was in fact an earlier description in 1892, where the disease was termed *Mikulicz's syndrome*. For more than 3 decades after the 1933 description, SS was considered a relatively uncommon diagnosis of older women. However, more recent data, obtained by the use of standardized criteria, suggest that SS may affect 0.5 to 2% of women. The incidence of SS increases with age, and SS is virtually absent in children. Nearly 2% of women older than 60 years have features of primary SS, particularly dry eyes and dry mouth. Other exocrine glands can also be affected, with subsequent development of pancreatic dysfunction, vaginal dryness, and dry cough. SS occurs in 10 to 25% of patients with systemic lupus erythematosus (Chapter 274) and in 30 to 50% of patients with rheumatoid arthritis (Chapter 272).

PATHOBIOLOGY

Multiple viral agents have been incriminated as etiologic factors for either the development or the modulation of SS; these include Epstein-Barr virus, retroviruses, and coxsackieviruses, but in all cases, the data remain controversial. SS does have a strong immunogenetic basis, however, and it was one of the first autoimmune diseases associated with specific major histocompatibility complex genes. Several genetic alleles have been found to occur more commonly in patients with SS, particularly human leukocyte antigen (HLA) class II antigens. As with other autoimmune diseases, the specific HLA gene association varies according to the ethnic background of the individual. The responsible mechanisms are unknown, and more extensive studies are required to map class II genes precisely, particularly in the DQB1 first hypervariable region. The following sequence of events has been proposed and is summarized in E-Figure 276-1: (1) viral stimulation of Toll-like receptors (TLRs); (2) stimulation of interferon-α (IFN-α)–associated genes, with modification by interferon regulatory factor 5 *(IRF5)* gene polymorphisms; (3) stimulation of the B-cell activation factor (BAFF); and (4) production of autoantibodies, including anti-M3 muscarinic receptor (M3R) antibodies; leading to (5) glandular dysfunction.

The significance of anti-Ro and anti-La antibodies in SS is speculative. These antibodies are found deposited in the salivary glands of affected patients. The Ro proteins colocalize to the blebs of apoptotic cells and may become an immune target or function as a primary immunogen. Nonetheless, serum levels of antibodies to Ro and La do not correlate with disease activity. A pathologic role of anti-Ro antibodies has been described because their passive transfer in pregnancy leads to neonatal congenital heart block. In fetuses of mothers with anti-Ro antibodies and heart block, therapy with dexamethasone, which readily passes across the placenta, is preferred to prednisone.

CLINICAL MANIFESTATIONS

The differential diagnosis of xerophthalmia (dry eyes) and xerostomia (dry mouth) is noted in Table 276-1; presentation is most common in women in their 30s to 50s. Dry mouth leads to difficulty swallowing, recurrent and unique dental infections, pain on eating salty or spicy foods, and difficulty talking. In many patients, impairment of fluid secretion within the nasal and throat passages predisposes to oral erythematous thrush. Dry eyes result in complaints of ocular itching, a sense of grittiness, eyelid symptoms, and an exaggerated sensitivity to ocular insults such as smoke. Other upper and lower respiratory symptoms are secondary to dryness and include a nonproductive cough and occasionally tracheobronchitis.

Classically, SS manifests with painless enlargement of the salivary glands, generally beginning unilaterally. This enlargement may be dramatic and cyclic in nature and is generally absent in patients with coincidental rheumatoid arthritis. The symptoms of SS develop insidiously, and often the diagnosis is not considered for several years because the complaints of sicca are attributed to medications (e.g., antihistamines, antidepressants), a dry

environment, or aging. The neurologic components of SS include peripheral and cranial neuropathies and a multiple sclerosis "look-alike" central nervous system disease. Skin manifestations include palpable or nonpalpable purpura, papules, urticarial lesions, and annular lesions. Xerosis is frequently found on examination. A nonerosive arthritis, polyarthralgia, and Raynaud's phenomenon are typically seen in SS. In addition to tracheobronchitis, lung involvement in SS may include bronchiectasis, interstitial pneumonitis, and fibrosis. Smoking is an additional major risk factor for pulmonary disease in patients with SS. Renal involvement may include interstitial nephritis, renal tubular acidosis, and hyposthenuria with glomerulonephritis, a more recently recognized problem. Autoimmune liver disease and pancreatitis are seen occasionally.

The classic exocrine symptoms of SS are listed in Table 276-2, but theoretically, SS can affect all major organ systems (Table 276-3). Patients may initially present with only extraglandular symptoms, especially a nonerosive rheumatoid factor–positive arthritis. In addition, as a component of the inflammatory process and pro-inflammatory cytokine release, patients may manifest chronic fatigue and low-grade fevers. Finally, mucosa-associated lymphoid tissue (MALT) and B-cell lymphomas (Chapter 191) have been described as secondary events in SS. The incidence of lymphoma in SS varies among studies and may depend on local referral patterns (selection bias); lymphoma develops in approximately 5% of patients.

Laboratory Findings

The most commonly used test for the diagnosis of SS is the Schirmer test, performed without anesthetic eye drops. This involves measuring the wetting of standardized tear test strips applied between the eyeball and the lateral inferior lid. Tear osmolarity may be a better test for SS. Salivary flow and labial salivary biopsy are also commonly used for diagnosis. Patients with SS have antinuclear antibodies of either homogeneous or speckled patterns (80 to 90% frequency), antibodies to Ro (SSA; 60 to 75% frequency) and La (SSB; 40% frequency), presence of rheumatoid factor (70 to 90% frequency), mixed cryoglobulin with rheumatoid factor activity (type II; <5%), and antibodies to centromere (<5%). The presence of mixed cryoglobulinemia suggests hepatitis C infection; these complexes contain rheumatoid factor, hepatitis C antigen, and complement. Antibodies to mitochondria have likewise been described in SS, but they are found reliably only in patients with coexistent primary biliary cirrhosis. It has been reported that patients with SS develop antibodies to three new autoantigens called IFI16, KLHL12, and KLHL7. These autoantigens represent a family of transcription regulators; KLHL12 and KLHL7 are kelch-like proteins of unknown physiologic function. Although diagnostic tests for these autoantigens are not widely available, we believe they will become important biomarkers for the clinical diagnosis of SS.

TABLE 276-3 EXTRAGLANDULAR MANIFESTATIONS OF PRIMARY SJÖGREN'S SYNDROME

CONSTITUTIONAL SYMPTOMS
Fatigue
Low-grade fever
SKIN AND VASCULAR
Small vessel vasculitis
Raynaud's phenomenon
Photosensitivity reactions similar to subacute cutaneous systemic lupus erythematosus
Xerosis
UPPER AND LOWER AIRWAYS
Pyogenic sialadenitis or parotitis
Interstitial pneumonitis or fibrosis
Chronic bronchitis
Bronchiectasis
Bronchiolitis obliterans with organizing pneumonia
Pseudolymphoma with intrapulmonary nodules
Chronic obstructive pulmonary disease
MUSCULOSKELETAL
Polyarthralgia, polyarthritis
Myopathy, polymyositis
RENAL
Type I renal tubular acidosis

TABLE 276-4 CLASSIFICATION CRITERIA FOR SJÖGREN'S SYNDROME

I. OCULAR SYMPTOMS
A positive response to at least one of these three questions: 1. Have you had daily, persistent, troublesome dry eyes for more than 3 months? 2. Do you have a recurrent sensation of sand or gravel in the eyes? 3. Do you use tear substitutes more than three times a day?
II. ORAL SYMPTOMS
A positive response to at least one of these three questions: 1. Have you had a daily feeling of dry mouth for more than 3 months? 2. Have you had recurrent or persistently swollen salivary glands as an adult? 3. Do you frequently drink liquids to aid in swallowing dry food?
III. OCULAR SIGNS
Objective evidence of ocular involvement, defined as a positive result in at least one of the following two tests: 1. Schirmer test (≤5 mm in 5 min)* 2. Rose bengal score (≥4 according to van Bijsterveld scoring system)
IV. HISTOPATHOLOGY
A focus score ≥1 in a minor salivary gland biopsy specimen (a focus is defined as an agglomerate of at least 50 mononuclear cells; the focus score is defined by the number of foci in 4 mm^2 of glandular tissue)
V. SALIVARY GLAND INVOLVEMENT
Objective evidence of salivary gland involvement, defined by a positive result in at least one of the following three diagnostic tests: 1. Salivary scintigraphy 2. Parotid sialography 3. Unstimulated salivary flow (≤1.5 mL in 15 min)*
VI. AUTOANTIBODIES
Presence in the serum of the following autoantibodies: antibodies to Ro (SSA) or La (SSB) antigens, or both
RULES FOR CLASSIFICATION
In patients without any potentially associated disease, primary Sjögren's syndrome is diagnosed if: four of six criteria are met, including IV or VI; or three of four criteria from III, IV, V, and VI are met
For secondary Sjögren's syndrome, criteria I or II plus any two from criteria III, IV, and V should be met
EXCLUSION CRITERIA
Preexisting lymphoma, AIDS, sarcoidosis, graft-versus-host disease, past head and neck radiation treatment, use of anticholinergic drugs, and hepatitis C

*Because it has been shown that this test may be reduced in normal subjects older than 60 years, it should be excluded from the criteria or not considered indicative for a diagnosis of Sjögren's syndrome in elderly subjects.

From Vitali C, Bombardieri S, Johnsson R, et al. Classification criteria for Sjögren's syndrome: a revised version of the European criteria proposed by the American-European Consensus Group. *Ann Rheum Dis.* 2002;61:554-558.

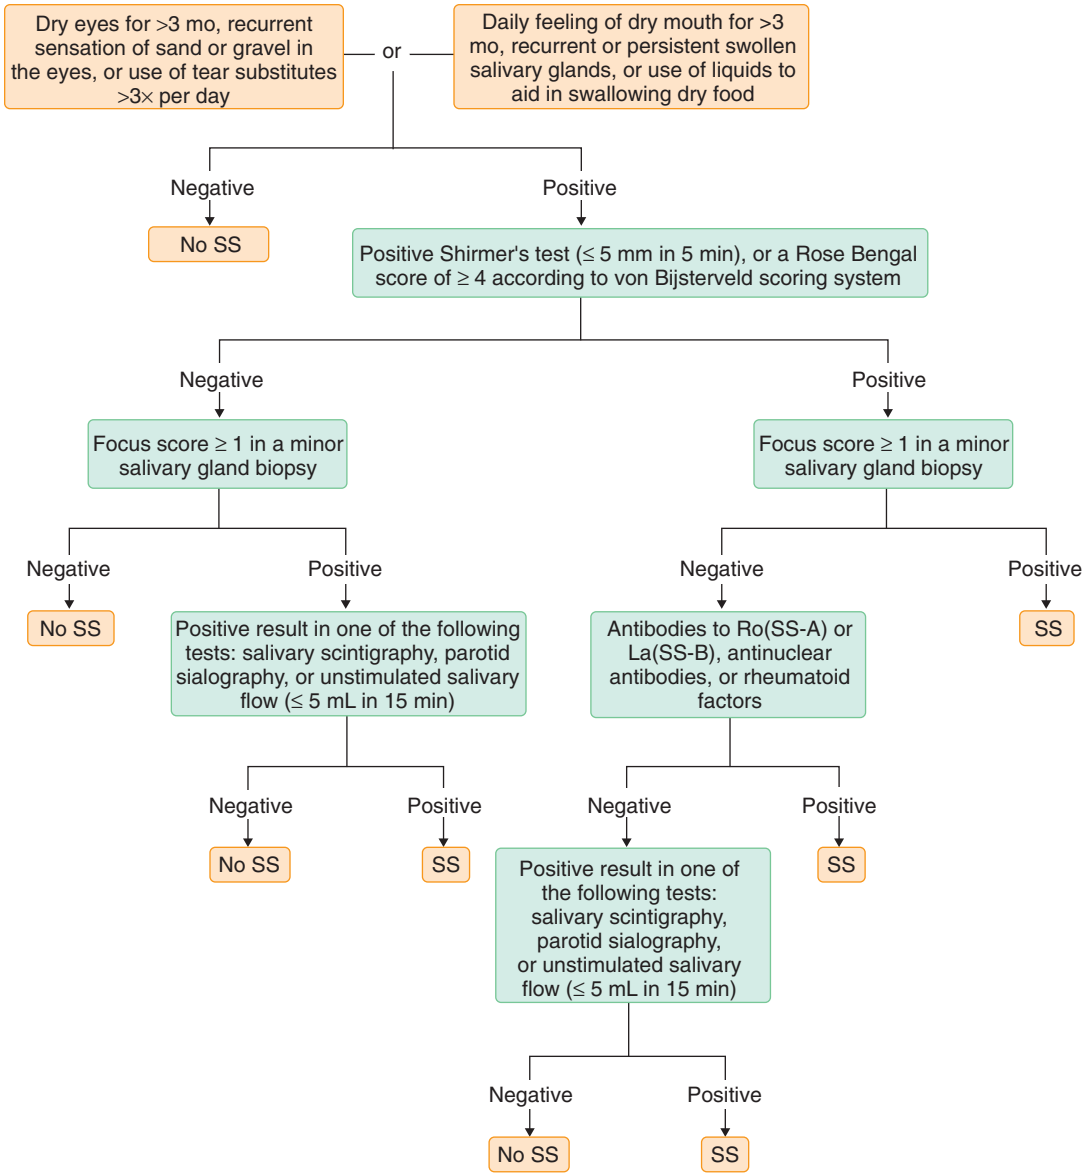

FIGURE 276-1. Algorithm for the diagnosis of Sjögren's syndrome (SS). (From Tzioufas AG, Moutsopoulos HM. Sjögren's syndromes. In: Klippel JH, Dieppe PA, eds, *Rheumatology*, 2nd ed. London: Mosby; 1998.)

Patients with SS exhibit a dramatic polyclonal B-cell activation. Several other autoantibodies have been described with variable frequencies, including antibodies to carbonic anhydrase, α-fodrin, proteosomal subunits, and the muscarinic M3 receptor (M3R); the last-mentioned protein is found on salivary glands and may explain glandular dysfunction in SS. There is also evidence for altered B-cell differentiation. An SS-like disorder develops in mice transgenic for BAFF (a member of the tumor necrosis factor-α [TNF-α] superfamily that regulates B-cell proliferation). Anemia (including autoimmune hemolytic anemia), leukopenia, and thrombocytopenia occur in SS and are most commonly found in patients with chronic disease.

The serious immune system abnormalities in SS include lymphadenopathy, pseudolymphoma, and lymphoma. The transition from a rheumatoid factor–positive MALT polyclonal gammopathy to a rheumatoid factor–negative oligoclonal or monoclonal gammopathy augurs a change from a benign to a malignant process. This process can be enhanced if the V_K3b-related and the G6 (V_H1-related) idiotypes are present. On histologic examination, the intense lymphoid infiltration includes germinal centers in the exocrine glands; the intense lymphocytic infiltrate is predominantly $CD4^+$ T-cell TCRαβ CD45RO cells. Finally, the degree of inflammation seems to be associated with a T_H1 response, with striking production of IFN-γ, interleukin-2, and interleukin-10. The development of severe histologic changes may be a prodrome of lymphoma. The migration of mononuclear cells to exocrine glands is mediated by chemokines and their cognate receptors, particularly macrophage inflammatory protein-1 (MIP-1) and RANTES.

DIAGNOSIS

Diagnostic Criteria

The diagnostic criteria of SS continue to evolve, but revised American-European classification criteria are currently employed (Table 276-4 and Fig. 276-1). These criteria cannot be used if the patient has compounding medical problems, including preexisting lymphoma, acquired immunodeficiency syndrome, sarcoidosis, graft-versus-host disease, past head and neck irradiation, use of anticholinergic drugs, and hepatitis C—diseases commonly included in the differential diagnosis. A Sjögren's-like disorder is associated with graft-versus-host disease. Diffuse infiltrative lymphocytosis syndrome (DILS) is a Sjögren's-like syndrome occurring in HIV-positive patients, characterized by salivary gland enlargement, peripheral $CD8^+$ lymphocytosis, and the presence of sicca and extraglandular features. The diagnosis of graft-versus-host disease is clinically obvious on the basis of the history. DILS occurs more commonly in males in the absence of the unique autoantibody profile of SS. The classification criteria are helpful in distinguishing between SS and sicca syndrome secondary to medications. An abnormal finding on lip biopsy and the presence of autoantibodies suggest a systemic autoimmune disease. SS is more commonly associated with several other autoimmune diseases, including Hashimoto's thyroiditis, primary biliary cirrhosis, chronic active hepatitis, celiac sprue, myasthenia gravis, and pernicious anemia. The development of universally accepted classification criteria has been hampered by small sample sizes; a National Institutes of Health–funded Sjögren's International Collaborative Clinical Alliance has begun an International Sjögren's Syndrome Registry to acquire a sufficiently large database to develop such classification criteria.

TREATMENT

Rx

The primary treatment of SS is to minimize discomfort by the use of substitutes for the dysfunctional exocrine secretions (e.g., artificial tears, artificial saliva, increased oral fluids, ocular lubricants, vaginal lubricants). Ocular steroids are not recommended because they predispose to serious secondary infections. Goggles and punctal occlusion are also used to slow the loss of tears. Topical cyclosporine is a recently added treatment, although there is a concern about herpesvirus infections. Oral pilocarpine and cevimeline may stimulate functional exocrine glands and improve symptoms,[1] but the response varies greatly among patients. The appearance of thrush warrants prompt treatment because it severely aggravates oral symptoms; nystatin is generally effective for this complication. Finally, regular dental examinations and oral hygiene are crucial for reducing subsequent oral health issues (i.e., caries and periodontal disease associated with xerostomia). TNF-α inhibitors have proved largely disappointing, likely due to increases of IFN-α and BAFF. Rituximab is reportedly beneficial in SS-associated lymphoma (Chapter 191) and for sicca symptoms in early disease. Multiple other biologic agents are under development, including belimumab and bortezomub.

Extraglandular manifestations of SS are also managed in a symptomatic fashion. Treatment of arthritis includes nonsteroidal anti-inflammatory drugs, prednisone, hydroxychloroquine, methotrexate, and TNF-α inhibitors. Constitutional symptoms are treated with hydroxychloroquine or prednisone. Inflammatory organ system disease (involving the lung, liver, neurologic system, hematologic system, and kidney) is treated individually with prednisone, methotrexate, azathioprine, or TNF-α inhibitors. Careful surveillance for infectious complications and neoplasia is crucial because the risk of both is increased in SS. Intravenous immunoglobulin has been suggested as a treatment of SS, but there is no evidence to support its use. The mortality of patients with SS has been estimated to be 2.7-fold greater than that of a control population.

FUTURE DIRECTIONS

It is ironic that although much has been learned about the effector mechanisms of SS, little is known about the inductive mechanisms. It is likely that future therapy will focus on interrupting the inflammatory pathways, even without understanding how the disease begins. If the latency time for the development of an autoimmune disease is measured in years, it will be extremely difficult to identify the etiologic agents involved. Future work will focus on specific cytokines, chemokines, and their cognate receptor interactions in efforts to block the exocrine gland destruction. Topical glandular secretagogue use (e.g., diquafosol) is under development. It is also likely that more specific therapy for the anti-Ro-mediated complete heart block of newborns will be developed, again focusing on the abrogation of effector inflammatory pathways. Finally, it is anticipated that newer biologic agents will directly influence effector mechanisms, but they will probably be effective only if they are given to patients early in the disease course.

TABLE 277-1 CRITERIA FOR THE DIAGNOSIS OF POLYMYOSITIS AND DERMATOMYOSITIS AFTER EXCLUSION OF ALL OTHER FORMS OF MYOPATHY*

1. Symmetrical, often progressive, proximal muscle weakness
2. Characteristic electromyographic triad:
   Short-duration, small, low-amplitude polyphasic potentials
   Fibrillation potentials, seen even at rest
   Bizarre high-frequency repetitive discharges
3. Elevations of serum activities of myositis-associated enzymes:
   Creatine kinase
   Aldolase
   Lactate dehydrogenase
   Transaminases—aspartate transaminase and alanine transaminase
4. Evidence of chronic inflammation in muscle biopsy specimen:
   Necrosis of type I and type II muscle fibers
   Degeneration and regeneration of myofibers, with variation in myofiber size
   Focal collections of interstitial or perivascular mononuclear cells
5. Characteristic rashes of dermatomyositis:
   Scaly, erythematous, palpable eruptions over the metacarpophalangeal or interphalangeal joints, knees, elbows, or medial malleoli (Gottron's papules)
   Scaly, erythematous macules over the metacarpophalangeal or interphalangeal joints, knees, elbows, or medial malleoli (Gottron's sign)
   Periorbital purplish discoloration (heliotrope rash)

*Criteria originally proposed by Bohan and Peter in 1975:
Definite disease: for polymyositis, all of the first four criteria; for dermatomyositis, any three of the first four criteria plus the rash.
Probable disease: for polymyositis, any three of the first four criteria; for dermatomyositis, any two of the first four criteria plus the rash.
Possible disease: for polymyositis, any two of the first four criteria; for dermatomyositis, any one of the first four criteria plus the rash.

277 POLYMYOSITIS AND DERMATOMYOSITIS

FREDERICK W. MILLER

DEFINITION

Polymyositis and dermatomyositis are the most common forms of a family of acquired, systemic, connective tissue diseases known as the *idiopathic inflammatory myopathies*. These disorders are characterized by the clinical and pathologic effects of chronic muscle inflammation of unknown cause. Other forms of idiopathic inflammatory myopathy include inclusion body myositis and myositis seen in association with cancer or with other connective tissue diseases (e.g., scleroderma, systemic lupus erythematosus, rheumatoid arthritis) as a myositis overlap syndrome. The idiopathic inflammatory myopathies, also known as the *myositis syndromes*, are diagnosed on the basis of a combination of clinical, laboratory, and pathologic findings (Table 277-1).

EPIDEMIOLOGY

Polymyositis and dermatomyositis are rare disorders that were first described more than a century ago in Europe; they are now known to be worldwide in distribution and are likely to be increasing in frequency. The estimated annual incidence ranges from 5 to 10 per million, and the estimated prevalence is 50 to 110 per million. Polymyositis and dermatomyositis peak in prevalence in childhood (7 to 15 years) and in midlife (30 to 50 years), whereas the malignancy-associated forms and inclusion body myositis are more common after 50 years of age. Current studies suggest, however, that the prevalence, frequency of clinical forms, and risk factors for development of the idiopathic inflammatory myopathies are likely to differ in different parts of the world. There is an approximately 3 : 1 female predominance in all forms except for inclusion body myositis, in which the female-to-male ratio is inverted (approximately 1 : 3). Certain ethnic groups, including persons of African or Latino descent, may be at increased risk for idiopathic inflammatory myopathies and have poorer outcomes compared with those of European ancestry. Anecdotal clusterings in time and space suggest strong environmental influences on polymyositis and dermatomyositis, but the specific agents involved remain elusive.

PATHOBIOLOGY

An immune-mediated component to the myositis syndromes is suggested by (1) the inflammatory process, (2) the frequent finding of autoantibodies and other immune abnormalities, (3) the overlap with autoimmune diseases such as systemic lupus erythematosus in some patients, (4) the immunogenetic risk factors, and (5) the clinical response to anti-inflammatory agents. Nonetheless, by definition, the pathogenesis remains unknown. Many lines of evidence suggest that chronic immune activation in genetically susceptible individuals, after exposure to environmental triggers, plays a pivotal role in the development of idiopathic inflammatory myopathies.

The pathologic change in the muscle, skin, and other affected tissues is characterized by focal collections of mononuclear cells. Lymphocytes are the most common cells in the infiltrates, but macrophages, plasma cells,

TABLE 277-2 CLASSIFICATIONS OF THE IDIOPATHIC INFLAMMATORY MYOPATHIES

CLASSIFICATION GROUP	ASSOCIATED CLINICAL FEATURES	SEVERITY OF MYOSITIS	RESPONSE OF MYOSITIS TO THERAPY	PROGNOSIS (5-YR SURVIVAL)
CLINICAL GROUPS				
Polymyositis	None of the features below	Variable	Variable	Moderate (~80%)
Dermatomyositis	Gottron's papules or heliotrope rash	Mild to moderate	Good	Moderate (~85%)
Connective tissue myositis	Overlap with other connective tissue diseases	Mild	Excellent	Good (~90%)
Cancer-associated myositis	Cancer diagnosed within 2 yr of idiopathic inflammatory myopathy	Variable	Moderate to poor	Poor, secondary to cancer (~60%)
Juvenile myositis	Diagnosis before age 18 yr Dermatomyositis » polymyositis Subcutaneous calcifications Gastrointestinal vasculitis	Variable	Moderate to good	Good (>95%)
Inclusion body myositis	Insidious onset in older white men Distal involvement, atrophy, and asymmetrical weakness Poor response to therapy	Mild but progressive	Poor	Few deaths, but significant morbidity (>85%)
SEROLOGIC GROUPS				
Antisynthetases	Acute onset in polymyositis or dermatomyositis Interstitial lung disease, fever, dyspnea on exertion, arthritis, mechanic's hands, Raynaud's phenomenon	Moderate to severe	Moderate, but flares with taper	Poor (~75%)
Anti–signal recognition particle	Acute onset in black female Palpitations, cardiac disease, severe weakness No rash (clinically polymyositis)	Severe	Poor	Very poor (~30%)
Anti-Mi-2	Classic dermatomyositis "V" and "shawl" rashes, cuticular changes	Mild	Good	Good (>95%)

basophils, and neutrophils are sometimes present. In certain variants, eosinophils (eosinophilic myositis) or granulomas (granulomatous myositis) predominate. The muscle cells (myocytes) show evidence of necrosis, with degeneration and regeneration (E-Fig. 277-1), and there is often increased connective tissue or fibrosis in the interstitial areas around the myocytes.

Immunohistochemical and other studies implicate different mechanisms of pathogenesis in the various forms of myositis. In polymyositis and inclusion body myositis, the pathologic change suggests a cytotoxic T lymphocyte-mediated process with $CD8^+$ T cells surrounding and invading otherwise normal-appearing myocytes in endomysial areas. In dermatomyositis, however, the infiltrate is composed predominantly of B lymphocytes, dendritic cells, and $CD4^+$ helper T cells in perimysial areas around the fascicles and small blood vessels. Blood vessel pathology, with endothelial cell damage from complement deposition, and atrophy of the myofibers at the periphery of the fascicle (called *perifascicular atrophy*) are also characteristic findings in dermatomyositis. A type I interferon signature is present in the blood cells and in muscle and skin biopsies from a majority of dermatomyositis patients and in some polymyositis patients, although its role in pathogenesis remains to be elucidated. Inclusion body myositis differs from polymyositis and dermatomyositis by the presence of characteristic reddish inclusions and vacuoles, rimmed by purple granules, inside the myocytes, as demonstrated in trichrome-stained frozen muscle sections. Additional features of inclusion body myositis include frequent endomysial fibrosis, amyloid deposition, marked variation in myofiber diameter, and characteristic intranuclear and intracytoplasmic filamentous tubules seen on electron microscopy.

Autoantibodies are found in more than 90% of patients with polymyositis and dermatomyositis, although it remains unclear what role, if any, they play in pathogenesis. The most frequent of these are antinuclear antibodies, but many others are commonly seen, including rheumatoid factor, anti-U1RNP, anti-La, anti-Ro, anti-PM/Scl, and anti-Ku autoantibodies. None of these is diagnostic for polymyositis or dermatomyositis, but if present, they do assist in distinguishing the idiopathic inflammatory myopathies from other forms of myopathy. More than one third of patients with idiopathic inflammatory myopathy have autoantibodies that are diagnostic, known as myositis-specific autoantibodies. The most common of these are antisynthetase autoantibodies (and the most common antisynthetases are anti-Jo-1 autoantibodies), anti–signal recognition particle autoantibodies, and anti-Mi-2 autoantibodies that are directed against a nuclear helicase. Each of these autoantibodies is strongly associated with a distinct clinical presentation, response to therapy, and prognosis, suggesting that each autoantibody may be representative of a truly different myositis syndrome (Table 277-2). The myositis-specific autoantibodies are available commercially, but they need not be obtained in all patients. They may be particularly useful in the diagnosis of perplexing cases or in predicting prognosis. Several other autoantibodies, called *anti-p155* and *anti-MJ autoantibodies*, have recently been identified in association with dermatomyositis and appear to be common in children with the disease.

As is the case for other autoimmune conditions, polymyositis and dermatomyositis are complex disorders that are likely caused by the interaction of multiple genetic and environmental risk factors. The strongest genetic risk factors identified to date are the polymorphic human leukocyte antigen (HLA) genes that regulate the immune responses in the major histocompatibility complex (Chapter 45). In patients of European descent, the ancestral HLA haplotype containing A1, B8, DRB1*0301, and DQA1*0501 alleles is most strongly associated with all forms of myositis. The major clinical and autoantibody groups, however, each have additional HLA risk and protective alleles. In other ethnic groups, such as Koreans and Mesoamericans, HLA genes are not risk factors. In these ethnic groups, alleles of the genes encoding immunoglobulin proteins, which regulate levels of antibody responses to infectious agents and are known as *GM* and *KM loci*, are the major genetic risk factors for polymyositis and dermatomyositis. Alleles of other polymorphic genes, including those that regulate cytokine responses to environmental exposures, such as alleles of tumor necrosis factor-α and interleukin-1 receptor antagonist genes, have recently been associated with the childhood myositis syndromes. The environmental triggers for polymyositis and dermatomyositis are not known, but selected viral and bacterial infections, as well as certain drugs, cytokines, dietary supplements, vaccines, medical implants, and occupational exposures, have been implicated in case reports and in some epidemiologic studies. In the first worldwide study of myositis, global surface ultraviolet light intensity was found to correlate with the proportion of dermatomyositis compared with polymyositis cases and with the proportion of patients with anti-Mi-2 autoantibodies at the referral centers in the study. In a U.S. study, similar associations were seen only in women, suggesting that men and women may have inherently different responses to ultraviolet radiation.

CLINICAL MANIFESTATIONS

Myositis may present acutely, subacutely, or insidiously, and patients can exhibit single or multiple episodic attacks or persistent disease activity. The

idiopathic inflammatory myopathies can be divided into groups on the basis of clinical-pathologic or serologic features, and each of these groups has characteristic clinical and prognostic associations (see Table 277-2). Therefore, the manner in which the disease presents can suggest the form of idiopathic inflammatory myopathy present. For example, an acute, severe onset of polymyositis with pulmonary fibrosis may herald a difficult course with persistent disease, as is often seen in patients with anti-Jo-1 and other antisynthetase autoantibodies. In contrast, a slowly progressive onset associated with proximal and distal weakness and thigh muscle atrophy in an older man suggests inclusion body myositis.

Symmetrical, proximal muscle weakness is present in most cases and results in difficulty arising from chairs, getting out of cars, reaching overhead, or combing hair. Many patients also report generalized fatigue or muscle pain. Patients with dermatomyositis may present with a variety of photosensitive rashes over the face, chest, and hands. Gottron's papules are raised, often scaly, palpable lesions overlying an erythematous base on extensor surfaces such as the metacarpophalangeal and proximal interphalangeal joints, elbows, and knees; these are virtually pathognomonic for dermatomyositis (Fig. 277-1). Other characteristic rashes of dermatomyositis are Gottron's sign (macules in a distribution similar to Gottron's papules) and a characteristic purplish rash over and sometimes surrounding the upper eyelids known as the *heliotrope rash*. Patients may also develop a rash in the V of the neck (V sign) or in the distribution of a shawl (shawl sign). Other findings in dermatomyositis include cuticular overgrowth, periungual capillary changes, and dilated capillaries in the gingiva, the latter of which are especially common in juvenile dermatomyositis (see Fig. 277-1). A roughening, scaling, and erythematous fissuring of the palmar and lateral aspects of the fingers, known as *mechanic's hands*, may be seen in patients with either polymyositis or dermatomyositis and is common in those with antisynthetase autoantibodies. On occasion, patients may develop classic dermatomyositis rashes without apparent muscle weakness or elevated muscle enzymes in a syndrome called *dermatomyositis sine myositis*. Some of these individuals, however, have subclinical myositis, as demonstrated by magnetic resonance imaging studies of muscle or muscle biopsy; in others, clinical myositis develops over time. Children with dermatomyositis are particularly at risk for the development of subcutaneous calcifications and occasionally present with life-threatening intestinal vasculitis.

Although the patient and physician often focus on skeletal muscle involvement, the idiopathic inflammatory myopathies are systemic diseases with frequent extramuscular manifestations that can become the most troubling aspects of the disease (Table 277-3). Patients may suffer from arthralgias and arthritis, a variety of skin disorders, and general symptoms such as fatigue, weight loss, Raynaud's phenomenon, or fever. The gastrointestinal, pulmonary, and cardiac systems may be involved, which can both complicate therapy and adversely affect prognosis. These extramuscular manifestations may precede or follow the development of myositis, and their severity may be independent of the degree of myositis.

DIAGNOSIS

Muscle pain and weakness are frequent complaints that can arise from many causes, including intrinsic muscle diseases (myopathies), disorders of the nerves innervating the muscle (neuropathies), or the effects of drugs, toxins, or infectious agents. All these entities must be carefully considered and excluded to allow the diagnosis of polymyositis or dermatomyositis (Table 277-4). A careful medical and family history, exposure history, complete physical examination, and directed laboratory testing with electromyography and muscle biopsy should reveal the cause of muscle weakness in most cases. Given that the pathologic changes of muscle in idiopathic inflammatory myopathy are often focal and not evenly distributed, magnetic resonance imaging of the muscle can be useful to identify where inflammation is present and to increase the yield of muscle biopsy.

Population-based studies have confirmed a two- to three-fold increased relative risk of a variety of cancers within 2 years of the development of dermatomyositis and, to a lesser extent, polymyositis and inclusion body myositis. Patients with myositis at disease onset should therefore be carefully assessed for malignant neoplasms, especially cancers for which they have other risk factors. The cancer work-up should be directed and should include a thorough history for any changes in habits that might suggest a neoplasm, careful physical examination and screening rectal examination, fecal occult blood test, urinalysis, blood chemistry studies, chest radiograph, and prostate-specific antigen testing in men. Women should undergo serial breast and gynecologic examinations with Papanicolaou's stain. Physicians should have a low threshold for performing pelvic ultrasonography or computed tomography to exclude ovarian cancer, given its frequency in women with dermatomyositis. Any abnormalities in these initial studies should be followed by appropriate investigations to conclusively exclude malignant disease.

FIGURE 277-1. Clinical findings in dermatomyositis. A, Erythematous to violaceous raised papules overlying the metacarpal and interphalangeal joints, known as *Gottron's papules*. These are considered the hallmark finding in dermatomyositis. **B,** Cuticular overgrowth and periungual capillary changes, which include dilated and tortuous blood vessels with areas of atrophy, telangiectasia, vessel dropout, and bushy loop formation along the fingernail bed. **C,** Erythema and minimal edema involving the upper eyelids, with occasional telangiectasia, known as the heliotrope rash. **D,** Dilated capillaries and bushy loop formations are sometimes seen in the gingiva, especially in juvenile dermatomyositis.

TABLE 277-3 EXTRAMUSCULAR MANIFESTATIONS OF POLYMYOSITIS AND DERMATOMYOSITIS

GENERAL
Fatigue
Malaise
Weight loss
Raynaud's syndrome
MUSCULOSKELETAL
Arthralgias, usually symmetrical and involving the hand joints
Nonerosive polyarthritis, usually symmetrical and involving the hand joints
Deforming arthropathy of hand joints
Joint contractures
Carpal tunnel syndrome
Osteopenia and osteoporosis
CUTANEOUS
Characteristic dermatomyositis rashes: Gottron's papules, Gottron's sign, heliotrope rash
Other rashes: V sign and shawl sign rashes; linear extensor erythema; roughening, scaling, and erythematous fissuring of the palmar and lateral aspects of the fingers (mechanic's hands)
Photosensitivity
Periungual abnormalities, including telangiectasias and cuticular overgrowth
Bleeding gums from dilated capillaries in the gingiva
Irregular indurated plaques over the fingers, with mucin accumulation in the dermis
Subcutaneous and intradermal calcification, which may ulcerate with secondary infection
Vasculitis with infarcts and digital ulcers
Subcutaneous inflammation (panniculitis)
Alopecia
GASTROINTESTINAL
Abnormal pharyngeal and cricopharyngeal function, often leading to dysphonia
Esophageal dysphagia with occasional nasal regurgitation or aspiration
Delayed gastric emptying and reflux
Dysmotility of the small and large intestines, sometimes leading to chronic abdominal pain
Malabsorption
Vasculitis with infarcts and necrosis of the bowel
PULMONARY
Ventilatory insufficiency due to respiratory muscle weakness
Atelectasis
Aspiration pneumonia
Interstitial lung disease (pulmonary fibrosis)
Pulmonary hypertension
Drug-related pneumonitis
Opportunistic infections in immunocompromised patients
CARDIAC
Myocarditis with arrhythmias and congestive failure
Cardiomyopathy
Cor pulmonale
Rare pericarditis and pericardial effusions

TABLE 277-4 DIFFERENTIAL DIAGNOSIS OF MUSCLE WEAKNESS

DRUG- AND TOXIN-INDUCED MYOPATHIES
Corticosteroids
Ethanol
Lipid-lowering agents (HMG-CoA reductase inhibitors and fibrates)
D-Penicillamine
Colchicine
Cocaine
Cyclosporine
Ipecac
Chloroquine, hydroxychloroquine
Zidovudine (AZT)
L-Tryptophan (eosinophilia-myalgia syndrome)
ENDOCRINE DISEASES
Hypothyroidism

Fungal (candidiasis, cryptococcosis, sporotrichosis, actinomycosis, histoplasmosis)
Viral (influenza; adenovirus; coxsackievirus; echovirus; Epstein-Barr virus; retroviruses, including human immunodeficiency virus and human T-lymphotropic viruses 1 and 2; hepatitis B and C viruses)

TREATMENT

Rx

Therapy for polymyositis and dermatomyositis is directed at decreasing inflammation in target tissues, relieving symptoms, and rebuilding endurance and muscle strength. It is important to distinguish the level of disease activity (reversible active inflammation in tissues) from the amount of disease damage (irreversible scarring or fibrotic changes that result from prior inflammation) present in all affected organ systems because the therapeutic approaches are very different. For active inflammation, corticosteroids are the initial and primary therapy for these diseases (Chapter 34). Several factors are important in determining corticosteroid responses. In addition to the patient's clinical and serologic groups, these factors include an adequate initial dose (at least 1 mg/kg/day of prednisone or equivalent), the continuation of prednisone until after the serum creatine kinase activity normalizes, and a slow rate of prednisone tapering (approximately 10 mg/month, or about 15% of the existing dose per month). High-dose intravenous corticosteroids (1 g/day for 3 days) and additional immunosuppressive therapy are probably useful as initial treatments in severe cases or for those in poor prognostic groups.

There is no consensus on the best treatment of corticosteroid-resistant patients. Intravenous immunoglobulin was successful in one short-term sudy, but it is expensive and neither proven nor practical for long-term use. Oral methotrexate (7.5 to 25 mg/week, depending on disease severity and body weight) and azathioprine (50 to 200 mg/day, depending on disease severity and body weight) are the major therapeutic options used in practice, but cyclosporin A, tacrolimus, mycophenolate mofetil, cyclophosphamide, anti–tumor necrosis factor agents, anti-B-cell agents such as rituximab, or combinations of these may also be beneficial in difficult cases (Chapters 34 and 35). With the

exception of the use of topical corticosteroids, hydroxychloroquine, and sunscreens to treat the dermatomyositis rash, no specific treatment other than that for the underlying myositis improves the systemic manifestations of the idiopathic inflammatory myopathies. Rehabilitation and physical therapy are important in maintaining range of motion and preventing contractures during active disease and are the primary treatment approaches for patients with only disease damage. Exercise probably improves strength and endurance when it is initiated in a graded way during periods of disease control.

The treatment of inclusion body myositis is controversial. Retrospective reviews of corticosteroid and cytotoxic therapy, as well as several prospective trials, suggest that the rate of deterioration may be decreased or stabilized and strength improved by treating patients with evidence of active myositis. Physical therapy, however, plays the most important role in the long-term care of those with inclusion body myositis.

PROGNOSIS

The prognosis of polymyositis and dermatomyositis has been poorly studied, but current information suggests that each clinical and serologic group may differ in response to therapy and outcome (see Table 277-2). Patients with myositis who also have another connective tissue disease (the overlap group) tend to have the mildest myositis, the best clinical responses, and the fewest exacerbations of myositis over time. Patients with dermatomyositis have more severe disease, followed by patients with polymyositis. Patients with inclusion body myositis do not respond to therapy as well as patients in the other clinical groups do. The serologic groups are also different in terms of disease courses and prognosis. Patients with anti-Mi-2 autoantibodies tend to have mild myositis with good responses to therapy and few disease exacerbations with tapering of therapy. Patients with antisynthetase autoantibodies have more severe disease with moderate therapeutic responses, and they exhibit frequent exacerbations with tapering of therapy. As a group, patients with anti–signal recognition particle autoantibodies have the most acute onset, the most severe myositis, the least response to therapy, and the most persistent disease. Other clinical features associated with a poor prognosis include delay from disease onset to therapy; pulmonary, cardiac, or gastrointestinal involvement; and poor responses to immunosuppressive therapy. Any patient with an unexpectedly unresponsive or perplexing clinical course should be reevaluated for possible misdiagnosis or the development of another cause of muscle weakness.

FUTURE DIRECTIONS

Given the incurable nature of the myositis syndromes and the poor outcomes in many patients, future directions are likely to focus on improved classification criteria to separate the idiopathic inflammatory myopathies from dystrophies and metabolic myopathies through the use of genetic, pathologic, and immunologic information. A more complete understanding of the molecular pathogenesis of these disorders may result in more focused therapies. A clearer understanding of which groups of patients have poor prognoses or respond to specific agents differently would also allow more effective treatments. Because these complex diseases probably arise from the interactions of genetic and environmental risk factors, defining these elements may provide insight into the mechanisms leading to the development of myositis. This knowledge might allow the future prevention of some myositis cases by the avoidance of certain environmental exposures in genetically susceptible individuals or by gene therapy.

278 THE SYSTEMIC VASCULITIDES

JOHN H. STONE

DEFINITION

The vasculitides are a heterogeneous group of disorders linked by the common finding of destructive inflammation within blood vessel walls. On the basis of current classification schemes, approximately 20 different forms of primary vasculitis are recognized (Table 278-1).

CLASSIFICATION

Classification by Vessel Size

The cause of most forms of vasculitis remains unknown, and major gaps exist in our understanding of the pathophysiologic processes. The most valid basis for classifying the vasculitides is the size of the predominant blood vessels involved: large, medium, or small (see Table 278-1). Within individual cases, however, there is frequently overlap in the size of the blood vessels affected.

Additional Considerations in Classification

Several considerations other than blood vessel size are relevant to the classification of vasculitis (E-Table 278-1): (1) age, gender, and ethnic background of the patient; (2) tropism for particular organs; (3) presence or absence of granulomatous inflammation; (4) participation of immune complexes in the pathophysiologic process; and (5) detection of characteristic autoantibodies in the patients' serum, such as antineutrophil cytoplasmic antibodies (ANCAs).

Age, gender differences, and ethnic variation are discussed later in the section on epidemiology. The organ tropisms of these disorders are illustrated by the following examples. Henoch-Schönlein purpura typically affects the skin, joints, kidneys, and gastrointestinal tract, whereas Wegener's granulomatosis classically involves the upper airways, lungs, and kidneys. In contrast, Cogan's syndrome involves the eyes, the audiovestibular apparatus of the inner ear, and the large arteries (in 10 to 15% of cases). The granulomatous features of some forms of vasculitis resemble fungal and mycobacterial infections or the inflammation induced by the presence of a foreign body, suggesting a role for chronic antigenic stimulation.

Immune complexes are essential to the pathophysiologic mechanism of some forms of small- and medium-vessel vasculitis. Complexes of immunoglobulin (Ig) A1 are found in Henoch-Schönlein purpura. Immune complexes consisting of IgG, IgM, complement components, and the hepatitis C virion characterize most cases of mixed cryoglobulinemia. In contrast, "pauci-immune" types of small- and medium-vessel vasculitis, such as Wegener's granulomatosis and microscopic polyangiitis, have little immunoglobulin or complement deposition within diseased tissues. Many but not all patients with pauci-immune forms of vasculitis are ANCA positive.

EPIDEMIOLOGY

The epidemiologic features of individual forms of systemic vasculitis vary tremendously by geography (Table 278-2). This may reflect genetic influences, variation in environmental exposures, and other unknown disease risk factors. For example, Behçet's syndrome is rare in North Americans, affecting only 1 in approximately 300,000 persons; this condition is several hundred times more common among inhabitants of countries bordering the ancient Silk Route. Similarly, although Takayasu's arteritis is rare in the United States—on the order of 3 new cases per million people per year—this disease is reportedly the most common cause of renal artery stenosis in India, where the incidence may be as high as 200 to 300 per million per year.

Age is an important consideration in the epidemiology of vasculitis. Eighty percent of patients with Kawasaki disease are younger than 5 years. In contrast, giant cell arteritis virtually never occurs in patients younger than 50 years, and the mean age of patients with this disease is 72 years. Age may also have an impact on disease severity and outcome. In the overwhelming majority of children with Henoch-Schönlein purpura (who represent 90% of all cases), the disease is self-limited, resolving within several weeks. In adults, however, Henoch-Schönlein purpura has a higher likelihood of chronicity and a poor renal outcome.

The gender distribution varies across many forms of vasculitis. Buerger's disease is the only form of vasculitis with a striking male predominance. The greater prevalence of smoking among males in most societies probably explains this predilection. In contrast, Takayasu's arteritis has an overwhelming tendency to occur in females (a 9 : 1 female-to-male ratio). The pauci-immune forms of vasculitis, such as Wegener's granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome, occur in males and females with approximately equal frequencies, but the phenotypic expression of these conditions may be affected by both age and gender.

The strongest link between any single gene and vasculitis is the association of HLA-B51 with Behçet's syndrome. Eighty percent of Asian patients with Behçet's syndrome have the HLA-B51 gene. The prevalence of HLA-B51 is significantly higher among patients with Behçet's syndrome in Japan than among control subjects without the disease (55% vs. <15%). Among the sporadic cases of Behçet's syndrome involving whites in the United States, however, HLA-B51 occurs in less than 15% of cases.

With the exception of Buerger's disease and smoking, no definitive associations have been confirmed between disease development and environmental or occupational exposures. Associations between exposure to silica and some types of pauci-immune vasculitis have been reported but not confirmed. Studies of potential associations between any type of exposure and vasculitis are complicated by the difficulty of obtaining reliable measurements of the levels of exposure, the likelihood of recall bias among patients who are diagnosed with vasculitis, and the choice of appropriate control groups.

TABLE 278-1 CLASSIFICATION SCHEME OF VASCULITIDES ACCORDING TO SIZE OF PREDOMINANT BLOOD VESSELS INVOLVED

PREDOMINANTLY LARGE-VESSEL VASCULITIDES
Takayasu's arteritis
Giant cell arteritis
Cogan's syndrome
Behçet's syndrome*
PREDOMINANTLY MEDIUM-VESSEL VASCULITIDES
Classic polyarteritis nodosa
Cutaneous polyarteritis nodosa
Rheumatoid vasculitis†
Buerger's disease
Kawasaki disease
Primary angiitis of the central nervous system
PREDOMINANTLY SMALL-VESSEL VASCULITIDES
Immune complex mediated
Cutaneous leukocytoclastic angiitis ("hypersensitivity" vasculitis)
Henoch-Schönlein purpura
Urticarial vasculitis
Cryoglobulinemia†
"ANCA-associated" disorders
Wegener's granulomatosis†
Microscopic polyangiitis†
Churg-Strauss syndrome†
Miscellaneous small-vessel vasculitides
Connective tissue disorders†
Paraneoplastic diseases
Infection
Inflammatory bowel disease

*May involve small, medium, and large blood vessels.
†Frequent overlap of involvement of small and medium-sized blood vessels.
ANCA = antineutrophil cytoplasmic antibody.

PATHOBIOLOGY

Table 278-3 illustrates the pathologic characteristics of selected forms of vasculitis. Specific pathologic features are discussed in the subsections on each disease. The type of inflammatory cell infiltrate in vasculitis is independent of the size of blood vessels involved. Mixed cell infiltrates in vasculitis are the rule rather than the exception, and histopathologic patterns of vasculitis may include leukocytoclasis (degranulation and destruction of neutrophils within blood vessel walls), granulomatous findings (with or without giant cells), lymphoplasmacytic infiltrates, varying degrees of eosinophilic infiltration, necrosis, and combinations of all these findings.

PATHOPHYSIOLOGY

Regardless of the size of the predominant blood vessels involved, some pathophysiologic mechanisms are common to many different forms of vasculitis. Immune complex deposition, for example, is present in several types of vasculitis that involve both medium-sized and small blood vessels. In this section, the general concepts related to the pathogenesis of large-vessel vasculitides are discussed separately from those of medium- and small-vessel vasculitides.

Large-Vessel Vasculitides

The pathologic process in large-vessel vasculitis appears to begin in the adventitia. In both Takayasu's arteritis and giant cell arteritis, abundant numbers of activated T lymphocytes are found within inflamed arterial walls, centering on the adventitia. In Takayasu's arteritis, most of these T cells appear to be of the $CD8^+$ subtype. Current evidence suggests that the cytotoxic functions of these cells, mediated by perforin and granzyme B, contribute to smooth muscle cell damage in this disease. $CD4^+$ T-cell responses in Takayasu's arteritis have not been well defined.

In giant cell arteritis, much evidence now suggests an antigen-driven disease, with the site of immunologic recognition events being the adventitia. $CD4^+$ T cells that secrete interferon-γ appear to be recruited to the adventitia by a specific antigen, the identity of which remains unknown. Both the T cells that orchestrate the transmural inflammation and the inciting antigens are theorized to reach the adventitia through the vasa vasorum. Subsequently, T-cell signals from the adventitia stimulate macrophages and multinucleated giant cells to elaborate an array of downstream mediators, such as metalloproteinases and platelet-derived growth factor. The results of this inflammatory cascade are granulomatous inflammation, destruction of the internal elastic lamina, arterial wall hyperplasia, smooth muscle cell proliferation, intimal thickening, vascular occlusion, and, in some cases, weakening of the vessel wall, leading to dilation and aneurysm formation.

TABLE 278-2 EPIDEMIOLOGY OF SELECTED VASCULITIDES

DISEASE	UNITED STATES	ELSEWHERE	AGE, GENDER, AND ETHNIC PREDISPOSITIONS
Giant cell arteritis	Incidence: 240/million (Olmsted County, MN)	220-270/million (Scandinavian countries)	Age >50 yr, mean age 72 yr; females 3:1; northern European ancestry
Takayasu's arteritis	Incidence: 3/million	200-300/million (India)	Age <40 yr; females 9:1; Asian
Behçet's syndrome	Prevalence: 3/million	3000/million (Turkey)	Silk Route countries
Polyarteritis nodosa	Incidence: 7/million	7/million (Spain)	Slight male predominance
Kawasaki disease	Incidence: 100/million*	900/million (Japan)	Children of Asian ancestry
Wegener's granulomatosis	Incidence: 4/million	8.5/million (United Kingdom)	Whites ≫ blacks

*Among children younger than 5 years.

TABLE 278-3 PATHOLOGIC CHARACTERISTICS OF SELECTED FORMS OF VASCULITIS

	TAKAYASU'S ARTERITIS	POLYARTERITIS NODOSA	WEGENER'S GRANULOMATOSIS	CHURG-STRAUSS SYNDROME	HENOCH-SCHÖNLEIN PURPURA	CUTANEOUS LEUKOCYTOCLASTIC ANGIITIS
Vessels involved	Elastic (large) or muscle (medium-sized) arteries	Medium-sized and small muscle arteries	Small arteries and veins; sometimes medium-sized vessels	Small arteries and veins; sometimes medium-sized vessels	Capillaries, venules, arterioles	Capillaries, venules, arterioles
Organ involvement	Aorta, aortic arch and major branches, pulmonary arteries	Skin, peripheral nerve, gastrointestinal tract, other viscera	Upper respiratory tract, lungs, kidneys, skin, eyes	Upper respiratory tract, lungs, heart, peripheral nerves	Skin, joints, gastrointestinal tract, kidneys	Skin, joints
Type of vasculitis and inflammatory cells	Granulomatous with some giant cells; fibrosis in chronic stages	Necrotizing, with mixed cellular infiltrate	Necrotizing or granulomatous (or both); mixed cellular infiltrate plus occasional eosinophils	Necrotizing or granulomatous (or both); prominent eosinophils and other mixed infiltrate	Leukocytoclastic, with some lymphocytes and variable eosinophils; IgA deposits in affected tissues	Leukocytoclastic, with occasional eosinophils

Medium- and Small-Vessel Vasculitides

Several different pathophysiologic mechanisms are operative among the medium- and small-vessel vasculitides. In many cases, the mechanisms outlined in the following sections overlap.

Immune Complex–Mediated Vascular Injury

Immune complex–mediated tissue injury does not produce a single clinical syndrome; rather, it applies to many forms of vasculitis and overlaps with injuries caused by other immune mechanisms. Numerous variables influence immune complex–mediated injury, including the physical properties of the immune complexes (e.g., their size), the ability of the immune complexes to activate complement, the antigen-to-antibody ratio, and the hemodynamic features of specific vascular beds. Immune complexes participate in the pathophysiologic process of some forms of both medium- and small-vessel vasculitis, including polyarteritis nodosa, cryoglobulinemia, Henoch-Schönlein purpura, cutaneous leukocytoclastic angiitis, and rheumatoid vasculitis.

Role of ANCAs

ANCAs are directed against antigens that reside within the primary granules of neutrophils and monocytes. Two types of ANCAs are relevant to vasculitis: (1) those directed against proteinase 3 (PR3), known as *PR3-ANCAs*; and (2) those directed against myeloperoxidase (MPO), termed *MPO-ANCAs*. ANCAs interact with cytokines, neutrophils, monocytes, and other elements of the immune system to amplify ongoing inflammation in certain forms of vasculitis. A striking and still unexplained feature of ANCA-associated vasculitis is that patients virtually never have antibodies to both PR3 and MPO. Despite the specificity of these antibodies, however, evidence of ANCA's primary role in causing human disease is still absent.

In Wegener's granulomatosis, abnormal cytokine regulation interacts with the production of ANCA to fuel the inflammatory response. T_H1 cytokines such as interferon-γ, interleukin-12, and tumor necrosis factor (TNF) appear to play important roles. Under the direction of interleukin-12, $CD4^+$ T cells from patients with Wegener's granulomatosis produce elevated levels of TNF, and peripheral blood mononuclear cells secrete increased amounts of interferon-γ. Serum levels of soluble receptors for TNF are elevated in patients with active Wegener's granulomatosis and normalize with the induction of remission. In vitro priming of activated neutrophils with TNF markedly enhances the ability of ANCA to stimulate neutrophil degranulation. Despite the strong rationale for anti-TNF strategies in Wegener's granulomatosis, however, a randomized trial of etanercept showed no efficacy in the maintenance of disease remission.

B-cell depletion was recently shown to be a more effective approach than intravenous cyclophosphamide to treat Wegener's granulomatosis and microscopic polyangiitis, particularly in relapsing disease,[1] although another study did not demonstrate the superiority of a rituximab-based regimen.[2] The efficacy of this treatment strategy probably relates to the removal of several B-cell functions beyond their evolution into plasma cells and the production of ANCA. These other B-cell functions include cytokine production, antigen presentation, and B cell–T cell crosstalk.

Superantigen Model

The degree of immune activation in Kawasaki disease and the acute but generally self-limited nature of this illness imply a potential role for superantigens. Superantigens are proteins produced by microbial pathogens (e.g., *Staphylococcus aureus* or *Streptococcus* species) that are capable of stimulating large populations of T cells in a manner unrestricted by the class II major histocompatibility complex (MHC). Superantigens bind directly to conserved amino acid residues outside the antigen-binding groove on class II MHC molecules, thereby selectively stimulating T cells that express particular β-chain variable gene segments. Through the binding of this MHC-superantigen complex to its cognate T-cell receptors, as many as 20% of circulating lymphocytes may become activated, leading to a potentially enormous outpouring of cytokines. With regard to the etiology of Kawasaki disease, substantial attention has focused on toxic shock syndrome toxin 1, an exotoxin produced by *S. aureus.* Superantigens have also been postulated to play roles in the susceptibility to disease flares in Wegener's granulomatosis. Nasal carriage of *S. aureus* and superantigens associated with these organisms has been linked to a greater likelihood of disease flares in some studies.

Antiendothelial Cell Antibodies

Antiendothelial cell antibodies can induce endothelial cell injury and lysis through either complement-mediated cytotoxicity or antibody-dependent cellular cytotoxicity. Both these mechanisms have been demonstrated to cause endothelial injury in in vitro assays employing sera from patients with systemic vasculitis. The ability of these antibodies to damage endothelial cells is an appealing argument for their potential role in forms of vasculitis in which the endothelium is the focus of inflammation (as opposed to the more external vessel wall layers). However, the true relevance of antiendothelial cell antibodies to human disease and their importance within the larger context of other disease mechanisms remain unclear.

CLINICAL MANIFESTATIONS

Large-Vessel Vasculitides

Takayasu's Arteritis

Takayasu's arteritis affects the aorta and its major branches. In contrast to atherosclerosis, which is characterized by focal, irregular lesions, the lesions of Takayasu's arteritis are long, smooth, tapered stenoses (E-Fig. 278-1A). The most commonly involved arteries are the subclavian and innominate arteries. Takayasu's arteritis has been termed *pulseless disease* because of its ability to obliterate peripheral pulses (particularly in the upper extremities). Exuberant collateral circulation develops over time in response to the gradual narrowing of major arteries, making the loss of digits or limbs from ischemia extremely rare. The pulmonary circulation is involved in approximately 50% of cases of Takayasu's arteritis.

Patients with severe narrowing of the aortic arch vessels supplying the head may develop Takayasu's retinopathy, a hypotension retinopathy leading to neovascularization. In contrast, patients with prolonged hypertension associated with renal artery stenosis demonstrate the classic ocular features

of hypertension: copper wiring and multiple retinal infarctions. This complication is particularly difficult to diagnose, and it is dangerous because vascular narrowings of large arteries to the arms and legs can cause underestimation of the true central aortic pressure. When Takayasu's arteritis involves the ascending aorta, it may lead to aortic dilation, aortic regurgitation, aneurysm formation, and aortic rupture (E-Fig. 278-1B).

The cornerstone of treatment of Takayasu's arteritis is glucocorticoids. For patients with marked symptoms and signs of an inflammatory phase, prednisone (1 mg/kg/day) is usually effective in controlling the disease. This dose should be tapered within 8 to 12 weeks to less than 20 mg/day and ultimately to less than 10 mg/day as a maintenance dose. Methotrexate (up to 25 mg/week), mycophenolate mofetil (1500 mg twice daily), and infliximab (3 to 5 mg/kg every 6 weeks) have been employed as steroid-sparing agents. Toclizumab, an inhibitor of the interleukin-6 receptor, also shows significant potential as a treatment modality.

Cogan's Syndrome

The combination of inflammatory eye disease and vestibuloauditory dysfunction is the sine qua non of Cogan's syndrome. In addition to inflammatory disease of the eyes and ears, up to 15% of patients with Cogan's syndrome have vasculitis involving medium-sized to large blood vessels. Although the ocular manifestations vary, the classic presentation is the combination of interstitial keratitis and sensorineural hearing loss. Cogan's syndrome may first appear in either the eyes or the ears. Although intervals as long as 1 to 2 years have been described between the onset of disease in one organ and the appearance of disease in the other, it is usually only a matter of months. Patients usually present with photophobia and blurry vision, sometimes accompanied simultaneously by auditory or vestibular dysfunction. The vascular disease in Cogan's syndrome resembles Takayasu's arteritis.

Rapidly progressive sensorineural hearing loss requires early, aggressive therapy with high doses of systemic glucocorticoids. Cytotoxic agents can be considered for patients with suboptimal responses to glucocorticoids who still have salvageable hearing. Many Cogan's syndrome patients become candidates for cochlear implants.

Behçet's Syndrome

Behçet's syndrome may affect small, medium, and large vessels in either the venous or the arterial circulation. The most typical lesions in Behçet's syndrome are mucocutaneous, reflecting the involvement of small blood vessels. The triad of recurrent mouth ulcers, genital ulcers, and eye inflammation is the classic presentation. The diagnostic criteria of the International Study Group for Behçet's Syndrome consist of one required manifestation—recurrent oral ulceration—plus at least two of the following: recurrent genital ulceration, characteristic eye or skin lesions, or a pathergy reaction (see later). However, the spectrum of Behçet's syndrome encompasses many manifestations not included in these criteria.

Large-vessel complications of Behçet's syndrome may include aneurysms in the pulmonary and systemic arterial systems. Venous complications include thromboses of the deep venous system, vena cava, portohepatic vein, and cerebral sinus. Pathergy—the development of pustules at the sites of sterile needle pricks—is a distinctive feature in many patients with Behçet's syndrome, particularly those of Turkish origin. The arthritis of Behçet's syndrome is a nondeforming, oligoarticular, asymmetrical arthritis of large joints. Gastrointestinal lesions in Behçet's syndrome typically consist of ulcerations of the distal ileum or cecum. Crohn's disease, which can cause genital ulcers as well as gastrointestinal tract disease, may be particularly difficult to distinguish from Behçet's syndrome.

Colchicine (up to 1.5 to 2 mg/day) is sometimes effective for the treatment of mild oral and genital ulcers in Behçet's syndrome. Thalidomide (100 mg/day) is also useful for mucocutaneous disease manifestations. Low-dose glucocorticoids are also effective for intransigent mucocutaneous disease and may have a better side effect profile than thalidomide. Intermittent courses of glucocorticoids during periods of particular mucocutaneous disease activity are also effective.

Severe disease in any organ system almost always requires high doses of prednisone (e.g., 1 mg/kg/day). TNF inhibition with infliximab or adalimumab has largely replaced cyclophosphamide or chlorambucil as the treatment of choice for patients with the most severe forms of uveitis or meningoencephalitis. Azathioprine (2 mg/kg/day), cyclosporine (3 to 5 mg/kg/day in two divided doses), methotrexate (up to 25 mg/week), and interferon-α (3 million to 5 million units three times a week) are also appropriate therapies for many complications of Behçet's syndrome.

Medium-Vessel Vasculitides

Polyarteritis Nodosa

Polyarteritis nodosa has a striking predilection for certain organs, particularly the skin, peripheral nerves, gastrointestinal tract, and kidneys. This disease usually begins with nonspecific symptoms that may include malaise, fatigue, fever, myalgias, and arthralgias. Overt signs of vasculitis may not occur until weeks or months after the onset of the first symptoms. Skin lesions of polyarteritis nodosa include livedo reticularis, subcutaneous nodules, ulcers, and digital gangrene. A majority of patients with polyarteritis nodosa (>80% in some series) have vasculitic neuropathy, typically in the pattern of a mononeuritis multiplex (Chapter 428).

The classic gastrointestinal manifestation of polyarteritis nodosa is "intestinal angina," the occurrence of postprandial abdominal pain. Polyarteritis nodosa can also affect individual gastrointestinal tract organs such as the gallbladder or appendix, presenting as cholecystitis or appendicitis. The typical renal manifestation of polyarteritis nodosa is vasculitic involvement of the medium-sized intrarenal arteries, leading to renin-mediated hypertension and renal infarctions. Cardiac lesions, which usually remain subclinical, may lead to myocardial infarction or congestive heart failure. Polyarteritis nodosa usually spares the lungs.

The diagnosis of polyarteritis nodosa requires either a tissue biopsy or an angiogram that demonstrates microaneurysms (Fig. 278-1). Simultaneous nerve and muscle biopsies (e.g., sural nerve and gastrocnemius muscle) have a high yield if there is clinical suspicion of vasculitic neuropathy. Symptoms suggestive of a neuropathy can be confirmed by electrodiagnostic studies that demonstrate a sensorimotor axonal neuropathy, often in a mononeuritis multiplex pattern. The pathologic changes in polyarteritis nodosa are limited to the arterial circulation; the lesions are segmental and favor the branch points of arteries. In gross pathologic specimens, aneurysmal bulges of the arterial wall may be visible. Histologic sections reveal infiltration and destruction of the blood vessel wall by inflammatory cells, accompanied by fibrinoid necrosis. Granulomatous inflammation is absent.

Approximately half of patients with polyarteritis nodosa achieve remissions or cures with high doses of glucocorticoids alone. Cyclophosphamide (2 mg/kg/day, adjusted for renal dysfunction) is indicated for patients whose disease is refractory to glucocorticoids or who have serious involvement of

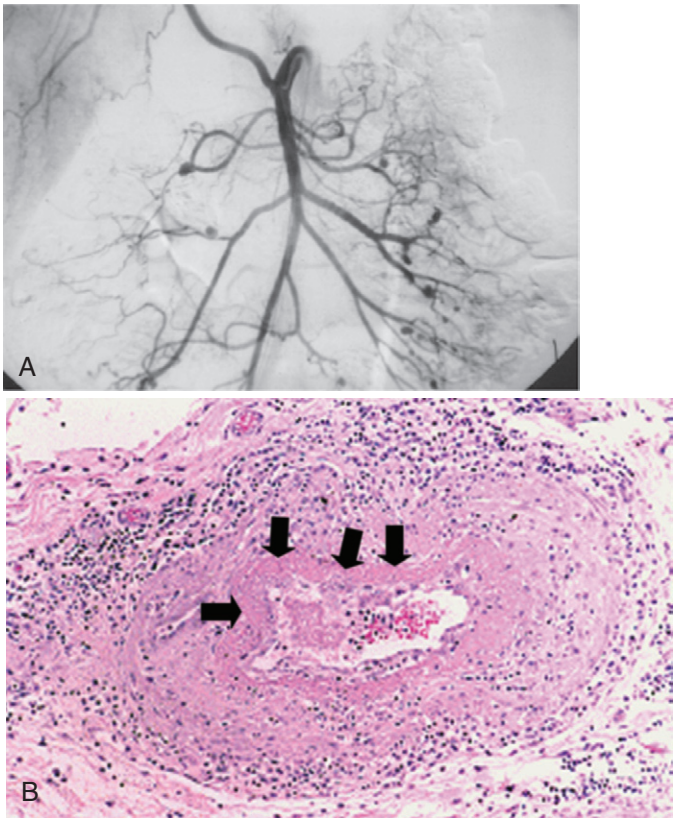

FIGURE 278-1. Vasculitis of medium-sized arteries in polyarteritis nodosa. A, Mesenteric angiogram showing numerous aneurysms in medium-sized arteries. **B,** Fibrinoid necrosis in a jejunal artery from a patient who required surgical resection of necrotic bowel.

major organs. In recent years, therapeutic regimens involving lamivudine or entecavir and plasma exchange have substantially improved the treatment of hepatitis B virus (HBV)–associated polyarteritis nodosa. Because of increasing use of the HBV vaccine, less than 10% of polyarteritis nodosa cases are now associated with HBV infections.

Buerger's Disease

Buerger's disease, also known as *thromboangiitis obliterans*, has a remarkably strong yet poorly understood association with cigarette smoking. Buerger's disease does not occur in the absence of exposure to tobacco. The vessels affected by Buerger's disease are the distal medium-sized arteries and veins, particularly vessels at the levels of the ankles and wrists. The disease is characterized by thrombotic obliterations that begin distally and proceed proximally. Buerger's disease tends to be segmental in nature, involving 5- to 10-cm lengths of blood vessels. Arterial obliteration leads to the development of collateral vessels with a "corkscrew" appearance on angiography. Vascular occlusion in Buerger's disease often leads to the loss of digits and, if smoking persists, to the loss of greater amounts of tissue (e.g., hands or feet). Despite the intense involvement of the extremities in Buerger's disease, internal organ disease almost never occurs.

Complete abstinence from tobacco is essential to the treatment of Buerger's disease. Failure to stop smoking is associated with a dramatic increase in the risk of limb loss by amputation. No other therapeutic interventions, including glucocorticoids and anticoagulation, have dramatic effects on Buerger's disease.

Kawasaki Disease

Kawasaki disease occurs exclusively in young children. Because of its striking mucocutaneous findings and lymphadenopathy, Kawasaki disease is also known as *mucocutaneous lymph node syndrome*. Features of Kawasaki disease include high fevers, cervical adenopathy, conjunctival congestion, buccal erythema, prominence of the tongue papillae ("strawberry tongue"), polymorphous truncal rash, erythema of the palms and soles, and desquamation of skin from the fingertips occurring days to weeks into the illness. In its acuity and severity, Kawasaki disease resembles toxic shock syndrome and scarlet fever, both of which are mediated by superantigens (see Pathophysiology).

In a small number of patients with Kawasaki disease, panvasculitis in the coronary vessels leads to acute cardiac complications. Coronary arteritis leads to narrowing of the vessel lumen by the migration of myointimal cells from the media through the fragmented internal elastic lamina. Direct complications include aneurysmal dilation and thrombosis of the coronary arteries, leading to myocardial infarction and possibly death (in 1 to 2% of patients with Kawasaki disease during the acute illness). Late mortality from myocardial infarction may occur from the thrombosis of coronary artery aneurysms formed during the initial inflammatory stage. Such myocardial infarctions have been reported in middle-aged individuals who had febrile illnesses consistent with Kawasaki disease in childhood.

The recommended therapeutic regimen in Kawasaki disease is the combination of intravenous immune globulin (IVIG; 400 mg/kg/day on 4 consecutive days) and acetylsalicylic acid (100 mg/kg/day, lowered to 3 to 5 mg/kg/day after resolution of the fever). IVIG prevents the formation of coronary aneurysms in most cases. Glucocorticoids are reserved for salvage therapy in patients in whom treatment with IVIG and acetylsalicylic acid has failed.■

Vasculitis of the Central Nervous System

Central nervous system (CNS) vasculitis includes two major categories of disease, one of which is not a true vasculitis: primary angiitis of the CNS (PACNS) and reversible cerebral vasoconstriction syndrome (RCVS). The diagnosis and management of these two conditions differ dramatically. The clinical, radiologic, and pathologic characteristics of PACNS and RCVS are shown in Table 278-4.

TABLE 278-4 PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM (PACNS) VERSUS REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME (RCVS)

	PACNS	RCVS
Gender ratio (female to male)	1:1	2–3:1
Onset	Subacute (weeks to months)	Sudden (seconds to minutes)
Headache	Insidious, dull	Thunderclap
Typical lumbar puncture findings	Abnormal in 50-80%: lymphocytic pleocytosis, elevated protein	Normal
Typical MRI findings	Multifocal subacute infarctions	Normal; watershed infarcts in minority
Typical angiogram findings	Normal in up to 40% of cases; abnormal angiographic features, when present, cannot be distinguished from RCVS	Multifocal stenoses/dilations
Utility of brain biopsy	Reasonable sensitivity in appropriately selected patients; important for excluding disease mimickers	Little to no role; helpful if confusing clinical situation confounds differentiation from PACNS or PACNS mimickers

MRI = magnetic resonance imaging.

PRIMARY ANGIITIS OF THE CENTRAL NERVOUS SYSTEM. PACNS typically develops in a subacute fashion, with the evolution of multifocal strokes, encephalopathy, headache, and other clinical features over months. Headache is often the first symptom. As the condition progresses, most patients develop lethargy, confusion, and memory loss. Some patients develop multifocal strokes, seizures, evidence of increased intracranial pressure, or myelopathy. The results of routine laboratory tests (e.g., erythrocyte sedimentation rate) are often normal in PACNS. Lumbar puncture demonstrates abnormalities of the cerebrospinal fluid in approximately 80% of cases, usually a modest monocytosis and elevated protein. Lumbar punctures should be performed in all patients in whom the diagnosis of PACNS is being seriously considered. Although the findings in PACNS patients are nonspecific, a normal lumbar puncture argues against PACNS, and the procedure frequently identifies important PACNS mimickers such as infection or malignancy.

Magnetic resonance imaging (MRI) is the critical imaging modality in PACNS. Because of the subacute nature of the disorder, MRI studies reveal multifocal CNS infarctions in most cases. Strokes, hemorrhagic lesions, and mass lesions typically occur in more than one vascular territory. A normal brain MRI argues strongly against the diagnosis of PACNS. Angiography is less helpful in the evaluation of patients with PACNS, for two main reasons. First, the blood vessels involved in PACNS are often too small to be visualized adequately, even by conventional angiography. The false-negative rate of angiography in PACNS is on the order of 35%. Second, the classic "string of beads" abnormality on angiography, produced by segmental arterial narrowing alternating with dilations, is entirely nonspecific and is mimicked perfectly by a host of nonvasculitic conditions (the most common of which is RCVS). No angiographic pattern is pathognomonic for PACNS, and there is a significant tendency to overdiagnose "vasculitis" on angiographic grounds alone. A normal brain MRI in the setting of an abnormal angiogram should make one think first of RCVS, not PACNS.

When employed in appropriately selected patients whose history and radiologic studies suggest PACNS, brain biopsy is associated with reasonable positive and negative predictive values and frequently identifies important PACNS mimickers. Prednisone and cyclophosphamide are appropriate treatments for patients with abnormal findings on brain biopsy. Treatment courses of 6 to 12 months are recommended.

REVERSIBLE CEREBRAL VASOCONSTRICTION SYNDROME. Eighty percent of patients with RCVS are women. RCVS is probably far more common than PACNS. Overtreatment of patients with RCVS who are misdiagnosed as having PACNS leads to substantial morbidity.

A careful history is the most important part of the evaluation. In contrast to the subacute course that typifies PACNS, RCVS usually begins in a more dramatic fashion with a thunderclap headache. Compared with PACNS, the neurologic signs are less severe (encephalopathy is less common). RCVS frequently occurs in the setting of precipitants associated with vasospasm, such as the postpartum setting or the use of vasoactive agents such as nasal decongestants and recreational drugs.

The lumbar puncture is usually normal in RCVS, and brain MRI usually does not show multifocal CNS infarctions, with the exception of watershed

infarctions. The typical angiographic findings in RCVS—vascular narrowing and beading—are generally indistinguishable from those of PACNS and conditions that mimic PACNS. Multifocal vascular narrowing is particularly characteristic of RCVS. The most distinctive angiographic feature of RCVS is that the abnormalities are completely reversible, usually within 4 to 8 weeks. These abnormalities in RCVS are caused by vasospasm rather than true vasculitis. In the evaluation of patients with potential RCVS, a diagnostic strategy that can clinch the diagnosis is a follow-up angiogram 4 to 8 weeks after the first. Angiographic abnormalities due to RCVS resolve during this interval.

Several approaches to the treatment of RCVS are reasonable. First, one may opt for watchful waiting. It is not clear that immunosuppression is either necessary or helpful. Moreover, attempts to treat vasospasm with calcium-channel blockers may lead to vascular steal phenomena, potentially causing more harm than good. However, because it is frequently difficult to do nothing for a patient with possibly serious CNS disease, calcium-channel blockers (e.g., nifedipine 30 mg three times daily) may be tried. Finally, because of the frequent diagnostic uncertainty at the time of presentation, some clinicians opt to treat empirically with glucocorticoids (prednisone 1 mg/kg/day) for 1 month, followed by a taper over several weeks. Cytotoxic therapy is not indicated in RCVS.

Small-Vessel Vasculitides

Wegener's Granulomatosis

Classic Wegener's granulomatosis involves the upper respiratory tract, the lungs, and the kidneys. Distinctive features may also occur in the eyes, ears, and other organs. The three pathologic hallmarks of Wegener's granulomatosis are (1) granulomatous inflammation in the upper or lower respiratory tract, (2) necrotizing vasculitis affecting arteries or veins, and (3) segmental glomerulonephritis associated with necrosis and thrombosis of capillary loops, with or without granulomatous lesions.

Approximately 90% of patients with Wegener's granulomatosis have nasal involvement, including crusting, bleeding, and obstruction. Cartilaginous inflammation may lead to nasal septal perforation and collapse of the nasal bridge ("saddle nose" deformity). Erosive sinus disease and subglottic stenosis (narrowing of the trachea just below the vocal cords) are highly characteristic of Wegener's granulomatosis.

Both conductive and sensorineural hearing loss can occur in Wegener's granulomatosis, although conductive lesions caused by middle ear disease are more common. Orbital masses ("pseudotumors" that develop behind the eye), scleritis, and peripheral ulcerative keratitis are the most dangerous ocular lesions. Episcleritis and conjunctivitis also occur. Anterior uveitis is rare. The clinical manifestations of Wegener's granulomatosis in the lung range from asymptomatic nodules to fulminant alveolar hemorrhage. The most common radiographic findings are pulmonary infiltrates, nodules, and cavitary lesions. Disease of the large airways leading to bronchial narrowing is a challenging diagnosis to make because patients present with few symptoms until advanced disease is present.

The clinical presentation of renal disease in Wegener's granulomatosis is usually rapidly progressive glomerulonephritis: hematuria, red blood cell casts, and proteinuria (usually non-nephrotic). Without appropriate therapy, end-stage renal disease may ensue within weeks.

Sixty percent of patients with Wegener's granulomatosis have musculoskeletal symptoms during the disease course. The presenting complaint is frequently arthralgias or an oligoarthritis that is migratory in nature. Skin lesions in Wegener's granulomatosis include the full panoply of lesions associated with cutaneous vasculitis, including purpura (Fig. 278-2). Cutaneous nodules over the extensor surfaces of joints, particularly the elbow, may mimic rheumatoid nodules. These lesions are known as *cutaneous extravascular necrotizing granulomas* or *Churg-Strauss lesions*. Meningeal inflammation, presenting with headaches, cranial neuropathies, and a clinical picture compatible with chronic meningitis, is perhaps the most common CNS manifestation of Wegener's granulomatosis. Mononeuritis multiplex may affect the peripheral nervous system.

Wegener's granulomatosis is the prototype of the conditions associated with ANCA. Positive results of immunofluorescence tests for ANCA in either the cytoplasmic (C-ANCA) or perinuclear (P-ANCA) pattern should be confirmed by enzyme immunoassays for antibodies to either PR3 or MPO. An ANCA-negative assay sample does not exclude Wegener's granulomatosis because a substantial minority of patients (between 15 and 40% overall) lack these antibodies. Furthermore, ANCA titers do not correlate reliably with disease activity.

FIGURE 278-2. Cutaneous small-vessel vasculitis showing palpable purpuric lesions with necrosis and crusting.

Manifestations of Wegener's granulomatosis that constitute immediate threats to either the function of a vital organ or the patient's life require urgent treatment. From the late 1960s until 2010, the combination of cyclophosphamide (2 mg/kg/day orally) and high doses of glucocorticoids (prednisone 1 mg/kg/day orally, tapered over 6 to 12 months) was the standard of care for Wegener's granulomatosis.■ Intermittent administration of cyclophosphamide by intravenous infusion is also effective in remission induction.■ However, based on the results of a multicenter clinical trial that compared rituximab with cyclophosphamide in patients with ANCA-associated vasculitis (either Wegener's granulomatosis or microscopic polyangiitis), rituximab (375 mg/m^2/week for 4 weeks) appears to be at least as effective for most patients with severe ANCA-associated vasculitis.■ In addition, rituximab seems to be more effective for patients who present with disease flares. An alternative dosing regimen, rituximab 1 g times two separated by 2 weeks, may also be effective. Limited forms of Wegener's granulomatosis may respond to the combination of methotrexate (up to 25 mg/week) and glucocorticoids. The role of rituximab in the treatment of limited Wegener's granulomatosis is not yet clear. Azathioprine and methotrexate both appear to be effective remission agents for maintenance therapy,■, and azathioprine is better than mycophenolate mofetil in this situation.■

Microscopic Polyangiitis

Microscopic polyangiitis is characterized by (1) nongranulomatous, necrotizing vasculitis, with few or no immune deposits; (2) involvement of small (and possibly medium-sized) blood vessels in the arterial or venous circulation; and (3) tropism for the kidneys and lungs. Many cases of small-vessel vasculitis once regarded as polyarteritis nodosa are now more properly classified as microscopic polyangiitis. In contrast to polyarteritis nodosa, an ANCA-negative disorder, 70% of microscopic polyangiitis patients are ANCA positive. Thus, microscopic polyangiitis is often considered to fall within the spectrum of ANCA-associated vasculitis. The ANCAs in microscopic polyangiitis are usually directed against MPO, leading to a perinuclear pattern of staining on immunofluorescence testing (P-ANCA). Upper respiratory tract symptoms in microscopic polyangiitis, if present at all, are much milder than those associated with Wegener's granulomatosis.

The approach to the treatment of microscopic polyangiitis is similar to that of Wegener's granulomatosis. The combination of rituximab and glucocorticoids is the treatment regimen of choice for most patients with microscopic polyangiitis.■

Churg-Strauss Syndrome

Churg-Strauss syndrome is an eosinophil-rich form of granulomatous inflammation that involves the respiratory tract and other organs. The disease is associated with necrotizing vasculitis of small to medium-sized vessels. Two hallmarks of Churg-Strauss syndrome are asthma and eosinophilia. Several phases of Churg-Strauss syndrome are described, as follows:

- A prodromal phase, characterized by the presence of allergic disease (typically asthma or allergic rhinitis), which may last months to many years;
- An eosinophilia–tissue infiltration phase, in which remarkably high peripheral eosinophilia may occur and tissue infiltration by eosinophils is observed in the lung, gastrointestinal tract, and other tissues; and
- A vasculitic phase, in which systemic necrotizing vasculitis afflicts a wide range of organs, ranging from the heart and lungs to peripheral nerves and skin.

Patients with mild disease may be treated with prednisone. Those with evidence of neurologic, cardiac, renal, or gastrointestinal involvement should be treated with cyclophosphamide in addition to glucocorticoids. Although clinical remissions are obtained in more than 90% of patients with Churg-Strauss syndrome, disease recurrence is seen in 25%. In most cases, relapses are heralded by the return of eosinophilia. Approximately 50% of cases of Churg-Strauss syndrome are associated with ANCA, usually directed against MPO, but the percentage may be higher among untreated patients.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) is characterized by nonthrombocytopenic purpura, arthritis, abdominal pain, and glomerulonephritis. The histopathologic findings are those of a leukocytoclastic vasculitis with IgA deposition. HSP can develop at any age, but 80 to 90% of cases occur in children. Although the cause is unknown, the disease's seasonal variation and the fact that two thirds of patients with HSP experience antecedent acute upper respiratory illnesses suggest an infectious trigger. Medications (e.g., antibiotics) can trigger HSP, and other environmental triggers are also likely. The diagnosis of HSP can be confirmed only by demonstration of IgA deposition within and around blood vessel walls.

The classic HSP patient presents with the acute onset of fever, palpable purpura on the lower extremities and buttocks, abdominal pain, arthritis, and hematuria. The clinician must be alert to the possibility of HSP even when only parts of the syndrome are present. Most patients with HSP, especially children, have a self-limited disease that lasts an average of 4 weeks. Glucocorticoids ameliorate the joint and gastrointestinal symptoms in most cases and improve the cutaneous manifestations in some. The efficacy of glucocorticoids in the glomerulonephritis of HSP is controversial. Uncontrolled studies suggest that methylprednisolone pulses (1 g/day for three doses), followed by oral prednisone combined with azathioprine or cyclophosphamide, may be useful in severe glomerulonephritis associated with HSP.

Cutaneous Leukocytoclastic Angiitis

Also termed *hypersensitivity vasculitis*, *cutaneous leukocytoclastic angiitis* is the preferred name because no hypersensitivity or allergy is evident in many cases. Histories of exposure to new medications or infections may be elicited, however, and immune complex deposition is central to the pathophysiologic process. Although it is occasionally associated with synovitis, other signs of systemic involvement are absent.

The skin lesions in cutaneous leukocytoclastic angiitis occur in "crops" following exposure to the inciting antigen. The usual interval between the exposure and the onset of clinically evident vasculitis is 10 to 14 days. The lesions typically occur first in dependent regions, such as on the lower extremities or buttocks. The rash may be asymptomatic but is usually accompanied by burning or tingling sensations.

Keys to the management of cutaneous leukocytoclastic angiitis include the exclusion of any underlying form of vasculitis that may cause subclinical involvement of other organs and removal of any agent (e.g., medication) that may have triggered the vasculitis. For patients in whom a precipitant can be identified, removal of the offending agent usually leads to resolution of the vasculitis within days to weeks. The type, intensity, and duration of therapy for cutaneous leukocytoclastic angiitis are based on the disease severity. Mild cases may be treated simply with leg elevation and the administration of nonsteroidal anti-inflammatory agents or H_1 antihistamines. For persistent disease not associated with cutaneous gangrene, colchicine, hydroxychloroquine, or dapsone may be tried. For severe cases, immunosuppressive agents may be indicated, generally beginning with glucocorticoids. Azathioprine is commonly used as a steroid-sparing agent.

Urticarial Vasculitis

At least three subtypes of urticarial vasculitis are known: (1) normocomplementemic, a form that is generally idiopathic and benign (and may be viewed as a manifestation of cutaneous leukocytoclastic angiitis); (2) hypocomplementemic, a form that is often associated with a systemic inflammatory disease; and (3) hypocomplementemic urticarial vasculitis syndrome (HUVS), a potentially severe condition usually associated with autoantibodies to the collagen-like region of C1q. Most patients with the hypocomplementemic subtype have an underlying systemic disorder, such as systemic lupus erythematosus (Chapter 274) or Sjögren's syndrome (Chapter 276). Many HUVS patients have C1q "precipitins," that is, IgG autoantibodies to the collagen-like region of C1q that trigger the classical pathway of complement activation. The role of anti-C1q antibodies in disease pathogenesis remains unclear.

The lesions of urticarial vasculitis must be distinguished from the far more common chronic idiopathic urticaria (Chapters 260 and 448). Unlike idiopathic urticaria, the lesions of urticarial vasculitis last more than 48 hours, often have a purpuric component (i.e., they do not blanch), and resolve with postinflammatory hyperpigmentation. In urticarial vasculitis, lesions associated with vasculitis are often accompanied by stinging or burning. Urticarial vasculitis affects the capillaries and postcapillary venules, showing leukocytoclastic vasculitis on light microscopy. Direct immunofluorescence studies reveal both immunoglobulin and complement deposition in or around blood vessels of the upper dermis or the dermoepidermal junction.

Patients with urticarial vasculitis whose serum complement levels remain normal during attacks often have self-limited disease and require little therapy. Other cases, especially HUVS, may cause life-threatening involvement of the lungs or other organs and require periods of intensive immunosuppression. Treatment decisions in HUVS must be individualized according to the patient's clinical status.

Cryoglobulinemia

Cryoglobulins are antibodies that precipitate from serum under conditions of cold and resolubilize on rewarming. Cryoglobulins are classified into types I, II, and III on the basis of whether monoclonality and rheumatoid factor activity (the ability to bind to the Fc portion of IgG) are present. Type I cryoglobulins, which are monoclonal but lack rheumatoid factor activity, are associated with certain hematopoietic malignant neoplasms (e.g., multiple myeloma) and often lead to hyperviscosity rather than to vasculitis (Chapter 193). In contrast, type II and type III cryoglobulins may be associated with systemic vasculitis involving small (and often medium-sized) blood vessels. Vasculitis results from the deposition of cryoglobulin-containing immune complexes within blood vessel walls and the activation of complement.

Cryoglobulin types II and III are termed mixed cryoglobulins because they consist of both IgG and IgM antibodies. The IgM components in both type II and type III cryoglobulinemia possess rheumatoid factor activity (i.e., assays for rheumatoid factor are positive, indicating binding of the IgM antibody to the Fc portion of IgG). Whereas the IgM component in type II cryoglobulin is monoclonal, the IgM in type III cryoglobulin is polyclonal. Ninety percent of patients with vasculitis secondary to mixed cryoglobulins are hypocomplementemic, with C4 levels characteristically more depressed than C3 levels. Infection with hepatitis C virus (HCV) accounts for at least 80% of the vasculitis cases associated with mixed cryoglobulins.

The optimal therapy for most cases of cryoglobulinemic vasculitis is successful treatment of the underlying HCV infection. For cryoglobulinemic patients with relatively mild disease (e.g., frequent purpuric lesions, shallow cutaneous ulcers), pegylated interferon-α2b (1 μg/kg/week) combined with ribavirin (1000 to 1200 mg/day) may be effective. For patients with mononeuritis multiplex or other manifestations of severe disease, glucocorticoids and possibly cyclophosphamide are required. Plasmapheresis may be a useful adjunctive therapy. Small case series also suggest that rituximab is an effective intervention.

DIAGNOSIS

Differential Diagnosis

The major categories of diseases that can mimic vasculitis are listed in Table 278-5. Certain features of a patient's case should raise the diagnostic suspicion for vasculitis. First, most cases of vasculitis do not begin suddenly; rather, they unfold subacutely during weeks or months. Second, pain is usually a prominent feature of vasculitis, resulting from arthritis or arthralgias, myalgias, headaches, neuropathy, testicular infarction, digital ischemia, sinusitis, otalgia, back pain (caused by aortic inflammation), postprandial abdominal pain (caused by mesenteric vasculitis), or other disease manifestations. Third, signs of inflammation, such as fever, rash, weight loss, and elevated acute phase reactants, are highly characteristic. Finally, multiorgan system involvement is the rule in vasculitis.

TABLE 278-5 MAJOR DISEASE CATEGORIES IN THE DIFFERENTIAL DIAGNOSIS OF VASCULITIDES

Other forms of vasculitis
Simultaneous occurrence of common medical problems in the same patient
Infections
Bacterial, viral, mycobacterial, fungal
Occlusive processes
Hypercoagulable states
Livedoid vasculopathy (atrophie blanche)
Atheroembolic disease
Malignant neoplasms
Lymphoma (including lymphomatoid granulomatosis)
Castleman's disease
Amyloidosis
Paraproteinemias
Connective tissue disorders
Systemic lupus erythematosus, mixed connective tissue disease
Systemic sclerosis
Rheumatoid arthritis
Miscellaneous
Atrial myxoma
Calciphylaxis
Fibromuscular dysplasia
Neutrophilic dermatoses
Pyoderma gangrenosum
Sarcoidosis
Reversible cerebral vasoconstriction syndrome

Ideally, the diagnosis of vasculitis is established through biopsy of an involved organ. Diagnoses based on angiography alone have many potential pitfalls, as discussed in the sections on PACNS and RCVS. Angiographic findings that are "consistent with vasculitis" must be interpreted in the proper context. A diverse array of other diseases, ranging from atherosclerosis to vasospasm to pheochromocytoma, may mimic the angiographic appearance of vasculitis. Systemic vasculitis is frequently mimicked by two or more common medical problems or treatment complications occurring simultaneously in the same patient. Finally, prominent in the differential diagnosis of any individual form of vasculitis are other forms of vasculitis. For example, digital ischemia and splinter hemorrhages may be secondary to idiopathic polyarteritis nodosa. They may also be caused by polyarteritis nodosa associated with HBV infection, Wegener's granulomatosis, cryoglobulinemia, microscopic polyangiitis, Churg-Strauss syndrome, Buerger's disease, or some other form of vasculitis. Because the appropriate interventions for these conditions vary widely, careful distinction among these potential causes is essential.

TREATMENT

The intensity of treatment in patients with vasculitis must be guided by the degree of disease activity. Specifically, the treatment of vasculitis should be predicated not only on abnormal laboratory test results but also on clear evidence of active disease. In addition, the intensity of treatment must be adapted to the type of vasculitis. For example, giant cell arteritis responds to high doses of glucocorticoids in essentially all cases, but Wegener's granulomatosis nearly always requires an additional agent (rituximab, cyclophosphamide, or methotrexate) for disease control. In contrast, despite the dramatic fashion in which they sometimes present, most cases of HSP and cutaneous leukocytoclastic angiitis require no immunosuppressive treatment at all. In a randomized trial of patients with ANCA-associated vasculitis, azathioprine (2 mg/kg/day) and methotrexate (0.3 mg/kg/week, progressively increased to 25 mg/week) were equally effective for the maintenance of disease remission.

Conventional therapies such as glucocorticoids, immunomodulating agents, and cytotoxic drugs induce remissions and control vasculitis in most cases. Moreover, in some cases—a variable percentage, depending on the type of vasculitis—the disease is curable. Unfortunately, the treatments of vasculitis have enormous potential for toxicity. Regular monitoring of patients' bone marrow, renal, and hepatic function is essential to avoid treatment-induced toxicity. Prophylaxis against opportunistic infections, particularly *Pneumocystis* pneumonia (Chapter 349), is an important part of many vasculitis treatment regimens. During the tapering of immunosuppressive medications, disease flares are common in many forms of vasculitis.

A common error is treating patients with high doses of immunosuppressive agents for too long. The most appropriate use of medications such as cyclophosphamide and glucocorticoids is to induce remission as quickly as possible with early, aggressive treatment regimens and then convert patients to safer treatments for the maintenance of remission. Rituximab is replacing cyclophosphamide as the drug of choice for some forms of vasculitis, particularly severe ANCA-associated vasculitides. In such patients, the appropriate timing of re-treatment is not clear. Current treatment approaches to the specific vasculitides are described under Clinical Manifestations.

PROGNOSIS

Assuming that the diagnosis is made before the patient has become catastrophically ill, the prognosis in systemic vasculitis is determined largely by the answers to four questions:

1. Was the diagnosis established before the occurrence of major, irreversible organ damage?
2. Was aggressive (but appropriately dosed) treatment begun in a timely fashion?
3. Was there careful monitoring during treatment, and were specific steps taken to avoid drug-induced toxicity (e.g., opportunistic infection)?
4. Were the potentially toxic medications that induced remission stopped at an appropriate juncture and replaced with less dangerous medications (or was treatment stopped altogether)?

For most forms of vasculitis, the factors that determine long-term, drug-free remissions remain poorly understood. The likelihood of achieving sustained remission after the discontinuation of all medications (or cures) varies according to the specific type of vasculitis.

FUTURE DIRECTIONS

Compelling laboratory and spontaneously occurring animal models of disease, combined with the known associations among HBV, HCV, and vasculitis in humans, suggest that additional links between infection and systemic vasculitis may be established in the future. Important strides have been made in the description of cytokine and chemokine pathways that are operative in vascular inflammation, but relevant anticytokine interventions remain to be defined for clinical therapies. B-cell depletion is rapidly emerging as the treatment of choice for some forms of severe vasculitis. Additional studies are required to define the full spectrum of the clinical utility of B-cell depletion strategies for remission induction, as well as to understand the appropriate timing of re-treatment.

POLYMYALGIA RHEUMATICA AND TEMPORAL ARTERITIS

ROBERT F. SPIERA AND STEPHEN A. PAGET

DEFINITION

Polymyalgia rheumatica (PMR) and temporal arteritis, also called *giant cell arteritis* (GCA), are systemic inflammatory disorders of unknown cause that represent a spectrum from severe proximal aches and pains and constitutional symptoms to an occlusive granulomatous vasculitis of medium and large vessels that can lead to permanent blindness or other organ and tissue damage. These disorders occur primarily in patients older than 50 years, in women more than in men; they are propagated by antigen-driven, cell-mediated (T_H1) immune mechanisms that may be associated with specific genetic markers, and they are highly responsive to corticosteroids.

EPIDEMIOLOGY

In the United States, the average annual incidence of PMR is 52.5 per 100,000 patients aged 50 years and older, and it increases with age. The prevalence is about 0.5 to 0.7%. Internationally, the frequency varies according to country, with the highest rates occurring in the Scandinavian countries. The incidence and prevalence of GCA are approximately one third those of PMR.

PATHOBIOLOGY

The cause of PMR and GCA is unknown, but both demonstrate familial aggregation, have a genetic association with human leukocyte antigen (HLA)-DR4, and are associated with a sequence polymorphism encoded within the hypervariable region of the HLA-DRβ1*04 gene. In genetically predisposed patients, disease may be triggered by environmental factors such as viruses or by internal antigens such as elastin. The inflammatory manifestations are directed by specific patterns of cell-mediated, T_H1-associated cytokines. Cytokine production by the mononuclear cells in the involved tissues appears to influence the clinical phenotype. Cytokine profiles characterized in temporal artery biopsy specimens obtained from patients with PMR and GCA differ. GCA tissue contains the T-lymphocyte products interferon (IFN)-γ and interleukin (IL)-2 and the macrophage products IL-1β, IL-6, and transforming growth factor-β. In PMR vascular tissue, transcripts are found for transforming growth factor-β, IL-1, and IL-2 but not for IFN-γ. Patients with GCA who present with fever of unknown origin and who do *not* have ischemic symptoms, such as visual loss, exhibit low IFN-γ levels in the arteries. Arteries that express high IFN-γ levels typically have multinucleated giant cells present; these cells remove debris and secrete cytokines that stimulate intimal hyperplasia and lead to angiogenesis.

The adventitia is considered the immunologic center in the pathogenesis of GCA. Macrophages and T lymphocytes enter the vessel wall through the vasa vasorum with the aid of adhesion molecules and come into contact with an inciting antigen. Here, it is likely that clonal proliferation of $CD4^+$ T cells is triggered by the presentation of unknown antigens by antigen-presenting cells. The activated CD4 cells produce IFN-γ, which attracts macrophages to the arterial wall. Some of these macrophages fuse at the intima-media junction to form multinucleated giant cells. These cells produce vascular endothelial growth factor, which triggers neovascularization both in the intima-media junction and at the level of the vasa vasorum, sprouting from the adventitia to the media. The subsequent immunologic events lead to a characteristic topography of mononuclear cells throughout the vessel wall. Products of giant cells and macrophages at the intima-media junction include collagenase and nitric oxide, both of which probably contribute to tissue damage. The pathologic impact of cytokines leads not only to the characteristic medial damage but also to the significant intimal hyperplasia that, if not treated, may eventually cause luminal narrowing and tissue ischemia.

In GCA, a transmural (involving all layers of the vessel) inflammatory infiltrate comprising predominantly mononuclear cells, and commonly with giant cells, is found in the superficial temporal arteries as well as in other large and medium-sized arteries. In elderly patients, fragmentation of the internal elastica is characteristic and helps differentiate this vascular lesion from that of atherosclerosis. Often, macrophages containing fragments of elastic tissue are found at the intima-media junction, the histologic center of the inflammatory process. As mentioned earlier, immunochemical techniques demonstrate differing patterns of cells and their pro-inflammatory and pro-fibrotic products in the adventitia, media, and intima. Intimal proliferation may be prominent and lead to luminal narrowing. Fibrinoid necrosis, a common histologic feature in polyarteritis nodosa, is not seen in GCA.

In PMR, mononuclear cell inflammation can be found not only in the proximal joints, such as the shoulders, but also in the surrounding tendons, bursae, and soft tissues, consistent with enthesitis. Although muscle pain may be present, no muscle inflammation is found.

CLINICAL MANIFESTATIONS

PMR and GCA are systemic inflammatory disorders that occur primarily in patients older than 50 years, in women more than in men (2:1), and in whites. PMR and GCA are particularly uncommon in African Americans.

Shared characteristics of the two disorders include significant cytokine-driven constitutional symptoms such as fever, fatigue, and weight loss, as well as a markedly elevated erythrocyte sedimentation rate (ESR), anemia, and thrombocytosis. The musculoskeletal hallmark of PMR is proximal, severe, and symmetrical morning or even day-long stiffness, soreness, and pain in the shoulder, neck, and pelvic girdles. Fifty percent of patients with GCA share this characteristic proximal pain syndrome. Carpal tunnel syndrome and hand and knee synovitis may be seen in patients with PMR, but the overall presentation remains predominantly proximal, as opposed to the presentation of rheumatoid arthritis, in which distal synovitis dominates. Although patients with PMR may appear to have proximal muscle weakness, this is invariably due to pain and not muscle inflammation. Magnetic resonance imaging and ultrasound studies in patients with PMR have confirmed the presence of inflammation of extra-articular synovial structures, in particular, subacromial and subdeltoid bursae in the shoulders.

Specific signs and symptoms of GCA are best appreciated in their anatomic and physiologic contexts. GCA preferentially affects certain blood vessels, including the branches of the external carotid artery; the ophthalmic artery and, in particular, its posterior ciliary branches; and the large arteries that arise from the aortic arch and abdominal aorta. Headache and scalp pain are probably the most frequent symptoms, occurring in 50 to 75% of patients. Headache is often the first manifestation of GCA and is described as boring, severe, and constant; unresponsive to simple pain medications; and persisting through the night. Classically, patients complain of persistent and prominent temporal headaches, but occipital pain can also occur. Ear, pinna, or parotid gland pain may occur secondary to involvement of the posterior auricular artery. Jaw claudication and pain due to masseter muscle ischemia on chewing occur in 50% of patients. Lingual and maxillary artery involvement can lead to jaw or tongue pain on chewing or talking. The superficial temporal artery may become tortuous, prominent, nodular, or tender, but these findings are not invariable, and an abnormal temporal artery may be found on biopsy in vessels that appear to be normal on examination.

Fixed or intermittent symptoms related to vasculitic involvement of the ophthalmic arteries and its branches are the most dreaded manifestation of this illness and demand immediate therapeutic intervention. These symptoms are related to vascular narrowing due to both active inflammation and endothelial injury–derived vasospasm. Decreased vision secondary to arteritis is the most common serious consequence of GCA, occurring in 20 to 50% of patients who present to ophthalmologists. It is the presenting symptom in 60% of patients with GCA who develop visual loss. A careful history obtained from patients who present with "sudden" visual loss reveals that headache, constitutional symptoms, and PMR preceded the visual loss in approximately 40% of patients. Even the evolution of the visual loss is often staggered, with amaurosis fugax in 10% and a partial field defect progressing to complete blindness over days. If GCA remains untreated, the second eye may become involved within 1 to 2 weeks. The posterior ciliary arteries are the most frequently involved; thus, anterior ischemic optic neuropathy is the most common lesion, which can be easily defined by an ophthalmologist. Occlusion of the central retinal artery and its branches is uncommon; thus, exudates, hemorrhages, and frank vasculitis are infrequent. Five percent of patients with GCA may present with diplopia or ptosis, which may precede visual loss. The final visual abnormality can be a composite of many ischemic events occurring together in the optic nerve, the extraocular muscles, the chiasm, and the brain itself. Because GCA primarily involves arteries that contain elastica, and the elastic lamina is lost as vessels pierce the dura, intracerebral lesions such as strokes are uncommon but may occur.

Large artery involvement most commonly presents as arm or leg claudication; rarer manifestations are stroke, subclavian steal syndrome, intestinal infarction, and symptomatic aortic aneurysm. Thus, a subclinical arteritis can exist and demands long-term monitoring.

Steroid-treated PMR and GCA are self-limited illnesses lasting 1 to 2 years in most patients. However, a subgroup of patients with both disorders can have active inflammatory disease, as manifested by persistent symptoms and blood test signs of active inflammation, for 7 to 10 years. Of note is the fact that thoracic aneurysms with giant cells in the tissue can develop as long as 15 years after the diagnosis, successful treatment, and discontinuation of steroids. Indeed, the incidence of thoracic and aortic aneurysms is markedly higher in patients with prior history of presumably successfully treated GCA than in age-matched control subjects. Conversely, in studies of repaired aortic aneurysms, pathologic findings consistent with GCA have been found in approximately 2% of specimens from individuals without previously recognized or suspected arteritis. In most studies, survival in those with PMR and GCA is similar to that of unaffected persons of the same age. However, one study showed that survival was decreased in a group of patients with GCA who had permanent visual loss and required more than 10 mg/day of prednisone at 6 months. This probably supports the observation that morbidity and mortality are caused by steroid-related treatment complications in this high-risk, elderly group of patients possessing many comorbid conditions.

DIAGNOSIS

The diagnoses of PMR and GCA are based on clinical facts, with support from laboratory tests and temporal artery biopsy (Fig. 279-1). No physician should await an abnormal finding on temporal artery biopsy or demand the presence of an elevated ESR before making the definitive diagnosis of GCA in the setting of a characteristic clinical picture. That said, the laboratory hallmark of PMR and GCA is an elevation in IL-6-stimulated acute phase reactants such as the ESR and C-reactive protein. The ESR is usually in excess of 50 mm/hour and may exceed 100 mm/hour. An ESR in the low 20s or 30s, however, does not exclude a diagnosis of PMR or GCA if other characteristic clinical features are present, and especially if the patient is already taking steroids.

Normocytic, normochromic anemia and thrombocytosis occur in approximately 50% of patients with both disorders and are excellent guides to the state of inflammation. In both PMR and GCA, the frequency of rheumatoid factor, antinuclear antibody, complement levels, monoclonal proteins, and cryoglobulins is no higher than in age-matched control subjects. Alkaline phosphatase activity may be elevated in one third of patients, primarily those with GCA. Although these tests are not indicated in PMR and GCA, muscle enzymes and electromyography are normal, and muscle biopsy shows type II fiber atrophy but no inflammation.

Superficial Temporal Artery Assessment

Temporal artery tenderness, nodularity, and diminished pulsation are typical findings on physical examination in a patient with GCA. Color duplex ultrasonography has been used as an adjunctive noninvasive diagnostic tool in GCA. A hypoechoic halo around the superficial temporal artery has been reported in 73% of patients with biopsy-proven GCA. The halo, representing edema in the arterial wall, was observed bilaterally in a significant subset of patients and disappeared at a mean of 16 days after the initiation of steroids. The presence of the halo had a sensitivity of 73% and was 100% specific for GCA in one study. Other groups have been unable to replicate this experience, however, and have found Doppler ultrasonography to be no more sensitive or specific than physical examination in patients thought to have the disease. Findings of stenosis or occlusion of temporal arteries by Doppler ultrasound have also been recognized as modestly sensitive and specific for the diagnosis of GCA in some studies. Operator dependency remains a challenge to the more widespread use of this modality diagnostically. [^{18}F]Fluorodeoxyglucose positron emission tomography may be helpful in identifying large-vessel inflammation suggestive of GCA, but it is not helpful in assessing the temporal arteries themselves, given their relatively small size and high background uptake in that area. Recent studies have suggested that magnetic resonance imaging or magnetic resonance angiography may be a helpful noninvasive diagnostic modality. Superficial cranial arteries can be visualized, and mural inflammatory changes and luminal narrowing can be identified. Large-vessel involvement can also be assessed. Studies have suggested that the sensitivities and specificities of magnetic resonance imaging and angiography are similar to those of biopsy in the diagnosis of GCA. Nevertheless, temporal artery biopsy remains the diagnostic "gold standard" in GCA, and given the relatively easy accessibility of the artery and potentially significant morbidity of therapy in GCA, histologic confirmation is favored in most cases.

Although temporal artery biopsy continues to be an important diagnostic test for the presence of GCA, a few caveats must be stated. First, in a patient

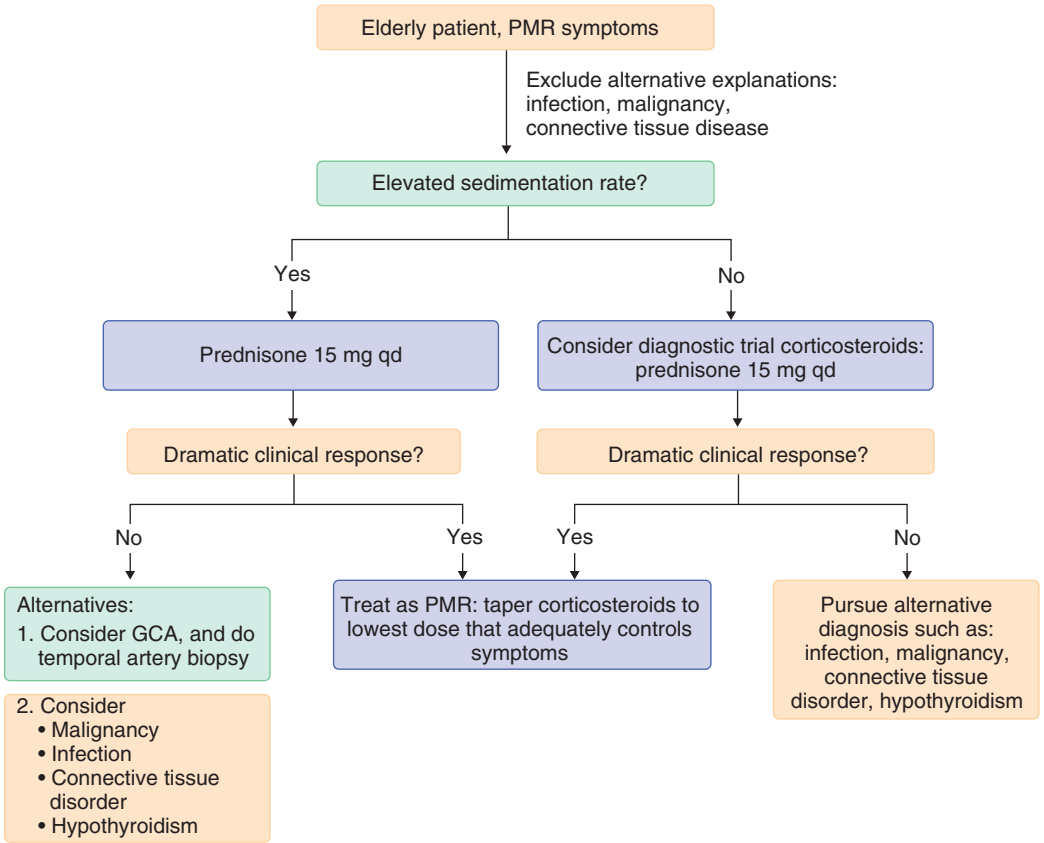

FIGURE 279-1. Diagnostic algorithm for polymyalgia rheumatica (PMR). GCA = giant cell arteritis.

in whom the clinical diagnosis is likely, treatment with steroids should be instituted immediately, without waiting for the biopsy results. Second, because of the skipped nature of the pathologic inflammatory lesions in the vessel wall, as many as 20 to 30% of biopsy specimens may be normal despite an overwhelming diagnostic likelihood of GCA. However, because the biopsy is helpful in confirming the diagnosis of GCA, in which high doses of steroids are used, the following guidelines are given: Patients with pure PMR and no GCA signs or symptoms do not need a biopsy. However, because 10% of these patients may develop clinical manifestations of GCA within the next year, they should be told to report such symptoms immediately. When GCA is likely, an outpatient biopsy should be performed on the symptomatic side of the head, preferably including inflamed areas with tenderness or nodularity and incorporating 2 to 3 cm of vessel. Multiple sections should be requested because of the segmental nature of the disease process. Some rheumatologists routinely perform bilateral biopsies, which may increase the likelihood of obtaining an abnormal finding by up to 5%, whereas others perform a contralateral biopsy if the first specimen is normal. Diagnostic biopsy findings continue to be present for as long as 2 to 4 weeks after the clinical diagnosis is made and steroid treatment is instituted.

Differential Diagnosis

The systemic nature of these disorders and the fact that they occur in the elderly demand careful diagnostic scrutiny to avoid missing a malignant neoplasm or major infection and possibly treating patients inappropriately with high-dose steroids. This is true in PMR because there is no diagnostic test, and it is true in GCA because the biopsy findings may be normal in the face of active, vision-threatening vasculitis. Infections that must be considered and ruled out if clinically appropriate include tuberculosis, endocarditis, and hepatitis B and C. Malignant neoplasms such as lymphoma and multiple myeloma may mimic PMR, and an age-appropriate cancer evaluation is always indicated in this age group. Autoimmune disorders such as elderly-onset rheumatoid arthritis and systemic lupus erythematosus, as well as dermatomyositis and other types of vasculitis, must be considered in the differential diagnosis and evaluated by clinical information and serologic testing. There is support for the concept that elderly-onset rheumatoid arthritis is the same disorder as PMR with a negative rheumatoid factor, a more proximal focus of joint inflammation, and a good response to low-dose prednisone. The distinction may be semantic, because neither disorder tends to evolve into an erosive arthritis. A more protracted clinical course, however, is often seen in patients in whom distal synovitis is a prominent feature, and these patients are classified as having elderly-onset rheumatoid arthritis. PMR and GCA should always be considered in the setting of a fever of unknown origin, because symptoms and signs may be occult or the history may be incomplete.

TREATMENT

Both PMR and GCA are highly responsive to corticosteroids, which are the preferred treatment choice. This response is so characteristic that an immediate and dramatic improvement in PMR and GCA symptoms within 1 to 3 days after steroid institution supports the diagnosis. Conversely, the lack of a rapid and significant improvement in signs, symptoms, and function within 5 to 7 days should be considered a major point against the diagnosis. The physician should then consider an alternative diagnosis (e.g., tumor, infection) or the presence of GCA in PMR patients, which might demand a higher steroid dose. Because the inflammatory set point of the two disorders is different, different doses of steroids are used at the onset of treatment. Whereas PMR usually responds to 15 mg/day of prednisone, GCA usually requires 60 to 80 mg/day of prednisone in divided doses or higher doses if organ or tissue damage is present or threatened. In GCA, if visual symptoms such as a fixed loss or amaurosis fugax are present, the patient should be treated with high-dose intravenous methylprednisolone at doses ranging from 40 mg every 8 hours to 1 g/day for 3 days, followed by high-dose oral steroids in divided doses.

Within 2 to 3 days after the institution of steroids, most symptoms of PMR or GCA clear rapidly, and patients describe a miraculous improvement. The steroid dose is then maintained for 2 to 3 weeks, during which time the ESR, C-reactive protein, hemoglobin, and platelet counts normalize. Steroid taper is then instituted and is guided by the clinical response. In PMR, the dose is commonly tapered by 1 mg every 7 to 10 days; in GCA, it is tapered by 5 to 10 mg every 7 to 10 days. In GCA, the use of alternate-day corticosteroid regimens to minimize steroid side effects is generally not recommended because randomized controlled trials have demonstrated higher rates of treatment failure with alternate-day dosing schedules. It is important that the taper be guided primarily by clinical findings (e.g., PMR stiffness, headache, fatigue) and that the level of ESR elevation be considered within that clinical context. One should never "chase the ESR," because this would inappropriately subject an elderly patient to a dangerously high cumulative dose of steroids, with the attendant side effects. An increased dose of prednisone should be based on a change in symptoms, not solely on an increase in the ESR. One possible exception is a patient with a history of GCA and prior abrupt vision loss in one eye, in whom any further compromise of vision would be catastrophic. The effective dose demanded for a flare is often as low as 5 to 10 mg of prednisone; uncommonly, up to 60 mg/day may be needed to control symptoms (e.g., visual abnormalities). A persistently elevated ESR (>50 mm/hour) without PMR or GCA symptoms should alert the physician to look for alternative causes, such as infection. Treatment is a careful balancing act between disease control and avoidance of steroid-related toxicity. The overall goal is to attain the best disease control with the lowest dose of steroids. In most patients, prednisone can be tapered safely in 1 to 2 years. However, some patients may need to take low doses of steroids for 2 years or more. Appropriate immunizations, osteoporosis regimens (calcium, vitamin D, and bisphosphonates), and metabolic monitoring are mandatory in all patients prescribed chronic steroid therapy.

The major feared outcome in GCA is ischemic complications of the disease, most often vision loss or, less frequently, cerebrovascular accidents. Vision loss is usually irreversible, and although it is uncommon once the diagnosis is suspected and glucocorticoid therapy is instituted, it can occur early in the course of treatment. Aspirin is known to be protective against ischemic events in patients with atherosclerosis and has anti-inflammatory effects in inflamed blood vessels, including inhibition of IFN-γ. Two retrospective studies have suggested that low-dose aspirin may be protective against cranial ischemic complications in GCA. Adjunctive therapy with low-dose aspirin should be considered unless there is a strong contraindication to its use.

Alternative immunosuppressive agents have been tested in both PMR and GCA patients in an attempt to "spare steroids" and control the inflammatory state. Studies examining the efficacy of methotrexate in GCA have yielded mixed results, with the largest, most recent study showing no incremental benefit from combined therapy.[1] One meta-analysis of three randomized placebo-controlled trials suggested a modest benefit to the use of methotrexate in GCA in terms of its steroid-sparing benefit and a reduced likelihood of flares.[2] Given the modest nature of the benefit demonstrated, the methodologic issues with such a meta-analysis, and the potential toxicities of methotrexate in this elderly population, methotrexate is not routinely incorporated as first-line therapy in GCA. In PMR, one study found that methotrexate provided a steroid-sparing benefit and possibly reduced the number of flares.[3] The magnitude of the benefit appears to be modest, however, and no reduction in corticosteroid-related side effects was demonstrated. At present, methotrexate is not standard in the management of either disease, but in individual patients with refractory disease or excessive corticosteroid morbidities, rheumatoid arthritis–type doses of methotrexate (7.5 to 20 mg/week) or azathioprine (2 mg/kg/day) are added in some instances.

Tumor necrosis factor inhibition has been of interest as a potential therapeutic strategy in GCA and PMR. Tumor necrosis factor has been demonstrated in the inflamed arteries of patients with GCA, and inhibition of this cytokine has a known clinical benefit in other inflammatory granulomatous disorders, such as Crohn's disease. Randomized controlled trials of infliximab in GCA[4] and PMR,[5] however, failed to demonstrate a benefit in terms of preventing relapses or offering a steroid-sparing effect.

FUTURE DIRECTIONS

Better understanding of the disease-causing roles of immunologically active cells and their cytokine products, along with genetics and correlations with clinical subsets, will lead to more focused treatment modalities and the avoidance of long-term treatment with steroids.

280 INFECTIONS OF BURSAE, JOINTS, AND BONES

ERIC L. MATTESON AND DOUGLAS R. OSMON

INFECTION OF BURSAE

Septic Bursitis

DEFINITION

Bursae are the satellite structures that form to protect tissues from bony prominences. The superficial bursae, including the olecranon, prepatella, infrapatella, and bursae over the first metatarsophalangeal bunions, are more likely to become infected than are the deep bursae, such as the subacromial, trochanteric, and iliopsoas bursae.

EPIDEMIOLOGY

Olecranon bursitis may occur in as many as 10 in 100,000 persons. The majority of cases occur in men, and antecedent trauma to the skin is frequent.

PATHOBIOLOGY

Septic bursitis of superficial bursae is most commonly due to direct inoculation through the overlying skin; less commonly, it is secondary to overlying cellulitis. Most cases of deep septic bursitis are due to contiguous spread from adjacent infected joints or hematogenous seeding.

Predisposing risk factors for septic bursitis include trauma to the skin, as may occur in plumbers, athletes, and patients with chronic obstructive pulmonary disease (COPD) who frequently lean on the elbows; pre- or infrapatellar septic bursitis occurs in housecleaners, gardeners, and carpet layers. At least one third of patients with septic bursitis have an underlying comorbid illness such as diabetes mellitus, rheumatoid arthritis, gout, COPD, or alcoholism.

CLINICAL MANIFESTATIONS

In immune-competent patients, septic bursitis often but not always presents with fever and erythema and warmth of the overlying skin; there may be swelling of the bursae. In contrast to those with septic arthritis, patients with septic bursitis of superficial bursae have intact range of motion of the joints, which may be limited only at the extremes of flexion. Pain on motion of the joint and restriction of joint range of motion are highly suggestive of septic arthritis. Acute phase reactants such as C-reactive protein, the sedimentation rate, and the white blood cell count (WBC) may be elevated.

DIAGNOSIS

Radiography should be performed to look for a foreign body and to evaluate the surrounding bones. Aspiration of bursal fluid is helpful in the diagnosis of patients who have pain, erythema, and/or swelling of an affected area. However, given the risk of contaminating the bursa if the aspiration occurs through cellulitic skin, many clinicians choose to aspirate a bursa only if empirical antimicrobial therapy has failed. Ultrasound or computed tomography (CT) guidance greatly enhances the successful aspiration of superficial bursae. Care must be taken not to violate the joint space when aspirating a bursa to avoid inoculating the joint space.

The leukocyte count of the bursal fluid is generally lower than that seen in septic arthritis, with a mean of 13,500 cells/mm^3. Even in immune-competent hosts, cell counts can range from less than 1500 to greater than 100,000/mm^3. A leukocyte count greater than 2000/mm^3 has a sensitivity of 94% and a specificity of 79% for superficial (olecranon or prepatellar) bursitis. Bacterial culture and in vitro susceptibilities must be obtained; if additional fluid is available, a Gram stain may be obtained, although its sensitivity may be as low as 15%. The presence of crystals does not exclude the possibility of septic bursitis.

Staphylococcus aureus (Chapter 296) is the most common cause of septic bursitis, present in more than 80% of culture-proved cases, followed by β-hemolytic streptococci. Aerobic gram-negative bacilli, including *Escherichia coli*, *Campylobacter jejuni*, and *Pseudomonas* species, are rare causes of septic bursitis. Chronic bursitis may be associated with systemic infections due to *Brucella abortus*, atypical mycobacteria, or *Mycobacterium tuberculosis*, as well as fungi; the presence of these infections should raise the possibility of systemic infection.

Differential Diagnosis

In the immune-competent host, nonseptic bursitis (Chapter 271) may have a somewhat more indolent presentation than septic bursitis. The differential diagnosis includes gout, pseudogout, arthritis, and trauma with hemobursa. An overlying cellulitis may be confused with bursitis. Fever is usually not present in nonseptic bursitis due to mechanical or friction trauma.

TREATMENT Rx

Treatment of septic bursitis is guided by knowledge of the putative underlying organisms, in most cases, *S. aureus*. Because the Gram stain is positive in less than two thirds of patients and cultures may be delayed, empirical therapy is guided by the clinical presentation. Most patients can be treated as outpatients, but those who are immunocompromised may require hospitalization for intravenous antibiotic therapy. Initial ambulatory treatment in patients without comorbidities may consist of an oral antistaphylococcal penicillin or first-generation cephalosporin. If community-acquired methicillin-resistant *S. aureus* (MRSA) is suspected, co-trimoxazole or minocycline may be added to one of these agents. In patients who are allergic to penicillin, oral clindamycin or linezolid may be used. Patients who have severe inflammation, are septic, or are immunocompromised may require hospitalization for initiation of treatment with intravenous nafcillin, oxacillin, or cefazolin; if MRSA is suspected, intravenous vancomycin, daptomycin, or linezolid should be used. Vancomycin can also be used in patients who are allergic to penicillin.

The duration of antimicrobial therapy is guided by the clinical response and comorbid states. It should be continued until there is no longer bursal inflammation. This may require several weeks of intravenous or oral therapy and multiple aspirations. Failure of the septic bursitis to respond to initial antibiotic therapy mandates a second course of therapy; recurrence thereafter or inability to adequately drain the bursa with needle aspiration is an indication for surgical intervention.

PREVENTION

Because superficial septic bursitis is often associated with occasional or avocational activities involving kneeling or resting on the elbows, using protective padding may be helpful.

PROGNOSIS

The optimal duration of therapy is unknown, but prognosis of superficial bursitis is generally excellent. The presence of comorbid conditions, especially those associated with deep bursal infections, including septic arthritis, bacteremia, and osteomyelitis, is associated with more intractable and difficult disease.

INFECTION OF JOINTS

Septic Arthritis

DEFINITION

Septic arthritis refers to infection of a joint by a microorganism. It is associated with increased morbidity and mortality, as well as loss of articular integrity and function. Septic arthritis is usually caused by a bacterial infection. Other microorganisms can cause infections with clinical characteristics that differ from those of bacterial infections; these are reviewed separately.

NONGONOCOCCAL SEPTIC ARTHRITIS

EPIDEMIOLOGY

The incidence of septic arthritis affecting native joints is about 5 to 8 in 100,000 patient years. Among patients presenting with an acutely swollen and painful joint, the prevalence of bacterial arthritis ranges widely, from less than 10 to as high as 27%, depending on the source population. Nongonococcal septic arthritis is the most common form of septic arthritis and is somewhat more common in men than in women.

PATHOBIOLOGY

More than 90% of cases of septic arthritis are due to staphylococci or streptococci (Table 280-1). Septic arthritis can result from direct inoculation (e.g., accidents, bites, surgery) or by extension from infected bone into an adjacent joint space. Approximately 75% of cases are due to hematogenous spread, particularly in patients with indwelling catheters and immunocompromised patients. Septic arthritis due to needle arthrocentesis (<1 in 10,000 procedures) or arthroscopy (4 cases per 1000 to 10,000 procedures) is very rare.

Bacteria causing septic arthritis produce an acute inflammatory reaction in the synovial membrane. Synovial hyperplasia and inflammatory cell immigration with the release of pro-inflammatory and cartilage-destroying cytokines and proteases result in damage to cartilage and bone. Bacterial toxins and DNA and superantigens, such as those seen in staphylococcal toxic shock syndrome, also contribute to cartilage and bone damage.

Risk factors for the development of septic arthritis include diabetes, alcoholism, cutaneous ulcers, intravenous drug use, prosthetic joints, rheumatoid arthritis, osteoarthritis, and low socioeconomic status, as well as advanced age, skin infection, indwelling intravenous catheters, cancer, and immunosuppressive therapies, including biologic response modifiers used in the management of autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease.

CLINICAL MANIFESTATIONS

Most patients with bacterial arthritis feel ill and have fever. Immunocompromised and elderly patients may not have a marked febrile response. Most cases (>80%) of septic arthritis are monoarticular; the knee is involved in more than 50% of cases. Polyarticular joint sepsis may be seen in immunocompromised patients and those with rheumatoid arthritis or systemic lupus erythematosus. Such patients frequently lack typical signs and symptoms of infection and may not appear to be particularly ill at presentation, but they may have rapid cardiovascular decompensation. This is particularly true for patients who are taking glucocorticosteroids, other immunosuppressive agents, and biologic response modifiers, including tumor necrosis factor-α (TNF-α) inhibitors.

Patients with septic arthritis affecting nondiarthrodial joints, such as the acromioclavicular or sacroiliac joints, may have a history of intravenous drug use or may have intravenous catheters in place to treat other medical conditions. Infection of the symphysis pubis is associated with previous urinary tract surgery, pelvic malignancy, intravenous drug use, or vigorous weight-bearing physical activity, such as long-distance running, in female athletes.

A finding of microorganisms in the joint should lead to an appropriate history and physical examination to identify a source of hematogenous infection, such as cellulitis, pneumonia, or urinary tract infection. Staphylococci and β-hemolytic streptococci may enter directly through open wounds, whereas gram-negative infection may be associated with bowel or bladder disease.

DIAGNOSIS

Plain radiography should be performed to evaluate the surrounding bones and joint space and to provide a baseline for comparison after therapy is completed. Imaging modalities such as magnetic resonance imaging (MRI), CT, and plain radiography are useful to determine whether there is associated osteomyelitis and in cases of diagnostic uncertainty. Blood cultures are positive in up to 50% of patients with bacterial septic arthritis and should be obtained in all patients in whom this diagnosis is suspected. If septic arthritis is suspected, synovial fluid arthrocentesis is indicated, and the fluid should be examined for bacterial culture and Gram stain; the latter is positive in only about 50% of patients. The choice of culture method is not critical, whether blood culture or conventional agar plate. Specific cultures and stains for fungal and mycobacterial organisms should be done if there is a history of exposure or if antibacterial therapy has failed. Polymerase chain reaction

(PCR) assays may be helpful for diagnosing less common joint infections such as *Borrelia,* but the value of PCR over standard culture for the diagnosis of staphylococcal or streptococcal joint infection has not been demonstrated. Other helpful examinations include leukocyte count and differential, as well as evaluation of the synovial fluid for the presence of crystals. The presence of gout or pseudogout crystals does not exclude the possibility of septic arthritis, particularly in patients whose WBC is above 50,000/mm^3.

A frequent clinical scenario is the patient who is anticoagulated. Because of the rapidly destructive nature of septic arthritis and the often profound systemic consequences, anticoagulation is not a contraindication to arthrocentesis. The procedure may be assisted by ultrasound guidance, especially when only small amounts of joint fluid are present or when the joint is difficult to aspirate. CT-guided arthrocentesis is particularly useful for aspiration of deep joints such as the hips and nondiarthrodial joints.

The total WBC and differential in synovial fluid is helpful in distinguishing infected from noninfected joints in immunocompetent patients. A diagnosis of septic arthritis is present in 47% of patients with a synovial WBC greater than 50,000/mm^3 and in 77% of patients with a WBC greater than 100,000/mm^3. It is important to realize that a WBC less than 50,000/mm^3, especially in immunocompromised patients, can be associated with septic arthritis, so the absolute WBC in synovial fluid is not, by itself, a reliable way to confirm or exclude a diagnosis of septic arthritis.

Differential Diagnosis

Symptoms of septic arthritis, such as acute joint pain, swelling, and even fever, with an increase in acute phase reactants, can be caused by crystalline arthritis (Chapter 281), especially pseudogout and gout, as well as psoriatic arthritis and reactive arthritis (Chapter 273). In patients who have preexisting inflammatory joint disease, such as rheumatoid arthritis, septic arthritis may be suspected if there is a sudden onset of acute or subacute monoarticular or pauciarticular joint swelling when the disease is otherwise well controlled. The presence or absence of fever is not a reliable indicator of an infected joint (Fig. 280-1).

TREATMENT Rx

As soon as the joint has been aspirated and, ideally, after blood cultures have been obtained, prompt treatment with antibiotics must be instituted. Removal of purulent material and, where appropriate, débridement are essential. The choice of empirical antimicrobial therapy is based on which organisms are the likely cause of the septic arthritis and on the results of Gram stain and culture. No advantage of one antibiotic regimen over another has been demonstrated. If the initial Gram stain of the synovial fluid reveals gram-positive cocci, vancomycin is recommended, given the increasing frequency of infection due to MRSA and the need to initiate effective antimicrobial therapy as soon as possible. Daptomycin and linezolid are alternative agents. If the initial

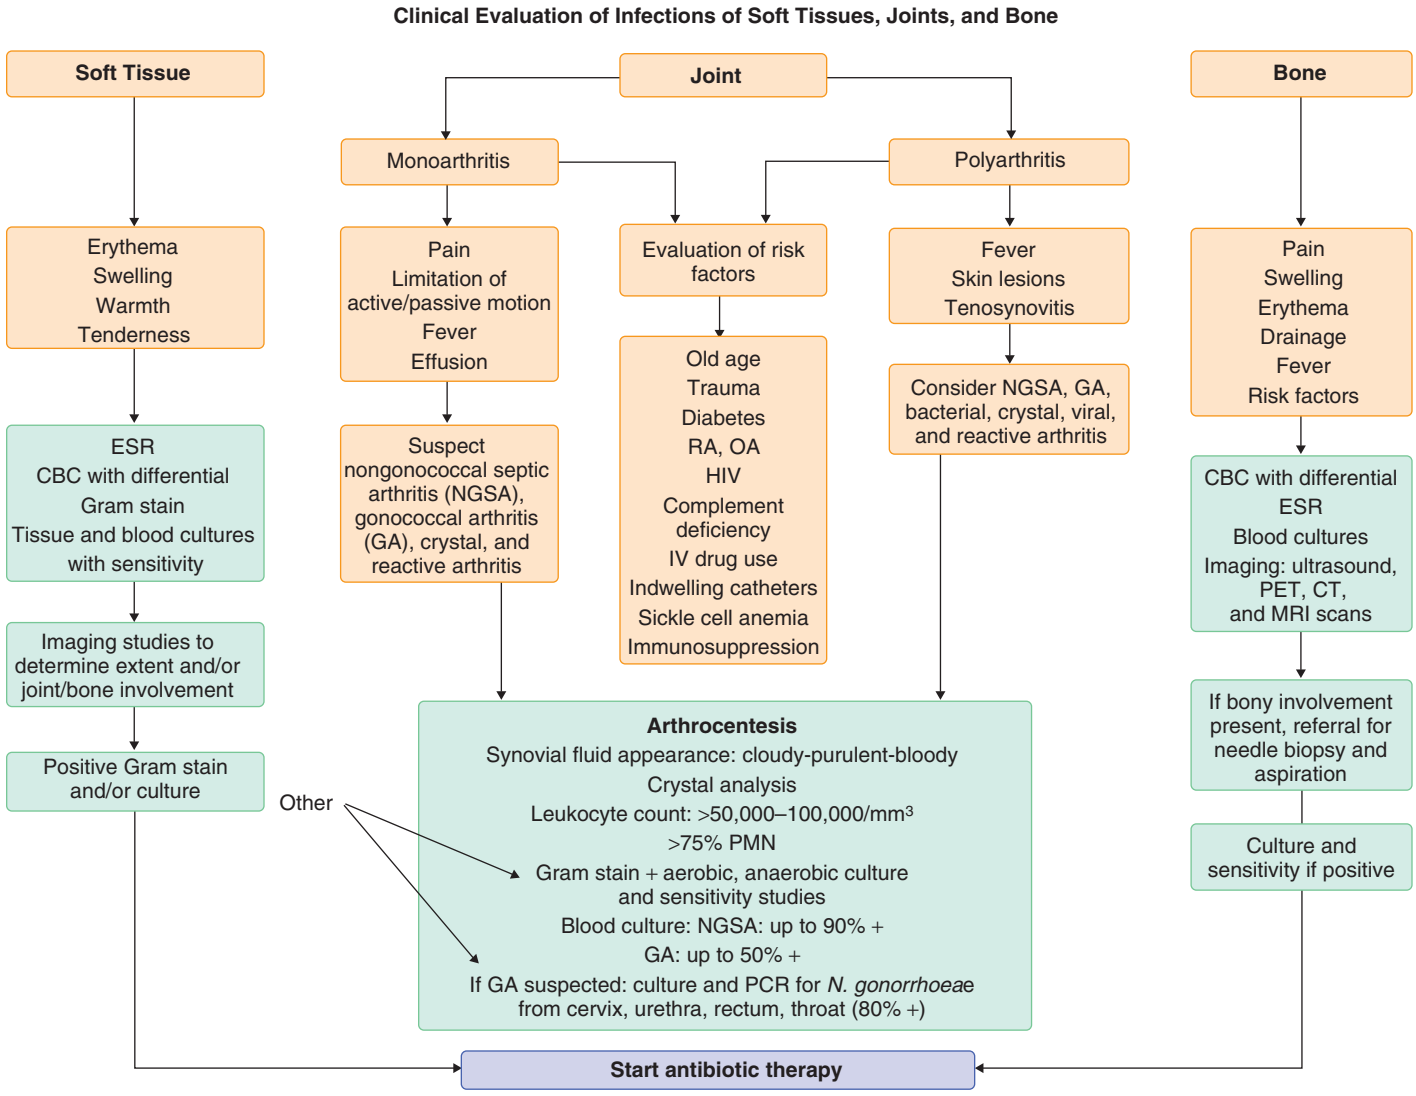

FIGURE 280-1. Clinical evaluation of infections of soft tissues, joints, and bone. CBC = complete blood count; CT = computed tomography; ESR = erythrocyte sedimentation rate; GA = gonococcal arthritis; HIV = human immunodeficiency virus; IV = intravenous; MRI = magnetic resonance imaging; NGSA = nongonococcal septic arthritis; OA = osteoarthritis; PCR = polymerase chain reaction; PET = positron emission tomography; PMN = polymorphonuclear leukocyte; RA = rheumatoid arthritis.

Gram stain reveals gram-negative bacilli, an agent with broad coverage, including activity against *Pseudomonas aeruginosa,* is recommended. Such agents include ceftazidime, cefepime, imipenem, meropenem, piperacillin-tazobactam, and intravenous ciprofloxacin. If the Gram stain is negative, vancomycin alone in immunocompetent patients or in those unlikely to have gram-negative infection based on history and examination, or vancomycin plus one of the gram-negative antibacterials listed, is reasonable. Once culture and in vitro susceptibility results are available, therapy can be modified. The duration of antibacterial therapy usually ranges from 2 to 6 weeks, with data suggesting that one aspiration and 2 weeks of therapy are usually adequate, at least in children.

The role of arthroscopic versus needle versus open drainage of the joint is unsettled. Surgical management is appropriate for septic arthritis of the hip, for patients who fail to respond to serial needle aspiration and antibiotic therapy, and for patients who appear to be developing life-threatening complications such as necrotizing fasciitis. No studies have demonstrated the utility of lavage with or without synovectomy by arthroscopy versus arthrotomy or débridement. Patients should be mobilized as rapidly as possible to prevent joint contractures. In children, concomitant oral dexamethasone for 4 days can lead to more rapid symptomatic improvements.

PREVENTION

In patients requiring immunosuppression or glucocorticosteroid therapy to manage their underlying diseases, every effort should be made to use the lowest possible dose of these medications.

PROGNOSIS

Up to one third of patients with septic arthritis have a poor functional outcome, particularly older patients, patients with preexisting diseases of the joints such as osteoarthritis or rheumatoid arthritis, and patients with prosthetic joints. Poor joint outcome is associated with *S. aureus* infection in more than 50% of patients; mortality may be as high as 10 to 15%, particularly in patients who are immunocompromised or have polyarticular sepsis.

GONOCOCCAL SEPTIC ARTHRITIS

EPIDEMIOLOGY

Neisseria gonorrhoeae (Chapter 307) is a common cause of polyarthralgias and arthritis as well as oligoarticular arthritis and tenosynovitis in young, healthy patients. Disseminated gonococcal infection occurs in 0.5 to 3% of patients with gonorrhea (Chapter 307). Many of these patients have arthritis. Disseminated gonococcal infection and septic arthritis due to *N. gonorrhoeae* occur two to three times more often in women than in men. Most patients do not have a recent history of a symptomatic genital infection. The incidence of gonococcal arthritis is 133 cases per 100,000 population per year. Predisposing factors for disseminated gonococcal infection with arthritis include pregnancy, recent menstruation, complement deficiencies (C5, C6, C7, or C8), and systemic lupus erythematosus.

CLINICAL MANIFESTATIONS

Patients with gonococcal arthritis usually present with one of two clinical syndromes. The first is a purulent arthritis without skin lesions; the second is the triad of tenosynovitis, dermatitis, and polyarthralgias without purulent arthritis. The latter patients may have bacteremia and fever as well as maculopapular, vesicular, necrotic, pustular skin lesions anywhere on the integument. The arthritis is usually asymmetrical and may involve large or small joints, typically the elbows and knees or joints distal to these.

DIAGNOSIS

A high degree of clinical suspicion is required for diagnosis because many patients are asymptomatic for the primary infection. A thorough joint evaluation is important, as is an evaluation of soft tissues, particularly for tenosynovitis affecting the hands and feet. Cultures of blood, endocervix, and urethra are essential; cultures of the pharynx and rectum may be very helpful. *N. gonorrhoeae* is isolated in less than 30% of patients with the tenosynovitis-dermatitis syndrome and in about 50% of those with monoarthritis. PCR may be used to detect the gonococcal DNA in synovial fluid, skin lesions, urine, and throat samples, which are culture negative. Cultures should be submitted on Thayer-Martin media. Patients with suspected gonococcal arthritis should be screened for other coexisting sexually transmitted diseases (Chapter 293) such as syphilis, HIV, and chlamydia, as well as hepatitis B and C.

TREATMENT

Rx

Ceftriaxone is given for 2 to 4 days, followed by oral therapy to complete a minimum of 7 days of therapy, although up to 14 days of therapy is recommended. There is emerging resistance to fluoroquinolones, and unless specific in vitro susceptibility testing is available, their use is not recommended. Patients should also be treated for concomitant chlamydia with the regimens recommended by the Centers for Disease Control and Prevention (CDC). Most patients respond well to outpatient therapy, with complete resolution of the infection. Given emerging antimicrobial resistance, the most recent CDC guidelines for treating *N. gonorrhoeae* should be reviewed.

Viral Arthritis

Patients with viral syndromes may have polyarthralgias or inflammatory polyarthritis, which can mimic rheumatoid arthritis (Chapter 272). The most common viral infections associated with arthritis include hepatitis A, B, and C; cytomegalovirus; parvovirus B19; rubella; measles; and HIV. Other forms of viral arthritis are caused by adenovirus, echovirus, Epstein-Barr virus, and herpes zoster in North America and Europe; chikungunya and o'nyong-nyong viruses, especially in Africa; and Ross River virus in Australia. Arthritis related to viral infections is likely principally reactive in nature, rather than being caused by direct synovial infection.

Other Forms of Infectious Arthritis

FUNGAL ARTHRITIS

Fungal arthritis is unusual and most commonly occurs in immunocompromised patients. Treatment with high doses of immunosuppressants, anti-TNF agents, and possibly other biologic response modifiers used in the treatment of rheumatoid arthritis and other autoimmune diseases may increase the risk for fungal infections. The infections are often systemic and may be indolent. An understanding of the epidemiology of the organisms as well as the patient's risk factors, including occupational and avocational risk factors, is essential to the diagnosis. The most common fungi in the United States include *Blastomyces dermatitidis*, *Coccidioides immitis,* and *Histoplasma capsulatum*. *Sporothrix schenckii* fungal infections may be seen, especially in gardeners. More unusual infections occur in immunocompromised patients, including *Aspergillus, Candida, Cryptococcus,* and *Nocardia.*

LYME ARTHRITIS

Lyme disease (Chapter 329) usually causes oligoarticular arthritis, most commonly affecting the knee. Antibiotic treatment, initially with a second-generation cephalosporin, is effective. Polyarticular disease affecting the small joints has been associated with HLA-DR4, which is found in greater frequency in patients with rheumatoid arthritis.

MYCOPLASMA ARTHRITIS

Mycoplasma hominis (Chapter 325) causes an oligo- or monoarticular arthritis. Risk factors include an immunocompromised state and hypogammaglobulinemia. The treatment of choice is tetracyclines, usually doxycycline; alternatively, clindamycin or fluoroquinolones can be used.

TUBERCULOUS ARTHRITIS

Most cases of tuberculosis (TB; Chapter 332) in Canada, the United States, western Europe, Australia, and New Zealand occur in immigrants. The arthritis is usually monoarticular or oligoarticular, affecting larger joints, and TB should be suspected in patients who have refractory mono- or pauciarticular arthritis thought to be secondary to another bacterial infection or to a systemic inflammatory disease such as rheumatoid arthritis. TB screening is mandatory for all patients before beginning treatment with immunosuppressive drugs or biologic response modifiers.

The diagnosis of TB may be delayed because of a lack of suspicion because patients may not have pulmonary disease. Atypical mycobacterial infection may occur in fishermen and immunocompromised patients. Appropriate treatment for septic arthritis due to TB is based on guidelines and in vitro susceptibility testing, but it often includes isoniazid, ethambutol, or rifampin and pyrazinamide as empirical therapy (Chapter 332). Atypical mycobacteria are often not susceptible to traditional antituberculous agents, and

infectious disease consultation is recommended. Patients with a history of TB in whom anti-TNF therapies are being considered should be appropriately treated for TB before these drugs are started. Patients with a positive purified protein derivative (PPD) test or QuantIFERON assay for TB without a history of diagnosed tuberculosis should be treated prophylactically for several months before starting anti-TNF therapy. Clinical suspicion and culture of synovial fluid or synovial membrane obtained at biopsy are essential to the diagnosis.

SYPHILIS

Musculoskeletal involvement by syphilis infections (Chapter 327) is manifold and includes mono- or oligoarticular arthritis, polyarthralgias, tenosynovitis, sacroiliitis, spondylitis, chondritis, osteitis, and periostitis. Charcot's joints, osteitis, and chronic arthritis are typical of tertiary syphilis. Most patients with syphilis-related arthritis can be treated successfully. Arthritis may complicate congenital, secondary, and tertiary syphilis.

PROSTHETIC JOINT INFECTION

More than 1 million joint replacements (Chapter 285) are done each year in the United States, and this number continues to increase. Infection occurs in 0.3 to 1.7% of hip arthroplasties and 0.8 to 1.9% of knee arthroplasties, and the infection risk is two- to three-fold higher in patients with rheumatoid arthritis. Prosthetic joint infections are classified as (1) early infections, occurring within 3 months of joint replacement; (2) delayed infections, occurring 3 months to about 1 year after joint replacement; and (3) late infections, occurring more than 1 to 2 years after joint replacement. Infections occurring within the first year are usually related to the implantation surgery itself, and late infections are usually due to hematogenous spread.

The development of a bacterial biofilm on the prosthetic joint is characteristic of prosthetic joint infection, increasing the susceptibility to infection in experimental animal models with as few as 100 colony-forming units. These biofilms are formed by bacterial glycocalyx, which increases the organisms' resistance to antimicrobial agents and likely accounts for the difficulty in obtaining viable organisms from the infected joint. More than half of all prosthetic joint infections of hips and knees are caused by staphylococci. Other organisms, including gram-negative bacilli, anaerobes, and *Candida* species, may also cause infection. In particular, *Propionibacterium* species are associated with infected shoulder arthroplasties. About 20% of cases are polymicrobial, and in 7%, cultures are negative.

Risk factors associated with the development of prosthetic joint infection include wound healing complications, prior superficial surgical site infection, prior infection of the joint, previous surgery on the joint, rheumatoid arthritis, advanced age, obesity, smoking, cancer, and diabetes mellitus. Other risk factors include simultaneous bilateral arthroplasty, prolonged operative time, requirement for blood transfusion, and infection occurring elsewhere in the body that can hematogenously seed the prosthesis.

Patients with early-onset infection may have classic symptoms and signs of septic arthritis, including joint pain, effusion, erythema, and fever. Patients with delayed infection may have only joint pain, with or without implant loosening, requiring a high degree of suspicion for the presence of infection.

The definitive diagnosis of prosthetic joint infection is based on the recovery of organisms from multiple specimens of synovial fluid and periprosthetic tissue, sonication of the prosthesis itself, acute inflammation suggestive of infection on pathologic examination of periprosthetic tissue obtained at surgery, or the presence of a sinus track communicating with the prosthesis, even in the absence of microorganisms.

An elevated sedimentation rate or C-reactive protein without another obvious cause, such as inflammatory arthritis or recent surgery, is very suggestive of infection in a patient with a painful, loose prosthesis. Plain radiographs may show loosening, new bone formation, and lucencies along the implant margin but are often nonspecific. Technetium-based scintigraphy combined with indium-labeled white blood cell scanning is suggestive of established infection but is often not performed owing to the expense. MRI and CT have low utility in diagnosing prosthetic joint infection.

Surgical treatment of prosthetic joint infection typically consists of débridement with retention of the prosthesis for acute infection, resection arthroplasty with or without staged reimplantation for chronic infection, or amputation in a few limited instances. Systemic antibiotic therapy in a patient with a prosthetic joint infection is pathogen directed and driven by the surgical therapy used to manage the infection. Following an attempt at salvage of the prosthesis with 2 to 6 weeks of effective intravenous antibiotic therapy, chronic suppressive therapy with oral antimicrobial agents is often used. In rifampin-susceptible staphylococcal infections, its addition to a companion intravenous or oral antimicrobial is recommended to avoid the emergence of resistance, to treat biofilm organisms, and to improve the chance of salvaging the prosthesis. Following resection arthroplasty, 4 to 6 weeks of pathogen-directed intravenous therapy is typical before an attempt at reimplantation several weeks later. The use of depot local antimicrobial therapy with antibiotic-impregnated polymethylmethacrylate spacers following resection arthroplasty is also very common.

PREVENTION

In addition to optimizing comorbidities such as diabetes mellitus and discontinuing tobacco use preoperatively, careful screening for infection, including asymptomatic urinary tract infection, is prudent when considering joint surgery. Perioperative antibiotic treatment with cephalosporin in patients undergoing prosthetic joint replacement reduces the risk of infection by approximately three-fold.■ Antimicrobial therapy should be given within 60 minutes of the initial incision, ideally before tourniquet application. Cefazolin or cefuroxime can be given to patients with normal renal function, and vancomycin can be used in patients who are allergic to penicillin.

Whether an antirheumatic agent should be stopped before joint replacement surgery is unclear. The usual practice is to hold drugs such as methotrexate and anti-TNF agents for one to four half-lives before and after surgery. The impact of this strategy on reducing prosthetic joint infections is unknown.

OSTEOMYELITIS

DEFINITION

Osteomyelitis is a bacterial infection of bone that causes destruction and can occur through a variety of mechanisms.

EPIDEMIOLOGY

Osteomyelitis of the bones of the foot in adult patients with diabetes, neuropathy, and arterial insufficiency is very common. Hematogenous seeding of the spine also occurs, but less frequently. The incidence of osteomyelitis due to trauma and surgery is increasing.

PATHOBIOLOGY

Osteomyelitis can develop from (1) hematogenous seeding from a distant infection, (2) contiguous spread from nearby skin and joints, and (3) penetration of microorganisms into bone at the time of trauma or surgery. Unless there is trauma or the presence of a foreign body, bone is typically very resistant to infection. Organisms such as *S. aureus* cause disease more frequently because they colonize the skin in up to 30 to 40% of individuals, frequently cause cellulitis and bacteremia, and have the ability to bind to bone through the expression of receptors for fibronectin and collagen.

Hematogenous causes of osteomyelitis typically present in the elderly; it usually involves two or more vertebrae and their intervening disc spaces. Bacteria gain access to these structures through the arterial and venous systems (Batson's venous plexus). Bacteremia from any source can cause osteomyelitis of the spine, but cellulitis, urinary tract infection, and pneumonia are the most common sources.

Contiguous focus osteomyelitis is common in adults, typically occurring in the elderly. It results from the spread of infection from nearby skin, often in the feet of patients with diabetes, neuropathy, or vascular insufficiency, or in pelvic bones in patients with decubitus due to impaired sensation from spinal cord injury or disease. Alternatively, it can occur at the time of orthopedic surgery, from contamination at the time of an open fracture, or from a human or animal bite.

Acute osteomyelitis has a duration of less than 10 days, whereas chronic infection has a duration of more than 10 days. *S. aureus* is the most common cause of hematogenous and contiguous osteomyelitis in adults. Osteomyelitis due to β-hemolytic streptococci and aerobic gram-negative bacilli is much less common, but it can occur if infections due to these organisms result in hematogenous seeding, if nosocomial contiguous osteomyelitis occurs due to surgical site infection, or if contamination occurs at the time of traumatic open fracture. Polymicrobial infection, including infection due to anaerobes, is very common in osteomyelitis of the bones of the feet associated with diabetes and vascular insufficiency. Coagulase-negative staphylococci can be pathogenic in patients with orthopedic implants.

CLINICAL MANIFESTATIONS

Localized pain over the affected bones is a hallmark of osteomyelitis. A sinus tract or swelling and erythema due to concomitant soft tissue infection or abscess may be present in osteomyelitis due to contiguous infection. Constitutional symptoms, including fever, are present in the minority of cases and more often in hematogenous osteomyelitis. If neurologic structures are involved, neurologic signs and symptoms may be present. Signs and symptoms due to a coexisting infection that has caused hematogenous osteomyelitis may be present as well. The differential diagnosis of osteomyelitis includes diseases that can cause acute and chronic bone pain in adults, including osteoarthritis, metastatic malignancy, fractures, and SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome, as well as postoperative pain and soft tissue infection without concomitant osteomyelitis.

DIAGNOSIS

The WBC is often elevated in hematogenous and acute osteomyelitis. Serum inflammatory markers such as the sedimentation rate and C-reactive protein are often abnormal, particularly in cases of hematogenous infection, but may be normal in chronic contiguous osteomyelitis. Blood cultures are positive in 25 to 50% of cases of hematogenous infection but are almost always negative in chronic osteomyelitis unless concomitant soft tissue infection is present. In the setting of chronic contiguous osteomyelitis, plain radiographs often show specific abnormalities; in vertebral osteomyelitis, they are often not helpful in confirming the diagnosis of infection.

The ability to percutaneously probe or palpate bone with a probe is a simple, effective diagnostic test in patients with diabetes mellitus and possible contiguous osteomyelitis of the feet. In one prospective study, the ability to palpate bone through a contiguous ulcer had a sensitivity of 66% and a specificity of 85% for osteomyelitis.

MRI is the most sensitive and diagnostic imaging technique to identify osteomyelitis, except when orthopedic implants are present. Gallium scans are more sensitive and specific than three-phase technetium (^{99m}Tc) bone scans or indium-labeled leukocyte scans for the diagnosis of vertebral osteomyelitis. Gallium scans are used when spinal hardware is present that degrades the magnetic resonance images and in cases of skull bone osteomyelitis due to malignant external otitis.

Multiple specimens of involved bone, contiguous soft tissue, and purulence should be sent for Gram stain, aerobic and anaerobic culture, and pathologic examination at the time of bone biopsy or surgical débridement. If the history, examination, or imaging is suggestive of atypical infection, culture for fungi and mycobacteria or other unusual organisms should be performed.

TREATMENT

Rx

There are no large randomized studies comparing antimicrobial therapy for osteomyelitis. Antimicrobials for specific pathogens based on in vitro susceptibility testing are recommended, and examples of antimicrobials used to treat common pathogens causing osteomyelitis and septic arthritis are shown in Table 280-2.

The duration of antimicrobial therapy is almost always dictated by surgical therapy in chronic osteomyelitis. For example, if an amputation is performed, a short course of antimicrobial therapy may be required, whereas if an extensive débridement of chronic osteomyelitis is performed, prolonged intravenous antimicrobial therapy for 4 to 6 weeks is typically recommended. If the surgical therapy could lead to a worse outcome than no surgery, chronic oral antimicrobial suppression may be recommended. Acute hematogenous vertebral osteomyelitis in adults is typically treated with 6 weeks of intravenous antimicrobial therapy, without surgical intervention, after identification of the pathogen through percutaneous or open biopsy. Hyperbaric oxygen therapy for chronic osteomyelitis is controversial.

PREVENTION

Improving the control of diabetes and decreasing the incidence of peripheral vascular disease will reduce the incidence of diabetic foot bone infection. Optimal strategies to prevent surgical site infection after orthopedic procedures will prevent orthopedic implant infection after surgery and open fractures.

PROGNOSIS

The success of osteomyelitis management depends on the medical and surgical therapy employed and the ability to improve comorbidities such as arterial insufficiency. The ability of orthopedic surgeons to perform more extensive reconstructive surgery has allowed more extensive débridement and higher success rates, as well as restoration of function. Treatment failure can lead to relapse of infection or progression of infection to involve more of the affected bone. Long-standing osteomyelitis can be complicated by amyloidosis, squamous cell carcinoma of the skin in a chronic sinus tract, or primary bone malignancy.

TABLE 280-2 ANTIMICROBIAL THERAPY FOR SELECTED MICROORGANISMS IN OSTEOMYELITIS OR SEPTIC ARTHRITIS IN ADULTS

MICROORGANISM	FIRST CHOICE*	ALTERNATIVE CHOICE
Methicillin/oxacillin/nafcillin–sensitive staphylococci	Nafcillin sodium or oxacillin sodium 1.5–2 g IV q4–6h for 4–6 wk *or* cefazolin 1–2 g IV q8h	Vancomycin 15 mg/kg IV q12h for 4–6 wk
Methicillin/oxacillin/nafcillin–resistant staphylococci (MRSA)	Vancomycin† 15 mg/kg IV q12h *or* daptomycin 6 mg/kg IV q24h	Linezolid 600 mg PO/IV q12h *or* levofloxacin† 500–750 mg PO/IV daily
Penicillin-sensitive streptococci	Aqueous penicillin G 20 × 10^6 U/24 hr IV either continuously or in 6 equally divided daily doses *or* ceftriaxone 1–2 g IV q24h *or* cefazolin 1–2 g IV q8h	Vancomycin 15 mg/kg IV q12h
Enterococci	Aqueous crystalline penicillin G 20 × 10^6 U/24 hr IV either continuously or in 6 equally divided daily doses *or* ampicillin sodium 12 g/24 hr IV either continuously or in 6 equally divided daily doses; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1–2 wk is *optional*	Vancomycin† 15 mg/kg IV q12h; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1–2 wk is *optional*
Enterobacteriaceae	Ceftriaxone 1–2 g IV q24h	Ciprofloxacin† 500–750 mg PO q12h
Pseudomonas aeruginosa	Cefepime 2 g IV q12h	Ciprofloxacin† 750 mg PO q12h *or* ceftazidime 2 g IV q8h

*Antimicrobial selection should be based on in vitro sensitivity data, as well as allergies, intolerances, and drug interactions in individual patients.
†Doses shown are based on normal renal and hepatic function and may need to be adjusted or serum levels monitored (vancomycin).
MRSA = methicillin-resistant *Staphylococcus aureus.*

281 CRYSTAL DEPOSITION DISEASES

N. LAWRENCE EDWARDS

The pro-inflammatory and destructive characteristics of intrasynovial crystals have been recognized for over a century. The mechanisms of crystal-induced inflammation and joint destruction have become much better clarified over the past several decades. The three most common crystal-induced arthropathies are caused by precipitation of monosodium urate monohydrate (MSU), calcium pyrophosphate dihydrate (CPPD), and basic calcium phosphate (BCP) and are termed *gout, pseudogout,* and *hydroxyapatite arthropathy,* respectively.

GOUT AND HYPERURICEMIA

DEFINITION

Gout is an inflammatory arthritis of metabolic origin that is caused by crystallization of MSU within joints. It is the most common inflammatory joint disease in men and older women. Its incidence and prevalence are increasing markedly worldwide. The metabolic derangement responsible for gout is the supersaturation of blood and body fluids with the urate ion to the point that crystal formation is possible. At physiologic pH and at normal body temperature, urate is considered to be supersaturated at concentrations of 6.8 mg/dL or greater. Therefore, from a biologic perspective, hyperuricemia is defined as any serum urate level greater than 6.8 mg/dL in both men and women. Although hyperuricemia is a prerequisite for developing gout, only a small percentage (15 to 25%) of all hyperuricemic subjects ultimately develop gout.

Gout is a progressive arthritis that begins as an intermittent mono- or oligoarthritis in the lower extremities and can progress over years to decades into a chronic, destructive, and debilitating polyarthritis involving almost any peripheral joint in the body. Also considered within the definition of gout is the spectrum of clinical conditions resulting from the deposition of MSU crystals in the subcutaneous tissues and kidney manifesting as tophaceous deposits, inflammatory cellulitis, urate nephropathy, and kidney stones.

EPIDEMIOLOGY

An elevation of serum urate that is sustained over a prolonged period is the primary risk factor for the development of gout. Hyperuricemia is very common in Western culture, with a prevalence as high as 15 to 20% reported in some recent population-based studies. This rate of hyperuricemia is more than twice that observed just 3 decades ago. A number of factors have been proposed to explain this dramatic rise, including the overall increase in longevity; the greater prevalence of hypertension, metabolic syndrome, and obesity; the ubiquitous use of thiazide diuretics and low-dose aspirin; changes in dietary trends, including the greater use of high-fructose corn syrup as a sweetener; and the increased survival of patients with end-stage renal disease and recipients of organ transplants.

There is a direct correlation between the degree of serum urate elevation and the likelihood of developing gout. The reported annual incidence of gout in subjects with baseline serum urate levels of 9 mg/dL or greater is 4.9%, compared with only 0.5% for those with serum urate levels of 7.0 to 8.9 mg/dL.

Multiple studies have reported that men are three to six times more likely to develop gout than women, and age has a decided impact on the prevalence of gout (Fig. 281-1). Overall, the prevalence of gout in the United States has been estimated at 13.6 per 1000 adult men and 6.4 per 1000 adult women. This prevalence varies from country to country; there is also marked variation within countries, depending on sociodemographic factors other than gender and age. In New Zealand, for example, the prevalence of gout among Maori men is 2.4 times higher than in men of European ancestry.

PATHOBIOLOGY

Uric acid is the end product of purine metabolism in humans. In most mammals, purine catabolism is taken one step further via the enzyme uric acid oxidase or uricase, with the purine end product in these species being the very soluble allantoin. Humans and most other hominoids lost the ability to produce the enzyme uricase nearly 18 million years ago. As a result, uric acid accumulation is possible. Whether caused by overproduction of uric acid or underexcretion by the kidneys (Table 281-1), this accumulation leads to the supersaturation of urate ion in blood and the precipitation of MSU crystals in synovial fluid, soft tissues, and organs. Urate is produced by the conversion of a very soluble molecule, hypoxanthine, to the less soluble xanthine, which in turn is converted to the very insoluble uric acid by progressive purine ring oxidations catalyzed by the enzyme xanthine oxidase. Xanthine oxidase is present in several organs, but most activity occurs in the liver and intestines. Because of its potential for causing disease, urate elimination is very important. The total daily accumulation of uric acid from de novo synthesis, nucleotide degradation, and dietary consumption is between 800 and 1200 mg/day and is balanced by the renal excretion of approximately two thirds of the total amount and intestinal elimination of the remaining one third.

Simply put, hyperuricemia occurs when urate production is not balanced by renal excretion. In 90% of all gout patients, the cause of this imbalance is renal underexcretion. The remaining 10% of gout cases are caused by purine overproduction or a combination of overproduction and underexcretion.

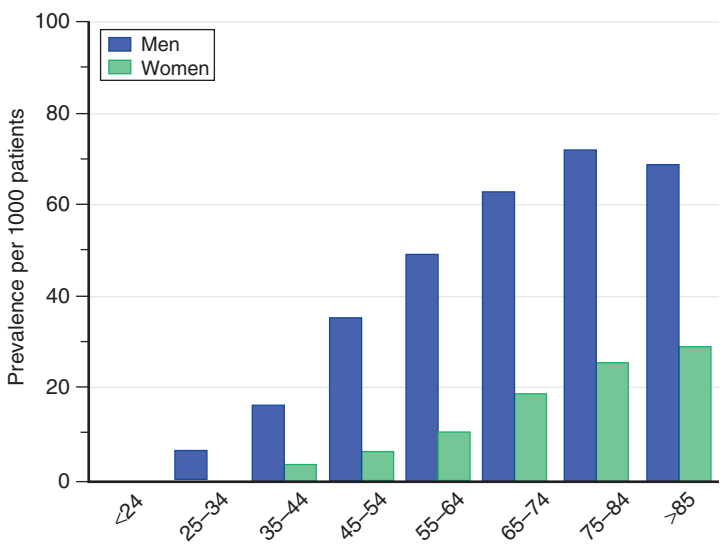

FIGURE 281-1. Prevalence of gout in men and women of different age groups. The overall prevalence in this 1999 study from the United Kingdom was 1.4%, and the male-female ratio was 3.6:1. The prevalence in women continues to rise with age, whereas the prevalence in men appears to peak in the 75 to 84 age group.

Renal Urate Underexcretion

The underexcretion of urate by the kidney may be caused by genetic factors (primary hyperuricemia), by clinical renal disorders (renal insufficiency or diminished glomerular filtration), by endogenous organic acid accumulation (lactate, β-hydroxybutyrate, acetoacetate), or by exogenous substances (low-dose aspirin, thiazides, β-blockers, cyclosporine, tacrolimus).

Because uric acid is small and not protein bound, it is completely filtered by the glomerulus. In normal persons, approximately 8 to 10% of the filtered load is ultimately cleared in the urine. The various renal tubular transporters responsible for determining how much of the filtered uric acid is actually excreted are located in the proximal convoluted tubules (Fig. 281-2). Both reabsorption and secretion occur in this segment through the actions of several organic acid transporters (OATs), with the net effect being the reabsorption of nearly 90% of the uric acid filtered at the glomerulus. These OATs are also responsible for eliminating organic acids other than uric acid, as well as many commonly used medications. The most important tubular transporter for handling uric acid is urate transporter 1 (URAT1). This transporter swaps urate ions for other monocarboxylate organic ions in both directions across the luminal membrane of proximal tubular cells. This system can be driven to reabsorb more uric acid from the tubular lumen by raising the tubular intracellular concentration of lactate, pyruvate, or the ketoacids acetoacetate and β-hydroxybutyrate. Certain drugs, when present in the tubular lumen, can displace uric acid from the transporter, causing more uric acid to be lost in the urine. These compounds, which include probenecid, losartan, and high-dose aspirin, are considered uricosuric.

TABLE 281-1 CLASSIFICATION OF HYPERURICEMIA AND GOUT

IMPAIRED URIC ACID EXCRETION
Primary gout with decreased uric acid clearance
Secondary gout
Clinical conditions
Reduced GFR
Hypertension
Obesity
Systemic acidosis
Familial juvenile hyperuricemic nephropathy
Medullary cystic kidney disease
Lead nephropathy
Drugs
Diuretics
Ethanol
Low-dose salicylates (0.3-3.0 g/day)
Cyclosporine
Tacrolimus
Levodopa
EXCESSIVE URATE PRODUCTION
Primary metabolic disorders
HPRT deficiency
PRPP synthetase overactivity
Glucose-6-phosphatase deficiency
Fructose-1-phosphate aldolase deficiency
Secondary causes
Clinical conditions
Myelo- and lymphoproliferative disorders
Obesity
Psoriasis
Glycogenoses III, V, VII
Drugs and dietary components
Nicotinic acid
Pancreatic extract
Cytotoxic drugs
Red meat, organ meat, shellfish
Alcoholic beverages (especially beer)
Fructose

GFR = glomerular filtration rate; HPRT = hypoxanthine-guanine phosphoribosyltransferase; PRPP = phosphoribosylpyrophosphate.

When the renal clearance of uric acid by normal adult men and gouty men is compared, the gouty subjects excrete only 70% as much uric acid as normal individuals at any given serum urate concentration. In general, gouty subjects require a serum urate concentration 1.7 mg/dL higher to obtain the same level of excretion seen in normals. This is apparently not related to a difference in the transport kinetics of the URAT1 protein in gouty subjects versus normal individuals but rather to the relative abundance of these transporters in the proximal convoluted tubule.

Hyperuricemia is also associated with type 2 diabetes mellitus (Chapter 237) in the fully expanded metabolic syndrome. Elevated insulin levels, like those seen in insulin-resistant states, stimulate the sodium-hydrogen exchanger, ultimately leading to increased reabsorption of sodium in certain organic acids, including uric acid.

Urate Overproduction

In approximately 10% of gouty subjects, hyperuricemia is caused by uric acid overproduction rather than reduced renal excretion. In most of these people, the hyperuricemia reflects accelerated cell turnover (e.g., lymphoproliferative and myeloproliferative diseases, psoriasis, chronic hemolytic states, and certain muscle glycogenoses) or other causes of enhanced purine nucleotide breakdown, such as that seen with alcohol abuse or fructose ingestion. In addition to these secondary causes of urate overproduction, some primary disease processes are responsible for urate overproduction. These are inborn errors of metabolism that result in increased de novo purine synthesis, as seen in phosphoribosylpyrophosphate synthetase overactivity, or decreased purine salvage, as seen in hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome). Regardless of the cause, urate overproduction is determined by a 24-hour urine collection showing greater than 1000 mg of uric acid while eating a standard Western diet.

Pathogenesis of MSU Crystals and Inflammation

MSU crystals in joints, soft tissues, and organs are the cause of pain and destruction in gout. Urate crystals form only when physiologic conditions permit. In plasma, urate becomes insoluble at concentrations of 6.8 mg/dL (408 µmol/L), with a pH of 7.40 and normal body temperature. A reduction in pH or temperature lowers the solubility threshold further. Not all people who are hyperuricemic form crystals. There appears to be an additional requirement of a "nucleation factor" that is still poorly defined for gout, along with other local factors that either promote or inhibit crystal growth.

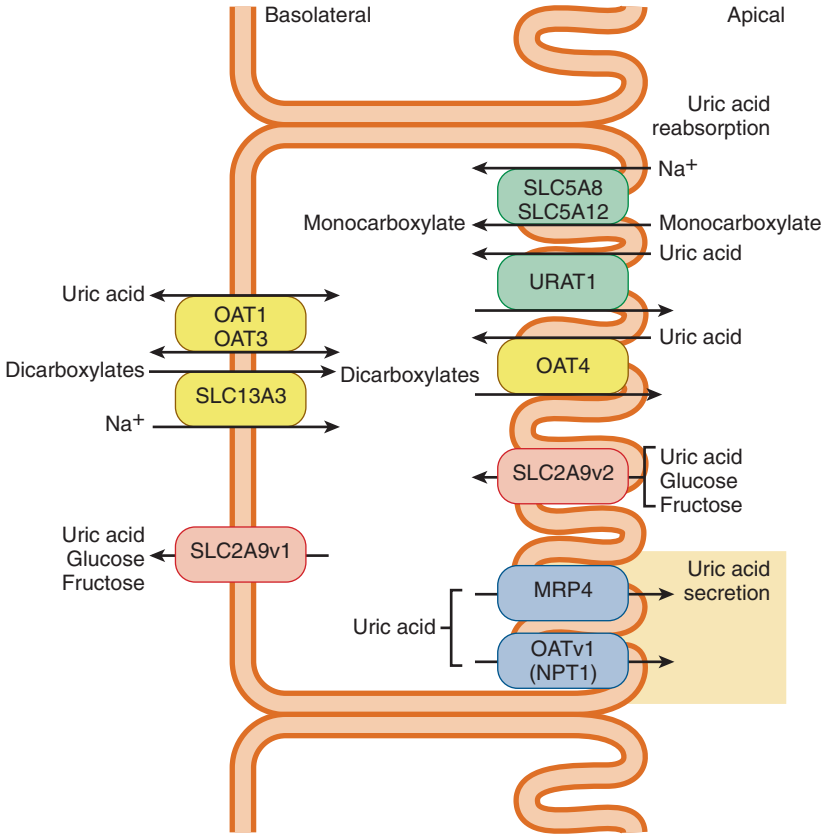

FIGURE 281-2. Urate transport in the proximal convoluted tubule. The proximal convoluted tubule is the major site of urate handling in the kidney. Urate reabsorption and secretion occur through the actions of a series of organic acid transporters (OATs; gene family *SLC22A*) that are linked directly to organic acid movement and indirectly to sodium reabsorption. The OATs are critical in the renal excretion of drugs and their metabolites. The predominant urate reuptake transporter in this system is URAT1 *(SLC22A-12)*, which is located on the luminal (apical) side of the tubular epithelium. Polymorphisms in this gene can lead to urate retention and have been reported in German families. A URAT1 mutation in a Japanese cohort appears to increase uric acid excretion by the kidney. The *SLC2A9* glucose-fructose transporter (GLUT-9) is also a urate transporter, and polymorphisms in this gene are associated with gout.

MSU crystals form in joints and soft tissues of individuals long before they have any symptoms of gout. They deposit in small lattice structures called *microtophi* on the surface of cartilage and in the synovial lining. These microtophi grow slowly but are generally stable as long as the surrounding environment does not change drastically with regard to pH, urate concentration, or temperature. At the time of the first and subsequent clinical flares, something changes in the joint environment to cause these crystal lattice structures to break apart and shed a massive number of crystals into the joint space. These newly released and nonopsonized crystals activate receptors on synovial macrophages; they are then phagocytized by monocytes and macrophages, leading to interaction with the NALP3 inflammasome. This results in the rapid production of interleukin-1 (IL-1), which is responsible for all the cardinal features of severe inflammation associated with acute gout. The gout flare is self-limited, probably caused by a physical change in the MSU crystals after they have been repeatedly phagocytized and partially digested. A maturation of the resident monocytes in the inflamed joint also appears to help terminate the gouty flare. Even after the acute attack subsides, low-grade inflammation persists in the asymptomatic joint. It is this persistent, ongoing inflammatory process that eventually leads to bony erosion, cartilage destruction, and synovial hypertrophy if the hyperuricemia is not treated and the MSU crystals dissolved.

CLINICAL MANIFESTATIONS

Classic Gout

The natural course of classic gout passes through three stages: asymptomatic hyperuricemia, acute intermittent gout, and chronic advanced gout. The rate of progression from asymptomatic hyperuricemia to chronic advanced gout varies considerably from one person to another and is dependent on numerous factors, the most important being the degree of increase in serum urate levels.

Asymptomatic hyperuricemia refers to a state in which serum urate exceeds the level of solubility (6.8 mg/dL) but symptoms of crystalline deposition have not occurred. Only 15 to 20% of all hyperuricemic people are prone to develop MSU crystals, and for this group, the period of asymptomatic hyperuricemia begins a stage of subclinical structural changes**.** In men, asymptomatic hyperuricemia frequently begins at puberty, whereas in women, it is usually delayed until menopause.

The initial episode of acute gout usually follows decades of asymptomatic hyperuricemia. In men, the first attack usually occurs between the fourth and sixth decades of life. In women, the age of onset is older and varies with several factors, the most important being the age at menopause. The classic acute gout attack is characterized by the rapid development of warmth, swelling, erythema, and exquisite pain in one or occasionally two joints. The characteristically severe pain evolves from its faintest twinge to its most intense level over an 8- to 12-hour period. Initial attacks are usually monoarticular and involve lower extremity joints. The most common joint involved is the first metatarsophalangeal joint (termed *podagra*), followed by the ankle, midfoot, and knee (Fig. 281-3). After years of acute intermittent attacks, upper extremity joints, including the wrists, elbows, and small joints of the hands, can also become involved. Systemic symptoms of fever, chills, and malaise may accompany acute attacks, along with an intense erythema extending beyond the area of the involved joint. This may lead to confusion with a septic process.

Factors capable of provoking episodes of acute gout are those that cause fluctuations in serum urate levels, including trauma, surgery, starvation, overindulgence in certain high-purine foods, and the ingestion of any medication that raises or lowers serum urate.

The other characteristic of classic gout flares is the self-remitting nature. For the first several acute flares, the duration of the attack is 5 to 8 days. The resolution of symptoms is gradual but complete, even if no anti-inflammatory therapy is administered. The periods between acute attacks are devoid of articular pain, although synovial fluid aspirates during this stage continue to show low-grade inflammation and the presence of MSU crystals.

Eventually the untreated patient progresses to chronic polyarticular gout, also referred to as *advanced gout*. This stage usually develops after 10 or more years of acute intermittent gout and is evident when the pain-free intercritical periods have disappeared. Gouty flares can continue to occur against this constantly painful background. The intensity of the chronic pain is not nearly as severe as that experienced with acute flares.

The subcutaneous tophus is the most characteristic lesion of advanced gout. The development of tophaceous deposits of MSU is a function of the duration and severity of hyperuricemia. Subcutaneous tophi can occur anywhere in the body but are most common in the fingers, wrists, ears, knees, and olecranon bursa and at pressure points under the ulnar aspect of the forearm and at the Achilles tendon (Fig. 281-4). Gout at this stage can be confused with rheumatoid arthritis, especially if tophi are confused with rheumatoid nodules.

Atypical Gout Presentations

Approximately 5% of patients with gout experience the onset of symptoms before age 25. These individuals with early-onset gout represent a special subset that generally has a genetic component (see Table 281-1). They have a more accelerated clinical course and require more aggressive antihyperuricemic therapy.

Gout develops in approximately 15% of heart transplant patients taking cyclosporine to prevent allograft rejection. A slightly lower frequency of gout is seen in kidney and liver transplant recipients. Cyclosporine-induced gout has a marked shortening of the asymptomatic and acute intermittent stages, with a rapid appearance of tophi in 1 to 4 years.

In most large reviews, women account for no more than 5% of all gout subjects. This demographic is changing as gout is becoming more common in older women. Most women with gout are postmenopausal. Women with premenopausal gout usually have renal insufficiency, are taking thiazide diuretics for hypertension, or have a strong genetic predilection. Gout in older women may differ from classic gout in its propensity to occur in joints previously damaged by osteoarthritis (Chapter 270), such as the knees or the distal interphalangeal joints with Heberden's nodes.

Saturnine gout is the term used to describe gout caused by chronic lead exposure (Chapter 21). In the middle of the 20th century, this was most commonly observed in consumers of "moonshine" whiskey. Occupational exposure in plumbers and environmental exposure from lead-based paints are other potential causes of this unusual form of gout.

DIAGNOSIS

Hyperuricemia is a critical risk factor for developing gout, but it is not a reliable diagnostic test because many people with elevated serum urate levels never develop gout. Serum urate levels during an acute flare of gout are also

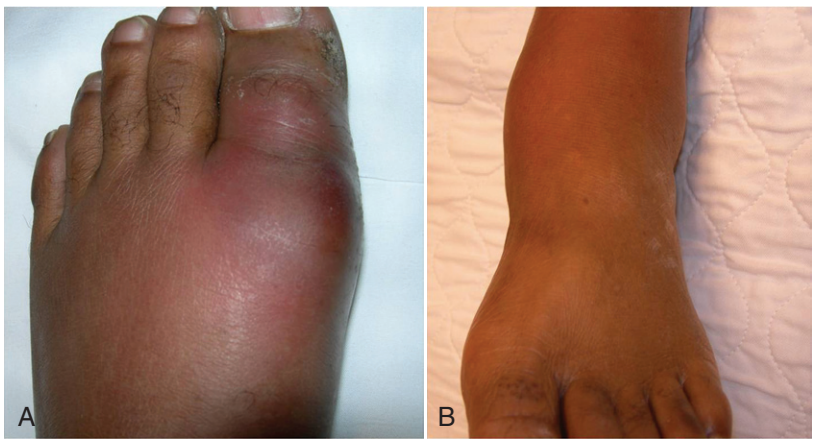

FIGURE 281-3. The intense inflammation of acute gouty arthritis. A, Marked swelling of the first metatarsophalangeal joint (podagra) is demonstrated. A dusky blue hue over an intense erythema is characteristic. **B, A**nkle swelling with erythema extending beyond the area of the tibiotalar joint.

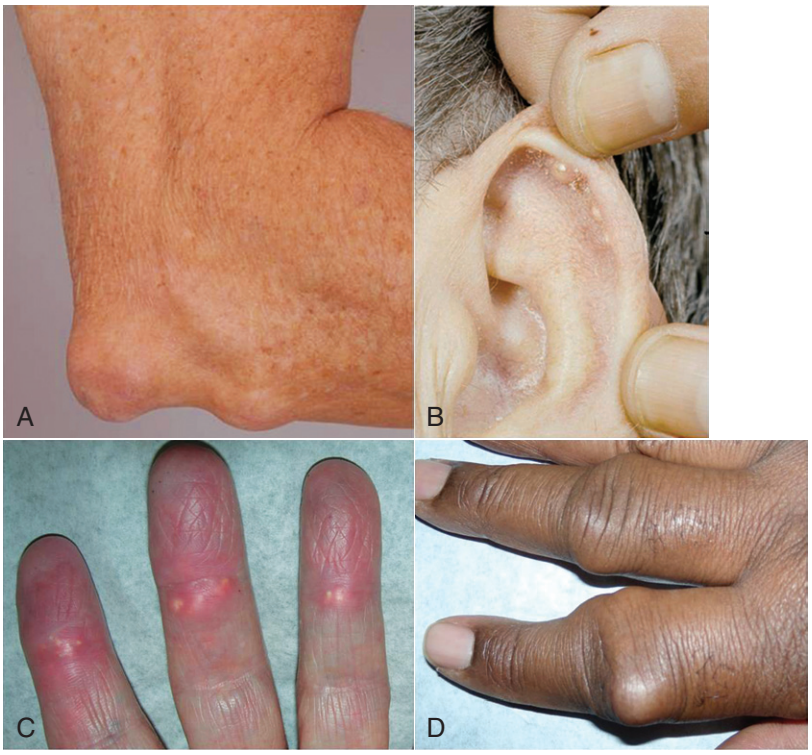

FIGURE 281-4. Characteristic locations of gouty tophi. A, At the elbow, tophi present as hard nodules along the ulnar ridge or as multiple nodules within the olecranon bursa. **B,** Ear tophi are uncommon but may be an easy source of crystal confirmation when present. **C,** Small subcutaneous tophi can occur along the ventral creases of fingers. **D,** Tophi over the proximal interphalangeal or distal interphalangeal joints may be confused with Bouchard's or Heberden's nodes, respectively.

unreliable because they may be suppressed by as much as 1.5 to 2.0 mg/dL from baseline values. The definitive diagnosis of gout is made by polarized compensated microscopy of a synovial fluid aspirate from the affected joint. The presence of intracellular needle-shaped crystals with strong negative birefringence is the diagnostic "gold standard" (Fig. 281-5). Similar microscopic results from a tophus aspirate or spontaneously draining fluid also confirm the diagnosis of gout.

Synovial fluid confirmation is obtained in as few as 10% of patients with gout. The presumptive diagnosis of gout is based on a pattern of acute joint symptoms coupled with the patient's own medical history or a family history. The patient's medical history may reveal comorbidities frequently associated with gout or the use of medications associated with urate retention.

The characteristic clinical presentation is the rapid onset (over 8 to 12 hours) of severe pain in one or several lower extremity joints (especially the great toe, midfoot, or ankle). The presumptive diagnosis has much greater credence if there have been similar previous attacks that spontaneously resolved to a symptom-free state.

Radiographic evaluation is not helpful in early attacks of gout, except to rule out fracture. In advanced gout, affected joints may show punched out periarticular erosions with classic overhanging edges. Ultrasonography can detect MSU crystals layered over articular cartilage in early disease and may be diagnostic. Magnetic resonance imaging is not part of the standard evaluation, but it can reveal soft tissue and intra-articular tophi long before they become clinically evident.

The differential diagnosis of acute gout includes bacterial infection, trauma, sarcoidosis, and CPPD arthropathy (pseudogout). Diseases occasionally confused with advanced gout include rheumatoid arthritis, reactive arthritis, and CPPD arthropathy.

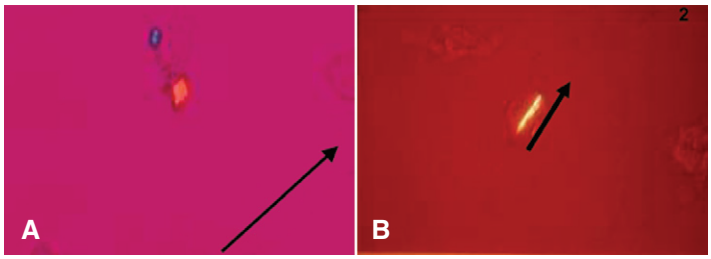

FIGURE 281-5. Comparison of calcium pyrophosphate dihydrate (CPPD) crystals (A) and monosodium urate crystals (B) by means of compensated polarized light microscopy of synovial fluid. Both crystal types are found within leukocytes, and both can be extracellular, as shown here for CPPD crystals. CPPD crystals are weakly birefringent and are more variable in shape, with rhomboid, square, or rod-like structures that can resemble urate crystals. Urate crystals are uniformly needle shaped and more brightly birefringent than are CPPD crystals. The arrows indicate the axis of slow rotation of light of the first-order red plate compensator used in compensated polarized light microscopy. Urate crystals are negatively birefringent (i.e., yellow when the long axis of the crystal is parallel to the red plate compensator axis, and blue when the long axis of the crystal is perpendicular to the compensator axis). CPPD crystals are positively birefringent (i.e., blue when the long axis of the crystal is parallel to the axis of slow rotation of the red plate compensator, and yellow when the long axis of the crystal is perpendicular to the axis of the compensator), as seen for the two CPPD crystals in **A**. These findings indicate the need to use compensated polarized light microscopy to both identify urate and CPPD crystals and to accurately distinguish between these crystal types. (**A**, Available at http://www.emedicine.com/med/topic1938.htm; **B,** ACR Clinical Slide Collection on the Rheumatic Diseases, American College of Rheumatology, 1998.)

TREATMENT AND PREVENTION

Rx

Weight loss, dietary modification to reduce animal-derived purine intake, reduction in alcohol intake, and regular exercise should be encouraged in all patients with gout. Soft drinks sweetened with fructose can increase serum urate levels and should also be restricted. Increased consumption of low-fat dairy products may be recommended for their urate-lowering impact. Such modifications may lower urate levels and help many comorbid conditions associated with gout, but they are rarely sufficient to obviate the need for pharmacologic intervention in acute and chronic gout.■

Acute Gout

The treatment goal for acute gout is to relieve pain and terminate the attack as quickly as possible. Resting the painful joint and applying topical ice are generally helpful, but pharmacologic intervention is usually necessary. The therapeutic options include nonsteroidal anti-inflammatory drugs (NSAIDs), oral colchicine, and corticosteroids. NSAIDs are the most widely used approach, but they may be inappropriate in subjects with renal insufficiency or peptic ulcer disease. Oral colchicine 1.8 mg/24 hours in divided doses for the first several days may also be effective. A recent randomized, double-blind, placebo-controlled study showed that self-administered low-dose colchicine (1.8 mg total over 1 hour) was comparable in efficacy to high-dose colchicine (4.8 mg total over 6 hours) for acute gout flare, and the safety profile of low-dose colchicine was indistinguishable from that of placebo.■ Corticosteroids administered orally, intramuscularly, or intra-articularly are a valuable option in patients with poor renal function or intolerance to colchicine. Issues critical to treatment success are rapid initiation, adequate dosing, and continuation of therapy until the flare has resolved. Anti–IL-1 therapies may also be beneficial in treating acute gout symptoms. During the acute gout flare, subjects already taking urate-lowering therapy should continue the drug; those not receiving this therapy should not be started on it.

Recurrent and Advanced Gout

The goal of therapy in subjects with multiple recurrent gout flares or advanced gout is to prevent disease progression. This is done by lowering serum urate levels to less than 6.0 mg/dL, resulting in the mobilization and depletion of MSU crystals so that recurrent flares are prevented and joint destruction is halted. Urate-lowering therapy is recommended for patients with two or more attacks of gout per year, tophi or urate kidney stones, joint damage, polyarticular attacks, or persistent synovitis. Urate-lowering therapy falls into three categories—uricostatic, uricosuric, and uricolytic agents. Allopurinol and febuxostat are uricostatic drugs, the most widely used approach. Both drugs work by inhibiting the enzyme xanthine oxidase to prevent urate formation. This class of drugs is effective in both overproducers and underexcreters of uric acid. Probenecid is a uricosuric agent that works by increasing the renal excretion of uric acid. This drug is not appropriate for subjects who are urate overproducers because of the risk of nephrolithiasis. Renal function is an issue with allopurinol and probenecid; dose adjustment is recommended if allopurinol is used in patients with chronic kidney disease, and probenecid is generally ineffective in anyone with a creatinine clearance less than 50 mL/minute. Allopurinol causes a rash in about 2% of patients, and allopurinol and febuxostat cause hepatic transaminase elevations in 5%. Allopurinol can also cause a rare (2 to 3 per 1000) but potentially fatal hypersensitivity syndrome that manifests with fever, severe exfoliative rash, eosinophilia, and hepatic and renal failure. All patients taking allopurinol should be cautioned to discontinue this drug at the first sign of rash. Pegloticase is a pegylated recombinant mammalian urate oxidase currently being studied in patients for whom conventional therapy with allopurinol, febuxostat, or probenecid is either ineffective or inadequate. This form of therapy is termed *uricolytic* because it degrades uric acid into a very soluble end product, allantoin. This is an intravenous therapy requiring infusions every 2 weeks.

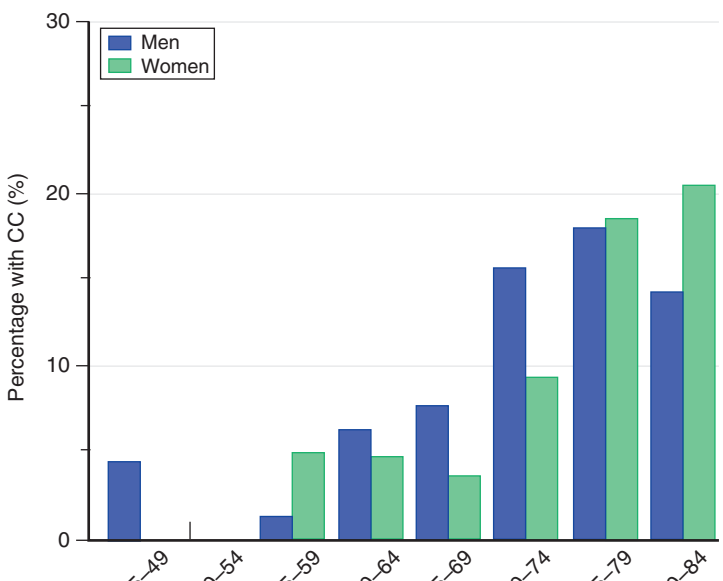

FIGURE 281-6. Prevalence of chondrocalcinosis (CC) in men and women of different age groups. The overall prevalence of chondrocalcinosis in this study from the United Kingdom was 7%. The strong association of age and gender with chondrocalcinosis of the knee is demonstrated. Fibrocartilage (meniscal) was affected in 95% of cases, and hyaline (articular) cartilage in 45%. Chondrocalcinosis was observed bilaterally in the knees in 72% of cases and in both medial and lateral knee compartments in 38%.

CPPD DEPOSITION DISEASE

DEFINITION

The heterogeneous group of clinical conditions associated with CPPD crystals is collectively called *CPPD deposition disease*. Within this spectrum is the common radiographic finding of chondrocalcinosis, which is frequently asymptomatic. The acute synovitis associated with intra-articular CPPD crystals can closely mimic the findings of gout and is thus referred to as *pseudogout*. The more chronic changes associated with CPPD-induced bone and cartilage destruction is referred to as *pyrophosphate arthropathy*. These conditions are further classified as familial (genetic), metabolic, and sporadic.

EPIDEMIOLOGY

The true prevalence of CPPD deposition disease is unknown, but it is generally thought to be underdiagnosed because of its confusion with other forms of arthritis. The prevalence of radiographic chondrocalcinosis has been studied extensively and is clearly an age-related phenomenon (Fig. 281-6). Chondrocalcinosis of the meniscal and articular cartilage of the knee is seen in 4% of people between the ages of 55 and 59, in 18% of those aged 80 to 84 years, and in approximately 27% of those older than 85.

PATHOBIOLOGY

Clinical CPPD deposition disease is divided into three categories, based on the cause of the altered inorganic pyrophosphate (PPi) metabolism: hereditary (familial), sporadic (idiopathic), and metabolic. All three types are associated with extracellular PPi accumulation around chondrocytes, and extracellular PPi is necessary for the formation of CPPD crystals. Intracellular PPi is a common byproduct of many synthetic reactions, and if it is allowed to accumulate intracellularly, it impedes the further synthesis of proteins, nucleotides, and lipids. Therefore, there are multiple mechanisms for removing PPi from the cellular cytoplasm, including specific and nonspecific membrane transporters in both intracellular and extracellular (ecto-) pyrophosphate hydrolysis.

Hereditary forms of CPPD deposition disease may be caused by increased transmembrane transport of chondrocyte intracellular PPi to its extracellular matrix owing to diminished activity of the protective pyrophosphate hydrolases, or because of altered influences of factors that lead to increased extracellular PPi, including transforming growth factor-β, bone morphogenetic proteins 2 and 4, ascorbic acid, and osteopontin. The best characterized of the hereditary causes is a gain-of-function mutation of the *ANK* anion transporter gene on the chondrocyte plasma membrane. These types of mutations are rarely observed in the sporadic form of CPPD disease. Aging chondrocytes in culture produce considerably more PPi than do younger chondrocytes, although the exact mechanism for this is unclear.

The metabolic diseases that predispose to CPPD deposition disease include hemochromatosis (Chapter 219), hyperparathyroidism (Chapter 253), hypomagnesemia (as in Gitelman's syndrome; Chapter 130), and hypophosphatasia (Chapter 121). All these metabolic conditions result in increased concentrations of extracellular PPi or in other alterations in the cartilage matrix that permit CCPD crystal formation.

CLINICAL MANIFESTATIONS

CPPD deposition disease can present in a variety of ways. It is frequently asymptomatic (lanthanic) and is recognized only by the appearance of chondrocalcinosis on radiographs. The most common clinical manifestation, accounting for approximately 60% of cases of CPPD disease, is a polyarticular, noninflammatory arthritis affecting joints not typically involved in primary osteoarthritis, including the wrists, shoulders, and metacarpophalangeal joints (particularly the second and third). This form of CPPD disease is called *pseudo-osteoarthritis,* and it may lead to occasional inflammatory attacks. The acute monoarticular presentation is known as *pseudogout*. The pain and swelling of pseudogout can be similar to that seen in gout; however, the onset is usually not as abrupt as in gout, and the attacks tend to last longer—frequently months. Pseudogout occurs more often in the large joints than in small joints. CPPD deposition disease occasionally presents as a chronic polyarticular inflammatory disease that may mimic rheumatoid arthritis or polymyalgia rheumatica.

DIAGNOSIS

CPPD disease is diagnosed by identifying chondrocalcinosis by radiography in a patient with a clinical history suggestive of the disease (Fig. 281-7). The diagnosis should be confirmed by aspiration of synovial fluid and examination for CPPD crystals by compensated polarized light microscopy (see Fig. 281-5).

TREATMENT AND PREVENTION

Rx

There are no specific therapies for CPPD deposition disease. In patients with CPPD disease associated with a metabolic disease, treatment and control of the metabolic disease can afford some improvement in the arthritis. For both acute and chronic forms of CPPD deposition disease, therapy is directed at symptoms. NSAIDs are the mainstay of treatment. Low-dose oral colchicine can be used in both acute and chronic settings. Intra-articular steroids have also proved to be beneficial for symptomatic CPPD deposition disease. However, intra-articular viscosupplementation (hyaluronic acid) may exacerbate joint symptoms.

FIGURE 281-7. CPPD arthropathy of the hand. Chondrocalcinosis of the triangular fibrocartilage of the wrist is demonstrated by the *large arrow*. Joint space narrowing, subchondral cysts, and large palmar (parrot-beak) osteophytes of the second and third metacarpophalangeal joints *(arrowheads)* are also characteristic of CPPD hand involvement. (From Jacobson JA, Girish G, Jiang Y, Sabb BJ. Radiographic evaluation of arthritis: degenerative joint disease and variations. *Radiology.* 2008;248:737-747.)

FIGURE 281-8. Diffuse idiopathic skeletal hyperostosis (DISH) in the lumbar spine. Thick, flowing anterior osteophytes at multiple levels in the thoracic and lumbar spine are characteristic of DISH. (From Nakhoda K. eMedicine Radiology. Medscape. Updated Aug. 17, 2009.)

APATITE-ASSOCIATED (BASIC CALCIUM PHOSPHATE) ARTHROPATHY

BCP crystals include several different crystal species. The most common of these is hydroxyapatite. The BCP crystals are unlike MSU or CPPD crystals, in that they are not identifiable by polarized microscopy. These very tiny crystals are responsible for several important clinical conditions. Although BCP crystals are found in 50% of osteoarthritic synovial fluids, the incidence and prevalence of the individual apatite-associated clinical manifestations have not been established. This is especially true of the most severe and destructive apatite syndromes, such as Milwaukee shoulder and tumoral calcinosis. The prevalence of the most common apatite-associated condition, calcific periarthritis of the shoulder, was 3% in a large North American study.

PATHOBIOLOGY

Like MSU and CPPD crystals, BCP crystals exert their pro-inflammatory effects by being phagocytized by resident synoviocytes and influxing leukocytes. Unlike MSU and CPPD crystals, apatite crystals apparently do not act through the NALP3 inflammasome. Rather, BCP crystals are dissolved in the acidic phagosome, raise intracellular calcium levels, and then activate the calcium-dependent signaling pathways. The synoviocytes are stimulated by these pathways to increase the production of tumor necrosis factor-α and IL-6, and influxing neutrophils are stimulated to increase pro-inflammatory oxygen radicals. The fibroblasts in the joint lining and surrounding soft tissues are stimulated to increase the production of many of the matrix metalloproteinases, such as collagenase 1, collagenase 3, and stromolysin 1.

CLINICAL MANIFESTATIONS

The clinical manifestations of BCP deposition can be acute or chronic, idiopathic, hereditary, or secondary to other diseases that cause hypercalcemia (Table 281-2). BCP crystals can be found in 50% of synovial fluids from osteoarthritic knees. The presence of BCP crystals correlates with more severe radiographic changes secondary to more rapid deterioration in these osteoarthritic knees. Acute inflammatory arthritis associated with BCP deposition is similar in many ways to that of gout and pseudogout and has been referred to as *pseudo-pseudogout*. The patients tend to be younger and usually have evidence of soft tissue BCP deposition elsewhere in the body. Periarticular calcifications are often asymptomatic. However, BCP deposition can cause an acute and severe inflammation of the ligaments, tendons, and bursae surrounding a joint, termed *acute calcific periarthritis*. This frequently occurs around the shoulders and hips but can also occur in fingers, toes, wrists, and ankles.

TABLE 281-2 CLINICAL MANIFESTATIONS OF BCP DEPOSITION DISEASE

Osteoarthritis and BCP deposition
Acute inflammatory arthritis
Acute calcific periarthritis
Chronic noninflammatory arthropathy
Diffuse idiopathic skeletal hyperostosis (DISH)
Tumoral calcinosis
Calcifications associated with hypercalcemic states
Hyperparathyroidism
Hypervitaminosis D
Sarcoidosis
Metastatic cancer
Myeloma
Leukemia

BCP = basic calcium phosphate.

The most destructive BCP-associated arthropathy is Milwaukee shoulder, which is characterized by large noninflammatory effusions containing BCP crystals with or without CPPD crystals. The process results in destruction of the rotator cuff, leading to marked instability and glenohumeral cartilage dissolution. This process can also affect the knees. Like acute calcific periarthritis, Milwaukee shoulder is observed four times more frequently in women than in men.

Diffuse idiopathic skeletal hyperostosis (DISH) predominates in men and the elderly. The radiographic appearance of this condition is flowing ossifications along the anterolateral aspect of spinal vertebrae, especially in the thoracic spine (Fig. 281-8). DISH is usually asymptomatic, but very large bridging osteophytes can cause pain and, in the cervical spine, can even result in dysphagia.

Idiopathic tumoral calcinosis is a rare disease most prevalent in young people of African descent. These patients have large, irregular calcifying masses in the soft tissues surrounding the shoulders, hips, and elbows. Some cases exhibit a familial occurrence and medical conditions associated with hyperphosphatemia.

Finally, metastatic calcifications can arise in any medical condition associated with hypercalcemia (Chapter 253), including hyperparathyroidism, hypervitaminosis D, sarcoidosis, metastatic cancer, myeloma, and leukemia.

TREATMENT AND PREVENTION

Rx

The treatment of most BCP-associated syndromes is conservative. For acute inflammatory arthritis and periarthritis, low-dose oral colchicine and NSAIDs are the mainstays of symptomatic therapy. The persistent large effusion seen in Milwaukee shoulder should be serially aspirated to decrease intracapsular pressure. The added effectiveness of corticosteroid injections in this setting is unproved. The calcinosis associated with abnormal calcium and phosphate metabolism is best managed by treating the underlying metabolic process.

282 FIBROMYALGIA AND CHRONIC FATIGUE SYNDROME

ROBERT M. BENNETT

Fibromyalgia (FM) and chronic fatigue syndrome (CFS) are multisymptomatic syndromes defined by the core features of chronic widespread pain and chronic unexplained fatigue, respectively. The 1990 American College of Rheumatology (ACR) classification criteria are universally used to diagnose FM (Table 282-1). The 1994 Centers for Disease Control and Prevention (CDC) criteria are widely used to diagnose CFS (see Table 282-1). According to these definitions, FM and CFS are separate entities, but in practice, there is great overlap, with many patients being given both labels. Myofascial pain is a universal experience that is usually self-limited; when it becomes persistent, it may accentuate and perpetuate the experience of chronic fatigue and FM.

FIBROMYALGIA

EPIDEMIOLOGY

Chronic musculoskeletal pain is commonly encountered in the general population with an estimated prevalence of about 35%. It is subdivided into chronic regional pain, with a prevalence of about 25%, and chronic widespread pain, with a prevalence of about 10%.

FM is considered to be a subset of chronic widespread pain and has a prevalence of about 2% in women and 0.5% in men. There is a steady increase in FM with age, with about 12% of women in their 60s being affected. Chronic musculoskeletal pain is associated with a reduction in overall health status, and FM patients have more impairment than do patients with chronic widespread pain or chronic regional pain. The prevalence of FM in the medical setting is much greater, with about 20 to 30% of rheumatology visits in the United States being made for FM.

PATHOBIOLOGY

There is persuasive evidence that FM pain results from abnormal sensory processing within the central nervous system. This is commonly referred to as *central sensitization* and results from an amplification of peripheral sensory stimuli and a deficit of descending inhibitory control from the midbrain. The magnification of peripheral sensory input is readily visualized as increased activity in somatosensory areas of the brain on magnetic resonance imaging in FM subjects versus healthy controls. Central sensitization is the result of a persistent neuronal hyperexcitability that continues long after the original sensitizing input has waned. The pathophysiology of this phenomenon is based, in part, on temporal summation of neural impulses. This occurs when pain fibers (unmyelinated C) are repetitively stimulated at a rate greater than one impulse every 3 seconds. At a biochemical level, such stimulation results in depolarization of *N*-methyl-D-aspartate (NMDA) receptors, which causes transcriptional changes that affect pain processing. Experimentally, this has been demonstrated in FM patients after repetitive thermal stimulation of the skin and after intramuscular electrical stimulation. Thus, persistent pain input may eventually give rise to central sensitization in some individuals, probably based, in part, on a genetic predisposition.

The frequent development of FM from focal pain states, such as in rheumatoid arthritis, post-traumatic injuries, and endometriosis, is thought to be a result of chronic nociceptive input stimulating central neuroplastic changes. However, the occurrence of FM in relation to persistent psychological stressors and infections cannot be so readily explained by temporal summation. FM developing in these settings is now thought to involve the activation of glial cells by cytokines, chemokines, and other neuronal activators. Several studies have reported elevated blood levels of interleukin-8 and a two- to three-fold increase in cerebrospinal fluid levels of substance P, glutamate, and nerve growth factor in patients with FM.

The descending pain system, originating in the periaqueductal gray nucleus of the midbrain and terminating in the dorsal horn, is important in modulating the transmission of nerve impulses to the brain. Activation of the nuclei in the midbrain involved in this system occurs in response to opioids, endorphins, emotions, and the placebo response. This modulation may upregulate or downregulate sensory processing, and in part, it underlies the influence of the psyche on the pain experience.

Understanding the biologic basis for central sensitization has provided an explanation for the common association of FM with other conditions such as irritable bowel syndrome, overactive bladder, multiple chemical hypersensitivity, and chronic daily headaches. Other common symptoms in FM, such as fatigue and cognitive dysfunction, cannot currently be explained by central sensitization. These symptoms are also common features of CFS, and their pathobiologic basis remains ill defined.

CLINICAL MANIFESTATIONS

Signs and Symptoms

Pain

The core symptom of FM is chronic widespread pain and stiffness. Characteristically, the pain is described as a constant dull ache that is worsened by muscle overactivity. FM-related pain is usually perceived as arising from muscle; however, many patients also report joint pain but have no objective evidence of arthritis.

Fatigue

Easy fatigability from physical exertion, mental exertion, and psychological stressors is typical of FM. Patients with CFS and FM share many similarities; about 75% of patients meeting the diagnostic criteria for CFS also meet the criteria for FM.

Disordered Sleep

FM patients have nonrestorative sleep. Even if they sleep continuously for 8 to 10 hours, they awake feeling tired. Many exhibit an alpha-delta electroencephalographic pattern that explains their failure to achieve restorative stages 3 and 4 of non–rapid eye movement sleep. A poor night's sleep is often followed by a worsening of FM symptoms the next day. Restless leg syndrome and the associated periodic limb movement disorder occur in up to 60% of FM patients.

Cognitive Dysfunction

Cognitive dysfunction is a prominent complaint of many FM patients. They commonly describe difficulties with working memory, semantic memory, concentration, logical analysis, and motivation. It has been estimated that the working memory deficit in FM is comparable to 20 years of aging. Recent studies have documented that these neurocognitive deficits correlate

TABLE 282-1 COMPARISON OF CLASSIFICATION CRITERIA FOR FIBROMYALGIA AND CHRONIC FATIGUE SYNDROME

	FIBROMYALGIA	CHRONIC FATIGUE SYNDROME
Primary symptom	Persistent, unexplained, widespread pain of ≥3 mo duration (*Widespread* is defined as pain in ≥3 quadrants of the body plus pain in an axial distribution, such as the neck, front of the chest, thoracic spine, or low back.)	Unexplained persistent or relapsing chronic fatigue of new or definite onset (not lifelong) that is not the result of ongoing exertion; is not substantially alleviated by rest; and results in a substantial reduction in previous levels of occupational, educational, social, or personal activities
Secondary features	None	Concurrent occurrence of 4 or more of the following symptoms, all of which must have persisted or recurred during 6 or more consecutive months of illness and must not have predated the fatigue: Sore throat Tender cervical or axillary lymph nodes Muscle pain Multijoint pain without swelling or redness Headaches of a new type, pattern, or severity Nonrefreshing sleep Postexertional malaise lasting >24 hr
Physical examination	The finding of ≥11 of 18 designated tender points examined at a palpation pressure of 4 kg	None
Exclusionary diagnoses	None	Any active medical condition that might explain the presence of chronic fatigue Any previous condition that might explain fatigue and is still ongoing Any past or current diagnosis of a major depressive disorder with psychotic or melancholic features, bipolar affective disorders, schizophrenia disorders, delusional disorders, dementias, anorexia nervosa, bulimia, or substance abuse within 2 yr before onset, or morbid obesity

with local brain morphology in the frontal lobe and anterior cingulate gyrus.

Psychological Distress

Having a chronic, painful disorder for which there is no generally accepted cure often produces an existential crisis. Approximately 30% of FM patients have significant depression at any given time, and about 60% have a lifetime prevalence of depressive illness. Although psychiatric disorders are common in FM patients, they do not seem to be intrinsically related to the pathophysiology of FM; effective treatment of depression with a selective serotonin re-uptake inhibitor (SSRI) does not eliminate FM pain. However, FM and depression show familial clustering, suggesting an underlying genetic susceptibility.

Associated Problems

FM patients often have a spectrum of other pain disorders that share similar features, such as not having a well-defined cause, being associated with mood disorders, and having no definitive cure. These accompanying disorders are often referred to as *central sensitivity syndromes* and include irritable bowel syndrome, painful bladder syndrome, temporomandibular pain disorder, chronic pelvic pain, chronic daily headaches, and chemical hypersensitivity syndrome.

History

Initiation and Maintenance of Fibromyalgia

FM seldom emerges "out of the blue." Many patients report an acute injury, repetitive workload, persistent stress, infections, and toxins related to the onset of FM. It is not uncommon for a regional pain state to evolve into FM. FM is commonly found as an accompaniment of other painful disorders, such as rheumatoid arthritis, low back pain, systemic lupus erythematosus, Sjögren's syndrome, inflammatory bowel disease, endometriosis, and osteoarthritis. There is increasing evidence that FM is a common occurrence in victims of post-traumatic stress disorder; for instance, both FM and CFS were common diagnoses after Operation Desert Storm in 1991.

DIAGNOSIS

The diagnosis of FM is usually based on the 1990 classification criteria recommended by the ACR (see Table 282-1). Following are the locations of the nine paired tender points:

- Occiput: bilateral, at the suboccipital muscle insertions
- Low cervical: bilateral, at the anterior aspects of the intertransverse spaces at C5-C7
- Trapezius: bilateral, at the midpoint of the upper border
- Supraspinatus: bilateral, at the origins, above the scapular spine near the medial border
- Second rib: bilateral, at the second costochondral junctions just lateral to the junctions on the upper surfaces
- Lateral epicondyle: bilateral, 2 cm distal to the epicondyles
- Gluteal: bilateral, in the upper outer quadrants of the buttocks in the anterior fold of muscle
- Greater trochanter: bilateral, posterior to the trochanteric prominence
- Knee: bilateral, at the medial fat pad proximal to the joint line

There is some recent evidence that the FM tender points are in fact typical myofascial trigger points, thus providing an important link to a peripheral source of pain input to the central nervous system. FM is not a diagnosis of exclusion; thus, laboratory tests and imaging studies play no role in establishing the diagnosis according to the 1990 ACR criteria, although they are often indicated in the evaluation of accompanying peripheral pain generators.

TABLE 282-2 MAJOR ISSUES IN THE MANAGEMENT OF PATIENTS WITH FIBROMYALGIA

Education
Pain
Fatigue
Sleep
Mood disorders
Deconditioning
Associated "central sensitization" disorders

TREATMENT Rx

Successful management of FM requires a thorough analysis in terms of the biopsychosocial model of disease. The major management issues that require attention are listed in Table 282-2.

Education

There is evidence that higher educational attainment is associated with a better prognosis in many chronic disorders such as FM. Education has a positive effect through cognitive behavioral strategies, such as goal setting and reassessment of priorities. Educated patients are more likely to take an active role in self-management.

Pain

In considering the management of pain in FM, it is logical to focus on the major sites of pain processing, namely, peripheral pain generation and central pain pathways. There is no specific tissue pathology, at least in peripheral

tissues, that is characteristic of FM. However, once the central nervous system is sensitized, not only are peripheral pain generators perceived as being more painful, but they also prolong and amplify the central neuroplastic changes. Thus, a critical first component of treating FM pain is to identify and effectively treat all peripheral pain generators, which commonly include peripheral arthritis, axial arthritis, spinal stenosis, myofascial trigger points, neuropathic pain, vascular headaches, visceral pain (e.g., irritable bowel syndrome, overactive bladder), postsurgical pain, and pelvic pain syndromes (e.g., endometriosis).

Management of central sensitization is typically initiated with heterocyclic antidepressant (HCA) medications such as amitriptyline, trazodone, cyclobenzaprine, or nortriptyline. There is good evidence that antidepressant medications with both re-uptake inhibition of serotonin and norepinephrine (e.g., venlafaxine, duloxetine, milnacipran) are more effective in treating FM pain. Both duloxetine and milnacipran have been approved by the Food and Drug Administration (FDA) for use in FM.[1,2] Importantly, the mechanism of action of these drugs is independent of any antidepressant effect and results from upregulation of the descending pain system that originates in the brain stem and uses serotonin and norepinephrine as neurotransmitters at dorsal horn synapses. Anticonvulsant medications such as gabapentin, pregabalin, and topiramate are increasingly being used in FM and other chronic pain states; they inhibit the presynaptic release of glutamate and thus modulate the activation of NMDA receptors.[3] Pregabalin has FDA approval for use in FM. Sedative-hypnotics such as zolpidem and zopiclone often help with nonrestorative sleep but not with pain. Sodium oxybate, an FDA-approved drug for narcolepsy, has been shown to improve not only sleep but also pain, stiffness, and fatigue in FM patients.[4]

Opioids are often used in the treatment of FM, but long-term trials are lacking. Although they should not be the first choice of analgesia, they should not be withheld if less powerful analgesics have failed. Tramadol (both Ultram and Ultracet) proved useful in reducing FM pain in two controlled trials.[5] Tramadol is a weak opioid agonist that also inhibits the re-uptake of serotonin and norepinephrine at the level of the dorsal horn. It is metabolized by CYP2D6, as are many antidepressant medications. FM patients who are taking tramadol or any of several antidepressants that are eliminated by CYP2D6 are at risk for developing a serotonin syndrome. Thus, careful review of concomitant medications is an important prerequisite before prescribing new medications, especially in difficult-to-treat patients who are often taking multiple medications.

Fatigue

A search for a treatable cause of fatigue is always indicated (Table 282-3). Common treatable causes of chronic fatigue in FM patients are inappropriate dosing of medications, depression, aerobic deconditioning, a primary sleep disorder (e.g., sleep apnea), nonrestorative sleep, a coexisting inflammatory disorder, and neurally mediated hypotension. As in CFS, the underlying cause of *primary* fatigue in FM is not known. Sodium oxybate, methylphenidate, and modafinil have improved fatigue in some FM patients.

Sleep

Low-dose HCAs are the mainstay of sleep pharmacotherapy in FM patients. Some patients cannot tolerate HCAs because of unacceptable levels of daytime drowsiness or weight gain. In these patients, short-acting benzodiazepine-like medications such as zolpidem, zapelon, and eszopiclone may be beneficial. Sodium oxybate is proving to be a useful medication in improving the nonrestorative sleep of FM. About 25% of male and 15% of female FM patients have sleep apnea, which usually requires treatment with continuous positive airway pressure or surgery. By far the most common sleep disorder in FM patients is restless leg syndrome or periodic limb movement disorder. Treatment is with dopamine agonists such as L-dopa/carbidopa (Sinemet), pramipexole (Mirapex), or ropinirole (Requip).[6]

Psychological Distress

Stressors related to psychosocial, economic, and health issues often develop in FM patients. Psychological intervention in terms of improving the internal locus of control and more effective problem solving is important in such patients. Cognitive-behavioral therapy is particularly well suited to effect these changes.[7] Although antidepressant medications are commonly used in the treatment of pain and disordered sleep in FM patients, the doses are often suboptimal for treating depressive illness.

Deconditioning

A carefully graded program of aerobic conditioning and stretching is a critical component of an effective FM treatment program.[8] The benefits of exercise are based on good scientific evidence, but overzealous exercise usually aggravates pain. Tai chi also may be an effective treatment for fibromyalgia.[9] In general, exercise needs to be added incrementally to the program *after* some control of pain, sleep, and depression has been achieved.

Endocrine Dysfunction

There is no good evidence that FM is primarily due to an endocrine disorder. However, common problems such as hypothyroidism and menopausal symptoms often aggravate pain and fatigue, and appropriate replacement therapy is often worth a trial.

TABLE 282-3 DIFFERENTIAL DIAGNOSIS OF CHRONIC FATIGUE

CHRONIC INFECTIONS	**CHRONIC INFLAMMATION**
Hepatitis C	Rheumatoid arthritis
Lyme disease	Systemic lupus erythematosus
Parasitic and fungal infections	Sjögren's syndrome
Tuberculosis	Polymyositis/dermatomyositis
Human immunodeficiency virus	Vasculitis
Xenotropic murine leukemia retrovirus	Sarcoidosis
SLEEP DISORDERS	**CARDIOPULMONARY**
Obstructive sleep apnea	Congestive heart failure
Restless leg syndrome	Neurally mediated hypotension
Circadian rhythm disorder	Postural orthostatic tachycardia syndrome
Upper airway resistance syndrome	Pulmonary hypertension
Narcolepsy/parasomnias	Chronic obstructive pulmonary disease
Alpha-delta sleep disorder	Mitral valve prolapse
ENDOCRINE/METABOLIC DISORDERS	**GASTROINTESTINAL**
Addison's disease	Celiac disease
Cushing's syndrome	Inflammatory bowel disease
Poorly controlled diabetes	Autoimmune hepatitis
Thyroid disorders	Hepatic cirrhosis
Hemochromatosis	**MALIGNANCY**
Hypopituitarism	Lymphoma and occult malignancies
Diabetes insipidus	Postchemotherapy syndrome
GENERAL MEDICAL DISORDERS	**NEUROLOGIC DISORDERS**
Anemia (any cause)	Multiple sclerosis
Chronic renal/hepatic failure	Myasthenia gravis
Malnutrition	Muscular dystrophies
Medication side effects	Parkinson's disease
Chronic pain disorders	Early dementia
PSYCHOLOGICAL	**LIFESTYLE FACTORS**
Mood disorders (depression, anxiety, bipolar)	Chronic overwork
Schizophrenia	Persistent unresolved stress
Post-traumatic stress disorder	Inadequate exercise
Anorexia nervosa/bulimia	Morbid obesity (body mass index >40)
Childhood abuse and/or neglect	Alcoholism/drug abuse

PROGNOSIS

FM symptoms usually persist for many years. However, patients seen in the community rather than at tertiary care centers reportedly have a 24% remission rate after 2 years. The consequences of pain, fatigue, and cognitive dysfunction negatively influence the sustained performance of physical and mental tasks. Everyday activities take longer for FM patients, who need more time to get started in the morning and often require extra rest periods during the day. A survey of FM patients seen at academic centers reported that 70% perceived themselves as being disabled, and 16% were receiving Social Security benefits.

CHRONIC FATIGUE SYNDROME

EPIDEMIOLOGY

Fatigue is a common symptom; indeed, some 50% of individuals report "feeling fatigued" in population surveys. Fatigue is one of the most common problems reported to primary care doctors. In a series of 1000 consecutive patients seen in primary care settings, 8.5% reported debilitating fatigue lasting 6 months or longer without apparent cause; only 15% satisfied the clinical definition for CFS shown in Table 282-1. In many cases, fatigue is self-limited or the causes are self-evident (e.g., insufficient rest, a medical illness, depression, insomnia). The prevalence of CFS has ranged from 0.006 to 3.0% in various population surveys. CFS is diagnosed predominantly in women aged 30 to 45 years. They are typically highly functional before the onset of the illness.

PATHOBIOLOGY

The cause of CFS remains poorly defined. There are many reports linking CFS with chronic infections; most have not stood up to careful scrutiny. The latest such study reported that 67% of patients with CFS versus 3.7% of healthy controls were infected with a retrovirus—the xenotropic murine leukemia virus (XMRV); two other studies failed to find an association with XMRV infection. Although many CFS patients complain of nonrestorative sleep, polysomnographic studies have been inconclusive. The similarity between CFS and early Addison's disease has prompted numerous neuroendocrine studies, which have failed to show a clinically treatable endocrine deficiency; however, subtle changes in the hypothalamic-pituitary-adrenal response to acute stressors is found in about 30% of patients. A similar proportion of CFS patients have abnormal results on tilt-table testing, with evidence of autonomic dysfunction in terms of neurally mediated hypotension or postural orthostatic tachycardia syndrome. This may be relevant in a subpopulation of patients, but treatment with fludrocortisone had no overall benefit in one large placebo-controlled study. Many studies have suggested a low level of immune stimulation in CFS, the most common abnormalities being reduced natural killer cell function and increased numbers of cytotoxic T cells. However, these findings are not diagnostically useful, and clinical improvement has not been associated with any significant change in immune markers. Extensive psychological testing in CFS patients has failed to reveal a common psychiatric denominator. Nevertheless, it is generally accepted, as in FM and other chronic illnesses, that psychosocial distress and maladaptive coping strategies play a role in symptom attribution and perpetuation.

CLINICAL MANIFESTATIONS

The chief complaint of patients in whom CFS is diagnosed is an abrupt onset of debilitating fatigue that causes significant impairment in daily activities, work ability, and social relationships. Typically, these patients report an excellent health status just before the onset of fatigue, which is often preceded by a flu-like prodrome. Symptoms suggestive of an infectious etiology include low-grade fever, night sweats, tender cervical lymph nodes, sore throat, myalgias, and headaches. As in FM, many CFS patients complain of generalized musculoskeletal pain, cognitive dysfunction, irritable bowel syndrome, temporomandibular pain disorders, nonrestorative sleep, and multiple chemical sensitivities.

DIAGNOSIS

The current diagnosis of CFS is based on the recommendations of the 1994 international CFS study group (see Table 282-1). This revision added the minor criteria of postexercise fatigue and cognitive dysfunction to the CDC's original 1988 working case definition. Unlike the criteria for FM, there are no physical findings in the CFS criteria. Furthermore, whereas the definition of FM contains no exclusionary criteria, the definition of CFS excludes patients with fatiguing medical disorders, melancholic depression, psychotic disorders, substance abuse, and severe obesity (body mass index >40). Because CFS is not a diagnosis of exclusion, it is important to systematically evaluate the patient for treatable causes of fatigue (see Table 282-3).

TREATMENT Rx

Management of CFS follows the general management guidelines for FM. Patients with presumed CFS should have a general medical work-up to exclude treatable causes of fatigue (e.g., hypothyroidism, anemia), and consideration should be given to more specialized studies such as polysomnography and tilt-table testing in selected cases. Currently, there is no generally accepted pharmacologic intervention for patients with CFS. Antidepressants (HCAs and SSRIs) are of minimal benefit, although two studies reported a modest benefit with the use of monoamine oxidase inhibitors in patients with significant vegetative symptoms. Inconsistent benefits have been described with fludrocortisone and low-dose corticosteroids. The mainstay of treating CFS is to engage the patient in a gently graded program of aerobic exercise.[10] Cognitive-behavioral therapy may correct dysfunctional thought patterns but seldom improves fatigue. Management of pain and psychological distress in CFS is the same as for FM.

TABLE 282-4 DIAGNOSTIC FEATURES OF A MYOFASCIAL TRIGGER POINT

Focal point of tenderness on palpation of involved muscle
Reproduction of pain complaint by trigger point palpation (≈3 kg pressure)
Palpation reveals induration of adjacent muscle ("taut band")
Often pseudoweakness of muscle involved (no atrophy)
Often referred pain on continued pressure (≈5-sec duration) over trigger point

MYOFASCIAL PAIN

Pain arising from muscle is a universal human experience. In most instances, it is due to muscle *macrotrauma* (i.e., muscle tear or sprain) or muscle *microtrauma* (i.e., injury at the sarcomere level resulting from repetitive muscle use or overexertion). After appropriate rest, the pain usually dissipates over a period of a few days to weeks. In some cases, a persistent pain focus develops that has the characteristics of a myofascial trigger point. This diagnosis should be considered if the patient complains of focal pain that is aggravated by muscle use or psychological stressors that cause increased muscle tension. Myofascial trigger points often play a role in poorly characterized focal pain syndromes such as low back pain, jaw pain, pelvic pain, and headache.

A myofascial trigger point is a well-defined point of focal tenderness within a muscle. Palpation usually reveals a rope-like induration referred to as a *taut band*. In many instances, firm palpation of this area causes pain in a referred distribution that reproduces the patient's symptoms. Importantly, referred pain from a trigger point does not follow a nerve root distribution (i.e., it is not dermatomal). Trigger points frequently cause dysfunction in terms of restricted range of movement and weakness; the involved muscle or muscles often demonstrate easy fatigability (Table 282-4).

Electromyographic recordings from trigger points show spontaneous low-voltage activity resembling end plate spike potentials. In normal muscle, depolarization of the motor end plate initiates the release of calcium ions from the sarcoplasmic reticulum, which in turn results in activation of the myosin-actin contractile elements ("contraction coupling"). It is thought that the areas of electrical hyperexcitability in trigger points result from a nonphysiologic focal contraction caused by an influx of calcium ions into the damaged sarcomeres. If this process is not "switched off," excessive utilization of adenosine triphosphate may result in a focal energy crisis in the injured muscle, thus perpetuating the problem. Functional magnetic resonance imaging studies have confirmed the hyperalgesic features of myofascial trigger points in terms of increased activity of brain regions involved in processing stimulus intensity and negative affect. Microdialysis of trigger point foci have shown a more acidic pH and an increase of inflammatory cytokines, bradykinin, substance P, and calcitonin gene–related peptide compared with adjacent muscle.

Factors commonly cited as predisposing to trigger point formation include deconditioning, poor posture, repetitive mechanical stress, mechanical imbalance (e.g., leg length inequality), joint disorders, and nonrestorative sleep. The muscle pain experienced by FM patients is often the result of pain originating from myofascial trigger points and amplified by central sensitization. Interestingly, FM tender points were recently reported to have the clinical and electromyographic features typical of myofascial trigger points. It is hypothesized that myofascial pain is an important peripheral pain generator that may, in some FM patients, perpetuate and accentuate the process of central sensitization.

TREATMENT Rx

Management of myofascial trigger points is based on the following principles.

Posture and Ergonomics

An important issue in the effective management of myofascial pain syndromes is correction of predisposing factors (see earlier). These factors interfere with the muscle's ability to fully recover and are the most common reason for treatment failure.

Stretching

Restoration of a muscle to its full stretch length breaks the link between the energy crisis and the contraction of injured sarcomeres (see earlier). Commonly used stretching techniques include spray and stretch with ethyl chloride, acupressure, post-isometric relaxation, and deep stroking massage.

Strengthening

Muscles harboring trigger points usually become weak because of the inhibitory effects of pain. A program of slowly progressive strengthening is essential to restore full function and minimize the risk of recurrence and perpetuation of satellite trigger points.

Trigger Point Injections

Needling the myofascial trigger point with a "peppering technique" often provides a worthwhile and long-lasting benefit. Although dry needling is effective, the use of a local anesthetic (1% lidocaine or 1% procaine) helps confirm the accuracy of the injection and provides immediate relief. Validation of the accuracy of the injection is suggested by the patient's report that the pain is reproduced on entry of the needle into the trigger point; in superficial muscles, a local twitch response may be observed, providing further evidence of an accurate injection. Both injections and lidocaine patches have shown effectiveness in controlled trials.[11]

Medications

Treatment of myofascial trigger points is mainly nonpharmacologic. Nonsteroidal anti-inflammatory drugs and other analgesics often provide moderate symptomatic relief. As in FM, drugs that modulate pain at the central level are a useful adjunct in difficult-to-treat patients, especially if central sensitization is suspected.

FUTURE DIRECTIONS

Both FM and CFS represent a major challenge to modern medicine in terms of understanding a constellation of common, often disabling symptoms that originate in the central nervous system but cannot be explained by a classic psychological disorder. The central sensitization demonstrated in FM patients has provided important insight into the physiologic basis for the complaint of widespread pain, but no such breakthrough has occurred in the comprehensive understanding of fatigue in either FM or CFS. Current research suggests that both these conditions have a genetic predisposition that interacts with environmental insults such as infections, trauma, myofascial foci, and psychological stressors. One common denominator being actively explored in both conditions is the activation of glial cells within the central nervous system by cytokines and chemokines. Both these disorders are prime examples of the need to integrate the classic biomedical model of disease with psychosocial influences (i.e., the biopsychosocial model of disease). The challenge that faces investigators in the 21st century is to discern whether mental processes can influence and interact with environmental stressors and focal pain generators to change the epigenetic expression of genes involved in pain processing and fatigue.

SYSTEMIC DISEASES IN WHICH ARTHRITIS IS A FEATURE

STERLING G. WEST

Arthritis, arthralgias, and myalgias can be significant features of several systemic diseases and may be the presenting symptoms for some of these disorders (Table 283-1). Appropriate evaluation of these musculoskeletal symptoms, including selected laboratory tests and radiographs, can provide clues to the early diagnosis of these diseases. Synovial biopsies are rarely necessary but can be diagnostic. Brief descriptions of the arthritic manifestations of some of these systemic disorders follow; a more detailed discussion of each entity is found in the chapters devoted to these diseases. Because of the rarity of many of these diseases, evidence-based treatments with Food and Drug Administration–approved medications are lacking.

AUTOIMMUNE HEPATITIS

Patients with type I autoimmune hepatitis (Chapter 151) may present with a syndrome resembling systemic lupus erythematosus (SLE; Chapter 274). Patients with the early-onset subset are frequently young and female, with complaints of polyarthralgia and occasionally fever. Laboratory examination may show leukopenia, a positive antinuclear antibody (70 to 90%), elevated erythrocyte sedimentation rate, polyclonal gammopathy, and elevated liver-associated enzymes. Antibodies against double-stranded DNA are usually not seen, whereas antibodies against the smooth muscle antigen (F1 actin) support the diagnosis. Joint radiographs show soft tissue swelling without erosions or deformity. Joint pain resolves with corticosteroid therapy for the liver disease.

PRIMARY BILIARY CIRRHOSIS

Up to 50% of patients with primary biliary cirrhosis (Chapter 158) have other autoimmune disorders, including rheumatoid arthritis (RA), Sjögren's syndrome, limited scleroderma, and autoimmune thyroiditis. In addition to antimitochondrial antibodies, rheumatoid factor, antinuclear antibodies, and anticentromere antibodies are often present. More than 10% of patients with primary biliary cirrhosis have a symmetrical or asymmetrical small joint inflammatory arthritis. Unlike RA, it can involve distal interphalangeal joints and is rarely erosive or deforming. Other musculoskeletal manifestations include osteomalacia related to vitamin D deficiency, osteoporosis related to renal tubular acidosis, and hypertrophic osteoarthropathy associated with liver disease.

WHIPPLE'S DISEASE

An inflammatory arthritis occurs in 60 to 90% of patients with Whipple's disease (Chapter 142) and may precede other clinical manifestations by

TABLE 283-1 SYSTEMIC DISEASES ASSOCIATED WITH ARTHRITIS

DISEASE	TEST*
GASTROINTESTINAL DISEASES	
Autoimmune hepatitis	Liver-associated enzymes, *ASMA*
Primary biliary cirrhosis	Alkaline phosphatase, *antimitochondrial Ab*
Pancreatitis-arthritis syndrome	Lipase, amylase, *abdominal CT scan*
Whipple's disease	*Tissue biopsy, PCR for Tropheryma whippelii DNA*
Gluten-sensitive enteropathy	*Antitransglutaminase antibody, small bowel biopsy*
Inflammatory bowel disease	Stool guaiac, *colonoscopy*
Hepatitis B/hepatitis C	Liver-associated enzymes, *hepatitis serology, cryoglobulins*
Intestinal bypass arthritis	*Cryoglobulins*
HEMATOLOGIC DISORDERS	
Hemophilia	PTT, *factor VIII and IX levels*
Hemoglobinopathies	CBC, *hemoglobin electrophoresis*
Hypogammaglobulinemia	Low total protein, *SPEP, immunoglobulins*
Plasma cell dyscrasias	High total protein, *SPEP, UPEP, IEF*
ENDOCRINE DISORDERS	
Diabetes mellitus	Glucose, *hemoglobin* A_{1c}
Thyroid disorders	TSH, *thyroxine*
Parathyroid disorders	Calcium, phosphorus, *PTH*
Acromegaly	Radiographs, *growth hormone*
Hyperlipoproteinemia	Lipid panel
Paget's disease	Alkaline phosphatase, radiographs, *bone scan*
MALIGNANT DISORDERS	
Hypertrophic osteoarthropathy	Radiographs (hands, wrists, chest)
Leukemia and lymphoma	CBC, LDH, *bone marrow/tissue biopsy*
Carcinomatous polyarthritis	*Cancer screen*
Palmar fasciitis and arthritis	*CA-125, pelvic CT scan*
OTHER DISEASES	
Hemochromatosis	Iron studies, radiographs, *HFE gene*
Multicentric reticulohistiocytosis	Radiographs, *skin/synovial biopsy*
Sarcoidosis	Chest radiograph, *ACE level, tissue biopsy*
Alkaptonuria	Radiographs, *homogentisic acid level*
Fabry's disease	Angiokeratomas, *α-galactosidase A level or gene mutation*
Relapsing polychondritis	*Cartilage biopsy*
Cystic fibrosis	Chest radiograph, *sweat chloride*
Pigmented villonodular synovitis	Synovial fluid analysis, *MRI, synovial biopsy*
Systemic infections	Cultures, serologies (RPR, HIV, parvovirus)

*Tests listed are common laboratory tests and radiographs that are frequently ordered; this information should provide a clue that a systemic disease is a possible cause of the patient's musculoskeletal symptoms. These tests, coupled with the history and physical examination, should be followed by more specific serologies and biopsies (listed in italics) to confirm the diagnosis.
Ab = antibody; ACE = angiotensin-converting enzyme; ASMA = anti–smooth muscle antibody; CBC = complete blood cell count; CT = computed tomography; HIV = human immunodeficiency virus; IEF = immunoelectrophoresis; LDH = lactate dehydrogenase; MRI = magnetic resonance imaging; PCR = polymerase chain reaction; PTH = parathyroid hormone; PTT = partial thromboplastin time; RPR = rapid plasmin reagin; SPEP = serum protein electrophoresis; TSH = thyroid-stimulating hormone; UPEP = urine protein electrophoresis.

years. The joint involvement is typically an intermittent, migratory oligoarthritis affecting large joints more than small joints or the spine, lasting from several hours to days. The synovial fluid is inflammatory, with a predominance of mononuclear cells. Subcutaneous nodules are occasionally seen, contributing to an erroneous diagnosis of rheumatic fever or RA. However, patients consistently test negative for rheumatoid factor and antinuclear antibodies. Synovial biopsies show rod-shaped bacilli on electron microscopy, which have been identified as *Tropheryma whippelii*. Diagnosis is typically made by duodenal, synovial, or lymph node biopsy showing periodic acid–Schiff–positive macrophages. Polymerase chain reaction to detect DNA of the organism in peripheral blood, cerebrospinal fluid, synovial fluid, or tissue biopsy specimens is under investigation and is not universally available. Typically, the arthritis does not cause radiographic changes or deformities. Prolonged antibiotic therapy results in resolution of musculoskeletal as well as other symptoms of this disease.

GLUTEN-SENSITIVE ENTEROPATHY (CELIAC DISEASE)

An asymmetrical oligoarthritis or symmetrical polyarthritis occurs in up to 25% of adults with celiac disease (Chapter 142). It may precede the enteropathic symptoms by months to years. Large joints such as knees and ankles, more than hips and shoulders, are most commonly involved. Axial involvement is reported. The arthritis does not cause deformities or radiographic changes and resolves with a gluten-free diet in 40 to 50% of cases. Another musculoskeletal manifestation is osteomalacia related to vitamin D malabsorption, which may mimic diffuse fibromyalgia.

PANCREATIC-ARTHRITIS SYNDROME

Pancreatic panniculitis is a systemic syndrome occurring in some patients with pancreatic acinar cell carcinoma and less commonly in patients with pancreatitis or hematologic malignancies. This syndrome is characterized by tender red nodules, usually on the extremities; these are frequently misdiagnosed as erythema nodosum, but biopsy shows areas of lobular panniculitis with fat necrosis. Arthritis occurs in 60% of patients and usually involves the ankles and knees. Synovial fluid is typically noninflammatory and creamy in color. It contains multiple lipid droplets because of necrosis of fat in the synovial membrane. Other manifestations include osteolytic lesions (10%) from bone marrow fat necrosis, pleuropericarditis, fever, and eosinophilia. The prominent fat necrosis is due to the release of lipase, amylase, and trypsin from the diseased pancreas. Another musculoskeletal manifestation resulting from pancreatic disease is osteomalacia from vitamin D deficiency related to malabsorption.

HEMOPHILIA

Hemophilia A (factor VIII deficiency) and hemophilia B (factor IX deficiency) (Chapter 177) are associated with hemarthrosis. Almost all patients with factor levels less than 1% of normal experience recurrent hemarthroses spontaneously or after minor trauma. Large joints (knees, elbows, ankles) are most commonly involved. Intramuscular hemorrhage can also occur. Recurrent hemarthrosis can lead to proliferative synovitis and cartilage degradation, resulting in both erosive and degenerative changes on radiographs. Physical examination shows bone enlargement, crepitus, atrophic muscles, and joint contractures. Treatment of acute monoarthritis consists of factor replacement to achieve a level of 30% or greater, given at the first sign of joint swelling. Patients with fever (temperature >38° C) or who fail to respond to factor replacement need joint aspiration to rule out septic arthritis, which occurs with an increased incidence in hemophilia. Chronic arthritis is treated with nonsteroidal anti-inflammatory drugs (NSAIDs), which do not inhibit platelet function; arthroscopic or radiation synovectomy for chronic synovitis; and total joint arthroplasty for end-stage joint disease. The regular prophylactic administration of factor replacement has reduced the risk of developing chronic arthropathy. Acute and chronic arthritis is less frequent and less severe in patients with hemophilia B compared with hemophilia A.

HEMOGLOBINOPATHIES

Patients with sickle cell anemia (Chapter 166) or the heterozygous state of sickle β-thalassemia, sickle-C disease, and sickle-D disease frequently experience polyarthralgia. Local sickling of cells leads to obstruction of the microcirculation and to bone infarctions. Patients most commonly experience painful crises causing chest, back, and joint pain. A painful large joint arthritis (usually in the knees), often with noninflammatory synovial effusions, lasting days to 2 to 3 weeks can also occur. Infarcts in the metaphyses of bones are commonly found on joint radiographs. Vertebral bodies have a characteristic "Lincoln log" appearance or a central cup-like indentation ("codfish vertebrae"). Femoral and humeral head osteonecrosis can occur in up to 33% of sickle cell anemia and sickle-C disease cases. Because of splenic dysfunction, septic arthritis and osteomyelitis (50% caused by *Salmonella*) have been associated with sickle cell disease. In adults, gout has been reported, whereas in children younger than 2 years, an acute, painful, nonpitting swelling of the hands and feet (hand-foot syndrome) associated with fever and leukocytosis may be the first manifestation of sickle cell anemia. Treatment includes intravenous hydration, oxygen, and analgesics. Hydroxyurea can reduce the frequency of painful crises. In patients with β-thalassemia major (Cooley's

anemia; Chapter 165), significant expansion of bone marrow develops as a result of increased erythroid precursors, leading to osteoporosis and microfractures that affect primarily the lower extremities.

HYPOGAMMAGLOBULINEMIA

Patients with congenital X-linked hypogammaglobulinemia (Bruton's disease) or acquired common variable immunodeficiency (CVID; Chapter 258) can develop a nonerosive, noninfectious large joint oligoarthritis that responds to intravenous gamma globulin therapy. However, septic arthritis caused by common pathogens or *Mycoplasma* can also occur and must be rigorously excluded. In adults with acquired CVID, autoimmune conditions are common (22%), including autoimmune cytopenias, RA, and pernicious anemia. Selective immunoglobulin A (IgA) deficiency (Chapter 258) is associated with various rheumatic manifestations, including positive autoantibodies, in the absence of clinical disease. Systemic autoimmune disorders, including SLE, juvenile RA, and others, as well as organ-specific autoimmune disorders such as type 1 diabetes mellitus and myasthenia gravis, also occur in IgA-deficient individuals.

DIABETES MELLITUS

Diabetic stiff hand syndrome of limited joint mobility (diabetic cheiroarthropathy) occurs in more than 30% of patients with long-standing, poorly controlled type 1 or type 2 diabetes mellitus (Chapters 236 and 237). Patients present with the insidious development of flexion contractures and thickened skin of the fingers, which may be confused with scleroderma. These changes may be due to excess glycosylation of tendinous structures and accumulation of sugar alcohols, producing excess water content in the tissues and leading to increased stiffness. As a result of the inability to extend the fingers fully, the "prayer sign" is observed on physical examination. Unlike diabetic stiff hand syndrome, Dupuytren's contractures are due to a chronic thickening of the palmar aponeurosis, causing flexion deformities of the third and fourth digits. It is a frequent musculoskeletal complication, occurring in more than 20% of type 2 diabetics. A less common manifestation is Charcot's, or neuropathic, joints, occurring in less than 1% of all patients with long-standing diabetes. All patients have a diabetic peripheral neuropathy and typically present with painless swelling of the feet caused, most commonly, by destruction of the tarsometatarsal joints. Deformities can occur with midtarsal collapse ("rocker bottom" feet), predisposing to ulceration and infection of the skin over desensate bony prominences. Radiographs are diagnostic, and treatment should include supportive footwear and protected weight bearing.

Unlike Charcot's joint, diabetic osteolysis and diabetic amyotrophy are unique to diabetes. The osteolysis is characterized by resorption of the distal metatarsal bone and proximal phalanges of the feet, giving radiographs a characteristic "licked candy" appearance. Pain is variable, and treatment is conservative because the process may terminate on its own. Diabetic amyotrophy is a lumbar polyradiculopathy (L2-L4) that arises with severe pain, dysesthesias, and rapid atrophy of the proximal muscles of one or both thighs. Carpal tunnel syndrome (25%), adhesive capsulitis of the shoulder (frozen shoulder), flexor tenosynovitis (trigger finger) of the hands, diffuse idiopathic skeletal hyperostosis (type 2 diabetes), osteopenia (type 1 diabetes), diabetic muscle infarction (usually of the thigh), osteomyelitis of the foot, and septic joints are all musculoskeletal conditions that occur with increased frequency in diabetic patients. Aggressive control of blood glucose helps prevent some of these musculoskeletal complications.

THYROID DISORDERS

Musculoskeletal symptoms occur in 33% of patients with clinical hypothyroidism (thyroid-stimulating hormone levels >20 μU/mL) (Chapter 233). Patients can present with carpal tunnel syndrome, Raynaud's phenomenon, or muscle aching and stiffness similar to fibromyalgia and polymyalgia rheumatica. Patients with severe hypothyroidism can experience a noninflammatory myopathy with proximal muscle weakness and elevated creatine kinase, which may be confused clinically with polymyositis. Similarly, myxedematous patients can develop a symmetrical arthropathy of the large joints, especially the knees, associated with noninflammatory synovial fluid with increased viscosity. The association of hypothyroidism with chondrocalcinosis is controversial, but clearly patients beginning thyroid replacement therapy can experience an acute attack of pseudogout. Patients with hyperthyroidism can develop proximal myopathy (70%), adhesive capsulitis of the shoulder (10%), osteoporosis, or thyroid acropachy. Thyroid acropachy occurs in less than 1% of patients with Graves' disease and consists of soft tissue swelling of the hands, digital clubbing, and periostitis, particularly involving the metacarpal and phalangeal bone shafts. Pain is usually mild, radiographs are characteristic, and there is no effective therapy. Patients with autoimmune thyroid disease have an increased prevalence of positive antinuclear antibodies and an increased association with systemic connective tissue diseases such as Sjögren's syndrome.

PARATHYROID DISORDERS

Primary hyperparathyroidism (Chapter 253) can arise with osteoporosis and fractures or with chondrocalcinosis and episodes of acute pseudogout. In severe hyperparathyroidism, which is rare, vague myalgias and arthralgias resembling fibromyalgia; a reversible, painless, proximal myopathy with normal creatine kinase; and osteitis fibrosa cystica with bone pain can be seen. Osteitis fibrosa cystica occurs primarily in patients with secondary hyperparathyroidism associated with renal failure and has a characteristic radiographic appearance, with subperiosteal resorption on the radial side of the phalanges, small erosions in the hands and distal clavicles, and discrete lytic bone lesions (brown tumors). Ectopic calcifications, joint laxity, and tendon ruptures have been reported in patients with severe hyperparathyroidism. Hypoparathyroidism has also been associated with myopathy and ectopic calcifications. Patients with type Ia pseudohypoparathyroidism and pseudo-pseudohypoparathyroidism have a shortened fourth metacarpal bone bilaterally.

ACROMEGALY

Up to 75% of patients with acromegaly (Chapter 231) develop an atypical form of osteoarthritis. The knees, shoulders, hips, and lumbosacral and cervical spine are the most frequently symptomatic areas, although the hands reveal the most characteristic radiographic changes, with widened joint spaces due to cartilage hypertrophy. Carpal tunnel syndrome (50%), Raynaud's phenomenon (33%), and proximal muscle weakness with normal creatine kinase can also occur.

HYPERLIPOPROTEINEMIA

Type IIa familial hyperlipidemia (Chapter 213) is associated with tendinous and tuberous-osseous xanthomas as well as episodic Achilles tendinitis. An acute migratory, inflammatory arthritis persisting up to a month and resembling rheumatic fever occurs in up to 50% of patients. Predominantly large joints are affected. In addition, a self-limited, acute monoarticular or oligoarticular arthritis involving the knee or ankle can occur. Patients with type III familial hyperlipoproteinemia can develop tendon and bone xanthomas. Patients with human immunodeficiency virus (HIV) infection taking protease inhibitor drugs can develop dyslipidemia leading to tendon xanthomas. In all hyperlipidemias, gout must be excluded before ascribing the symptoms to hyperlipoproteinemia. Therapy with NSAIDs and treatment of the underlying lipid disorder should be pursued. Notably, some of the therapies used to treat hyperlipidemia can cause musculoskeletal symptoms, including hyperuricemia and gout from nicotinic acid and myalgias (with or without elevated creatine kinase) from statin therapy.

PAGET'S DISEASE

Paget's disease (Chapter 255) can cause bone pain and deformity. An elevated bone-specific alkaline phosphatase and characteristic radiographic changes can help make the diagnosis. Joint pain caused by secondary osteoarthritis in areas of bone involvement by Paget's disease most commonly occurs in the hips, knees, or vertebrae. Spinal stenosis from Paget's disease of the spine has been reported. Bisphosphonate therapy is highly effective.

HYPERTROPHIC OSTEOARTHROPATHY

Hypertrophic osteoarthropathy is a syndrome that includes clubbing of the fingers and toes, periostitis of long bones (distal tibia, femur, radius), and arthritis (Fig. 283-1). Hypertrophic osteoarthropathy is classified into primary (hereditary) and secondary forms. Between 80 and 90% of secondary hypertrophic osteoarthropathy is associated with non–small cell lung cancer. Other causes include other neoplasms (mesothelioma), chronic pulmonary infections, congenital heart disease, cirrhosis, HIV infection, and inflammatory bowel disease. Patients with secondary hypertrophic osteoarthropathy can present with acute, severe, burning bone pain and a noninflammatory arthritis caused by periarticular periostitis. Pain is accentuated by dependency of the limbs. Pitting edema, warmth, and tenderness of the legs and forearms can be seen. Radiographs show diagnostic changes of periosteal elevation, new bone formation, or both along the distal ends of long bones.

A B

FIGURE 283-1. Hypertrophic osteoarthropathy. A, Severe clubbing of the nails. **B,** Radiograph demonstrating periosteal elevation of the distal radius and ulna.

Therapy is symptomatic, and hypertrophic osteoarthropathy improves with successful treatment of the underlying primary disease. In resistant cases, treatment with intravenous bisphosphonate has been effective in modulating symptoms.

LEUKEMIA AND LYMPHOMA

Leukemia can arise as an asymmetrical or migratory polyarthritis, monoarthritis (rare), back pain (10%), or nocturnal bone pain. Articular manifestations occur in 14 to 50% of children and 4 to 16% of adults with acute leukemia and can precede the diagnosis by months. Joint pain is attributed to leukemic synovial infiltration and usually involves the ankle or knee, but it can be polyarticular, resembling juvenile or adult RA. The joint pain is disproportionately more severe than the clinical findings. Synovial effusions are uncommon, and evidence of leukemic cells in the synovial fluid is rare. Bone pain occurs in up to 50% of patients with leukemia and is more common in the lower extremities. The peripheral white blood cell count may be normal initially, but serum lactate dehydrogenase is always elevated, frequently to very high levels. Radiographs are normal in 50% of cases. The musculoskeletal symptoms are poorly responsive to NSAIDs but can resolve with successful therapy of the leukemia. Musculoskeletal symptoms occur in 25% of patients with non-Hodgkin's lymphoma. Nocturnal bone pain is the most common presenting musculoskeletal complaint. A seronegative monoarthritis or polyarthritis can occur and should be suspected in patients with severe constitutional symptoms or lymphadenopathy out of proportion to the degree of arthritis. Patients with angioimmunoblastic T-cell lymphoma (Chapter 191) may occasionally develop a chronic, nonerosive polyarthritis with erythroderma.

CARCINOMATOUS POLYARTHRITIS

Polyarthritis can rarely be the presenting manifestation of an occult malignancy; it may precede the discovery of the malignancy by several months. Breast, colon, lung, ovarian, and lymphoproliferative malignancies are the most commonly associated cancers. Clinical features suggesting carcinomatous polyarthritis include the explosive onset of a rheumatoid factor–negative, asymmetrical polyarthritis involving predominantly the lower extremities and sparing the hands and wrists in a patient older than 60 years. Polymyalgia rheumatica and RA must be excluded. Treatment of the underlying malignancy results in improvement of the arthritis.

PALMAR FASCIITIS AND ARTHRITIS SYNDROME

Ovarian carcinoma (Chapter 205) is the most common malignancy found in patients with palmar fasciitis and arthritis. Patients present with a severe, painful, symmetrical inflammatory polyarthritis and fasciitis causing contractures primarily of the hands and, less commonly, the feet. Patients may have vasomotor instability, causing diagnostic confusion with reflex sympathetic dystrophy syndrome or RA. This syndrome portends a poor prognosis because it typically manifests after tumor metastasis. Response to treatment is poor, although clinical improvement can occur with successful eradication of the underlying tumor.

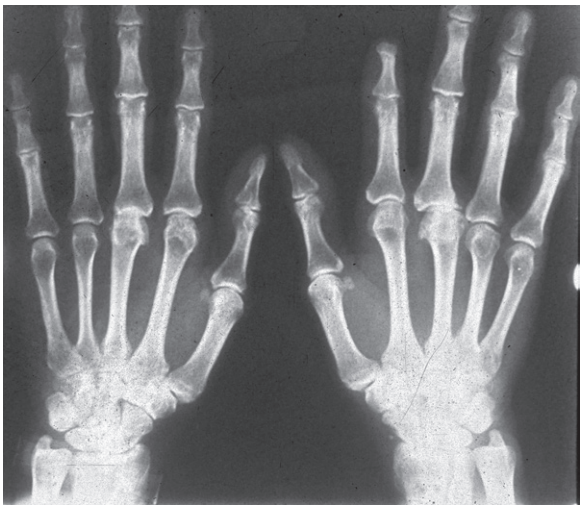

FIGURE 283-2. Hemochromatotic arthropathy. Radiograph demonstrating degenerative changes, with hook-like osteophytes of the second and third metacarpophalangeal joints bilaterally.

HEMOCHROMATOSIS

Joint involvement occurs in 40 to 75% of patients with hereditary hemochromatosis (Chapter 219) and may be the presenting symptom (Fig. 283-2). The metacarpophalangeal (MCP) joints (especially the second and third MCP joints), wrists, knees, hips, shoulders, and ankles are most often involved in a symmetrical pattern. The arthropathy resembles osteoarthritis, with joint swelling resulting from bone enlargement, but it is distinguished clinically by the involvement of atypical joints, such as MCP joints, wrists, and ankles. Radiographs show joint space narrowing, subchondral cysts, sclerosis, and osteophytes that are hook-like at the MCP joints. Chondrocalcinosis is present in up to 50% of patients. It is typically asymptomatic, but in some patients it leads to attacks of acute inflammatory synovitis (pseudogout), which may result in the misdiagnosis of RA. The prevalence of overt arthritis increases with age, and it may be only minimally symptomatic when the disease arises in other organs. However, it is not uncommon for articular pain to be the initial presenting complaint. Consequently, all patients (especially male) presenting with premature osteoarthritis occurring in atypical joints, especially MCP joints and wrists, should be screened for hereditary hemochromatosis with iron studies. The mechanism whereby iron causes arthritis is unclear, but it may be related to hemosiderin deposits in the synovial membrane and chondrocytes activating degradative enzymes. Treatment is symptomatic with NSAIDs and, when severe, total joint arthroplasties. Phlebotomy for iron removal does not alter the course of the arthritis. Additional rheumatic manifestations in patients with hemochromatosis include osteoporosis related to hypogonadotropic hypogonadism, osteomalacia related to

vitamin D deficiency when liver disease is severe, and an increased susceptibility to *Yersinia* septic arthritis.

MULTICENTRIC RETICULOHISTIOCYTOSIS

Multicentric reticulohistiocytosis (MRH) is a chronic, symmetrical, inflammatory polyarthritis most commonly affecting the hands and cervical spine. It may resemble RA but can be differentiated by its prominent distal interphalangeal joint synovitis. Joint involvement remits and relapses initially, but in 50% of cases it worsens into a severely deforming arthritis mutilans. Firm, nonpruritic, reddish brown or yellow papulonodular lesions ("coral beads") that wax and wane occur around the nail beds and on the face, hands, ears, and other areas predominantly above the waist. The skin lesions have a diagnostic histology. However, in 50 to 66% of patients, these diagnostic nodules follow the onset of arthritis by months to years. Additional associations include xanthelasma (33%) and malignancies of various types (25%), which may precede or follow the onset of MRH. MRH usually remits spontaneously in 8 to 10 years but often leaves permanent cutaneous and joint damage. Treatment may include cytotoxic therapy if the arthritis is aggressive. Anti–tumor necrosis factor-α (TNF-α) therapy is reportedly beneficial in resistant cases.

SARCOIDOSIS

Joint manifestations including arthritis, periarthritis, and arthralgias occur in 4 to 38% of patients with sarcoidosis (Chapter 95). Rheumatic involvement is divided into acute and chronic types. The first consists of the triad of arthritis, erythema nodosum, and hilar adenopathy on chest radiographs (Löfgren's syndrome), which may be accompanied by fever. Arthritis arises most often in the knees and ankles, and periarticular pain can be severe. Treatment is with NSAIDs, colchicine, or both, and symptoms usually remit spontaneously over several weeks. The less common type of joint involvement in sarcoidosis consists of synovitis that accompanies the slower-onset, more chronic, systemic form of sarcoidosis. Polyarthritis, oligoarthritis, or monoarthritis can affect the small or large joints; it is typically nondestructive but in some cases can be aggressive. Dactylitis resulting from sarcoid bone and soft tissue involvement can occur (Fig. 283-3). In contrast to the acute type, chronic sarcoid arthropathy is characterized by inflammatory synovial fluid and histologic granulomas on synovial biopsy. Treatment consists of NSAIDs, low-dose corticosteroids, hydroxychloroquine, and methotrexate or azathioprine. In refractory cases, anti–TNF-α therapy has been successful. Other musculoskeletal manifestations of sarcoidosis include lytic or sclerotic bone lesions (3 to 13%) and symptomatic acute or chronic myopathy (3%).

ALKAPTONURIA (OCHRONOSIS)

Although an inherited disorder, alkaptonuria is usually not diagnosed until the patient presents with progressive premature osteoarthritis as a young adult (before age 30 to 35 years) (Chapter 212). The spine is initially involved, followed by the knees, shoulders, and hips. Small peripheral joints are spared. Radiographs show multiple vacuum discs, disc space ossification, and osteoarthritic changes in the spine. Nonarticular features include bluish brown discoloration of ear pinna, sclera, and nasal cartilage. Deposition of ochronotic pigment onto collagen fibers causes the articular cartilage to become brittle and fragmented. The noninflammatory synovial fluid may show tiny shards of pigmented cartilage ("ground pepper"). The diagnosis of alkaptonuria is suspected when a patient gives a history of passing dark urine or when fresh urine turns dark brown or black on standing. The diagnosis is confirmed by quantitative measurement of increased homogentisic acid in urine or blood. There is no effective therapy for alkaptonuria. The arthritis is treated symptomatically with analgesics.

FIGURE 283-3. Sarcoid bone involvement. Punched-out lytic lesions of the middle phalanx, with soft tissue swelling.

FABRY'S DISEASE

Most patients with hereditary lysosomal storage diseases present and are diagnosed during childhood (Chapter 215). However, female heterozygotes and atypical variants of Fabry's disease may have a milder and later-onset phenotype. Fabry's disease is an X-linked lipid storage disease caused by a deficiency of lysosomal α-galactosidase A. Males with classic Fabry's disease usually develop neuromuscular symptoms in childhood, including painful crises with burning paresthesias of the distal extremities, often accompanied by fever. However, in female heterozygotes and males with low residual α-galactosidase A levels, disease manifestations may occur for the first time in adulthood. Neuromuscular manifestations can range from painful acroparesthesias to fibromyalgia. Progressive or isolated cardiac, cerebrovascular, and renal disease can develop later. Fabry's disease should be suspected in any patient with a paternal family history of early-onset renal failure. Patients should be examined for characteristic ocular stigmata (cornea verticillata) and dermal signs (angiokeratomas). The diagnosis is confirmed in males by determining α-galactosidase A activity in plasma or peripheral leukocytes. In contrast, female carriers must be tested for one of the specific gene mutations. Early diagnosis is important because enzyme replacement therapy can prevent irreversible organ damage.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is an uncommon multisystem disorder characterized by recurrent episodes of inflammation of cartilaginous tissues. Patients with relapsing polychondritis typically present with the sudden onset of pain and erythema involving the cartilage of the external ear, larynx, trachea, or nose. A nonerosive, seronegative polyarthritis or oligoarthritis affecting small, large, or parasternal joints (23 to 47%); ocular inflammation, including episcleritis or scleritis; and audiovestibular disturbances may also be presenting symptoms. The arthritis is typically acute, migratory, and episodic and resolves spontaneously over days to weeks. Rarely, it can become chronic. Tenosynovitis is also common. Relapsing polychondritis is presumably due to a cell-mediated immune response against cartilage components; biopsies showing acute and chronic inflammation destroying cartilage support the diagnosis. Late sequelae of relapsing polychondritis include deformity of the pinnae or nose, reduced vision or hearing, tracheal narrowing or collapse, and aortic insufficiency resulting from aortic ring dilation as well as other cardiovascular abnormalities. Patients with relapsing polychondritis frequently have associated coexisting diseases, such as systemic vasculitis, various connective tissue diseases (e.g., RA), myelodysplastic syndromes and other cancers, and thyroid disease. Treatment depends on the severity of the presentation and whether major organs are involved. Mild episodes of inflammation are treated with NSAIDs, colchicine, dapsone, and low-dose corticosteroids. Life-threatening or organ-threatening complications are treated with high-dose corticosteroids and immunosuppressive agents such as methotrexate or cyclophosphamide. Infliximab has been anecdotally effective in treatment-resistant cases.

CYSTIC FIBROSIS

In up to 10% of patients with cystic fibrosis (Chapter 89), an episodic, nondestructive, inflammatory oligoarthritis develops, most commonly involving the fingers and lower extremity joints. This arthritis is thought to be due to immune complex deposition caused by chronic lung infections. Attacks last for a few days and may be associated with fever and painful nodular skin lesions and purpura. Other musculoskeletal manifestations include osteoporosis and osteomalacia related to malabsorption and, more rarely, hypertrophic osteoarthropathy (5%) and a small-vessel vasculitis.

PIGMENTED VILLONODULAR SYNOVITIS

Pigmented villonodular synovitis occurs most commonly in the third and fourth decades of life. It is characterized by the onset of unilateral pain and swelling of a joint, typically the knee (80%). Unusually, a tendon, bursa, or another joint can be involved. The synovial fluid is characteristically brown or hemorrhagic, and radiographs may show soft tissue swelling, osteolysis, subchondral cysts, and bone erosions. Pigmented villonodular synovitis is a nonmalignant condition that is best diagnosed by synovial biopsy. Microscopic examination reveals a characteristic histology, including marked synovial cell hyperplasia and subsynovial invasion by masses of polygonal cells, multinucleated giant cells, and lipid-filled macrophages. Hemosiderin deposits are between and within cells and have a characteristic appearance on magnetic resonance imaging scans, with nodular foci of decreased signal on both T1- and T2- weighted images. The treatment for pigmented villonodular synovitis is synovectomy.

FUTURE DIRECTIONS

With the advances being made in immunology and genetics, there will be an increased understanding of the pathogenesis of many of these diseases. Treatments such as immunomodulating biologic agents or cartilage-preserving therapy with metalloproteinase inhibitors will be developed on the basis of new discoveries elucidating the etiology of these unusual disorders.

IDIOPATHIC MULTIFOCAL FIBROSCLEROSIS

WILMER L. SIBBITT JR.

DEFINITION

Idiopathic multifocal fibrosclerosis (IMF) is an inflammatory disease characterized by the development of inflammatory pseudotumors, resulting in some combination of retroperitoneal fibrosis, mediastinal fibrosis, orbital pseudotumor, Dupuytren's contracture, lymphoid hyperplasia, Peyronie's disease, vasculitis, thyroiditis, primary biliary cirrhosis, testicular fibrosis, and pachymeningitis. Retroperitoneal fibrosis (Ormond's disease) is a subset of IMF and is characterized by fibrosis of the retroperitoneum that entraps and distorts retroperitoneal structures, including the great vessels, ureters, nerves, kidneys, and biliary tree.

EPIDEMIOLOGY

IMF is a rare condition with a prevalence estimated at less than 20 in 100,000 and an annual incidence of 1.3 to 3 per 100,000. However, in relevant populations with predisposing conditions, the incidence is higher. IMF is epidemiologically associated with cigarette smoking, asbestos exposure, aortic atherosclerosis, aortic aneurysm, systemic inflammation, drugs (Table 284-1) and toxins, elevated immunoglobulin (Ig) G4, malignant tumors (metastatic carcinoma, carcinoid, lymphoma), retroperitoneal injury (hemorrhage, infection, radiation, surgery, stenting, angioplasty), autoimmune disease, Erdheim-Chester disease, tuberculosis, sarcoidosis, biliary tract disease, gonorrhea, and ascending lymphangitis. T-cell receptor gene rearrangements have been reported, as well as a 40% association with HLA-B27; however, these associations have not been proved. Mean age at presentation is 56 to 64 years, and the male-female ratio is 3 : 1.

TABLE 284-1 DRUGS ASSOCIATED WITH IDIOPATHIC MULTIFOCAL FIBROSCLEROSIS

HIGH-RISK DRUGS
Ergot-derived dopaminergic agonists (pergolide, pramipexole, lisuride, bromocriptine, cabergoline)
Other ergot-derived alkaloids (methysergide, ergotamine, lysergic acid diethylamide [LSD])
Adrenergic agents (amphetamines, cocaine, ephedrine)
Strychnine
Chemotherapeutic agents (carboplatin, mitoxantrone, 5-fluorouracil, cisplatin, floxuridine)
LOW-RISK DRUGS
Non-ergot dopaminergic agents and agonists (levodopa, carbidopa)
β-Adrenergic blockers (atenolol, metoprolol, timolol, sotalol, propranolol, oxprenolol, labetalol)
Diuretics (furosemide, hydrochlorothiazide, chlorthalidone)
Other antihypertensive drugs (methyldopa, hydralazine, prazosin, clonidine)
Acetaminophen

PATHOBIOLOGY

The histopathology of IMF is characterized by multifocal fibrosis, granulation tissue, B cells, T helper cells, large numbers of spindle-shaped cells expressing macrophage markers, and activated fibroblasts. Degenerative and inflammatory diseases of the aorta (atherosclerosis, aortitis, inherited diseases of collagen, trauma, infection, aortic aneurysm) cause the shedding of inflammatory lipids and oxidized lipoproteins through the aortic adventitia into the retroperitoneum, resulting in an intense inflammatory and fibrotic process. Thus, the presence of IMF should trigger an evaluation for aortic disease. Recently, elevated levels of IgG4 have been reported in IMF, suggesting a direct immune causation. Confounding syndromes, including lymphoma, crystal-storing histiocytosis, immunocytoma, neuroblastoma, diffuse retroperitoneal carcinoma (pancreatic, scirrhous gastric, prostate, ovarian, renal, uterine cervix, carcinoid), Wegener's granulomatosis, xanthogranulomatous pyelonephritis, chronic pyelonephritis, tuberculosis, guinea worm infestation, sarcoidosis, and aortic graft infection, should be excluded by appropriate imaging, biopsy, aspiration, and/or serologies.

CLINICAL MANIFESTATIONS

IMF commonly presents as (1) isolated retroperitoneal fibrosis; (2) retroperitoneal, mesenteric, pulmonary, and periarticular fibrosis accompanied by subcutaneous panniculitis; (3) a triad of sclerosing cholangitis, retroperitoneal fibrosis, and Riedel's thyroiditis (Chapter 233); or (4) other less common combinations. The retroperitoneal form of IMF typical presents as (1) ill-defined pain in the lower abdomen, lumbosacral region, or flank; (2) visceral obstruction resulting in vomiting, diarrhea, or dehydration; (3) hydronephrosis or renal insufficiency; (4) severe peripheral edema and venous varicosities; or (5) claudication, pain, dysesthesias, weakness, or spasticity secondary to nerve entrapment and epidural cord compression. Pulmonary emboli, deep vein thrombosis, and obstruction of the bowel, bladder, or bronchi can occur. Mediastinal fibrosis may result in a lymphoma-like mass and superior vena cava syndrome, with edema and venous dilation of the arms, neck, and head. Extrahepatic portal vein obstruction, portal hypertension, esophageal varices, and uveitis may occur. A definitive diagnosis should be made rapidly, and therapy should be seriously considered.

DIAGNOSIS

Computed tomography (CT), magnetic resonance imaging (MRI), and urography with appropriate contrast demonstrate a retroperitoneal inflammatory reaction; obstruction of the ureters, great vessels, biliary tree, or pancreatic ducts; or the presence of diffuse or discrete unifocal or multifocal retroperitoneal masses. Fibrosis may extend into the root of the mesentery,

the bladder, and peribronchial areas, resulting in traction, distortion, and obstruction of the gut, urethra, and bronchi. Indium-111–labeled leukocyte, gallium, and technetium-99m methylene diphosphonate radionuclide scans, and F-18 fluorodeoxyglucose positron emission tomography (PET), are useful to exclude abscess and tumor, demonstrate inflammatory processes, and follow disease activity. Appropriate questioning and testing should exclude autoimmune diseases, drug use, and toxin exposure. After suspicious masses are identified, a biopsy is usually essential to confirm the diagnosis and exclude confounding conditions, especially neoplasia and infection. Biopsy may be guided by CT, MRI, ultrasound, fluoroscopy, mediastinoscopy, laparoscopy, or retroperitoneal exploration, and it can often be accomplished by percutaneous needle biopsy.

PREVENTION AND TREATMENT

Rx

Surgical interventions are often necessary to preserve organ function. These include surgical lysis of fibrotic masses and stenting or catheter drainage of ureteral, biliary, venous, and arterial obstructions to preserve organ function. Surgical repair or stenting of an abdominal aortic aneurysm may be either an exacerbating or an ameliorating factor for IMF; thus, therapy for an aneurysm must be individualized. The most important treatment for IMF is removal of the cause, most commonly an offending drug. Otherwise, treatment for IMF is largely empirical, but it may be necessary because the disease can be progressive and fatal. There are no controlled trials; however, first-line therapy consists of pulse methylprednisolone initially, followed by high-dose oral corticosteroids for 6 months. Long-term maintenance is necessary with azathioprine, cyclophosphamide, colchicine, cyclosporine, tamoxifen, or mycophenolate, with the latter two drugs used most commonly. Statin drugs may also be of benefit. Lifelong anticoagulation is required for those patients with large vein involvement and associated deep vein thrombosis.

PROGNOSIS

The cumulative actuarial survival rate is 86% at 1 year and 78% at 2 years, suggesting that therapy is often indicated.

FUTURE DIRECTIONS

It is anticipated that further research in fibrosing diseases, including the role of inflammation, vascular injury, cholesterol pathways, chronic periaortitis, IgG4-secreting plasma cells, collagen-producing spindle-shaped macrophages, transforming growth factor-β, connective tissue growth factor, bone morphogenetic protein 7, the interleukins, and viral infections, will provide new avenues for the prevention and therapy of IMF.

SURGICAL TREATMENT OF JOINT DISEASE

C. RONALD MACKENZIE AND EDWIN P. SU

Estimates of the prevalence of arthritis and other rheumatic diseases demonstrate the enormous impact these conditions have on the U.S. populace and the health care system in general. More than 21% of U.S. adults (46 million people) currently report physician-diagnosed arthritis. Although the majority of this health burden arises as a consequence of osteoarthritis, the full span of rheumatic diseases contributes to the impact. Arthritis is already the leading cause of disability in the nation, and the number of adults with arthritis and arthritis-attributable limitations in activity is anticipated to approach 67 million by the year 2030. Ultimately, surgical intervention is required in many of these individuals. Factors such as increased patient awareness of the benefits of surgery, the desire for higher activity levels, and improvements in surgical techniques have, in concert with the increasing prevalence of chronic arthritis, fueled the growth in orthopedic surgery performed for the treatment of arthritis. In 2007 it was estimated that 270,000 primary total hip replacements and 507,000 primary total knee replacements were performed in the United States. It is predicted that by 2030, more than 500,000 hip replacements and 3 million knee replacements will be performed each year.

PATHOBIOLOGY

The pathobiology of joint arthritis leading to surgical intervention is essentially that of articular cartilage damage resulting in the loss of mechanical properties, accompanied by inflammation of the joint lining. With continued cartilage deterioration, stiffness and pain ensue. Without the protective layer of articular cartilage, the nociceptive and proprioceptive receptors in the periosteum are activated, leading to unremitting pain (Chapter 29).

Osteoarthritis is the most common cause of end-stage arthritis (Chapter 270). Osteoarthritis may be primary, due to biochemical changes in the cartilage, or it may be secondary to systemic disease affecting the cartilage, joint damage from preexisting inflammatory joint disease, or trauma. Mechanical overload and imbalances lead to further cartilage degradation. Important adaptive processes such as subchondral sclerosis and osteophyte formation occur in response to joint overload; if these become chronic, cyst formation in the subarticular bone may also result. Over time, the osteophytes or bone spurs lead to restricted range of motion (Fig. 285-1).

Inflammatory arthritis, by contrast, is a constellation of diseases involving the synovium. Included in this class of disorders are such important conditions as rheumatoid arthritis (Chapter 272), psoriatic arthritis, and the seronegative spondyloarthropathies (Chapter 273). On a pathologic level, all involve the release of inflammatory mediators in the adjacent synovium, leading secondarily to cartilage destruction. In contrast to osteoarthritis, there is no mechanical overload as a primary mechanism, and no bone sclerosis or osteophyte formation is seen. Rather, the inflammatory synovitis leads to characteristic loss of cartilage matrix, marginal bony erosions, destruction of the joint capsule, and osteopenia (Fig. 285-2).

Trauma is another important cause of joint destruction. Post-traumatic arthritis is initiated by cartilage damage at the time of injury or by secondary mechanical imbalances that result from fractures of juxta-articular bone. Abnormal loading conditions subsequently lead to a wear-and-tear form of cartilage damage.

FIGURE 285-1. Radiograph of an osteoarthritic left hip. Note the asymmetrical joint space narrowing and subchondral sclerosis, which are characteristic of a wear-and-tear pattern of joint deterioration.

FIGURE 285-2. Radiograph of a left hip with end-stage inflammatory arthritis. Note the symmetrical pattern of cartilage loss and the presence of osteopenia.

Osteonecrosis (Chapter 256) is another entity that may lead to joint arthritis. In this process, the blood supply to the bone is compromised, leading to necrosis of the bone supporting the articular surface. The most commonly affected joints are the hip, shoulder, and knee. As the disease progresses, the necrotic bone may collapse, resulting in the loss of articular integrity and progressive cartilage deterioration.

Other causes of arthritis that may lead to joint damage include metabolic disorders (chondrocalcinosis, gout), tumor (synovial chondromatosis), infections (post-septic), and bleeding disorders (hemophilia; Chapter 177).

PREOPERATIVE CONSIDERATIONS

The indications for orthopedic surgery are refractory joint pain and disability. Ultimately, the patient and his or her physicians need to agree that the possible benefits of surgery outweigh the risks. The decision to proceed with surgery therefore reflects a consensus among the patient, the orthopedic surgeon, and the patient's primary physician or rheumatologist. Achieving the necessary decision-making balance may be complicated, especially given the increasing burden of comorbidity in aging patients.

In the elective setting, joint replacement and spine surgery are the most common procedures under consideration. With the former, severe pain and functional limitation unrelieved by conservative treatment are the most common indications for surgical intervention. In the case of spine surgery, severe radiculopathy, nerve dysfunction (e.g., acute footdrop), or myelopathy are additional considerations. In contrast to elective surgery, there are circumstances when a deliberative approach is not possible owing to the development of more urgent, occasionally life-threatening clinical problems. Examples include hip fracture, acute myelopathy, or an infected native or prosthetic joint. In these settings, the patient's general health is at risk, so the medical-surgical team must stabilize the patient as quickly as possible to optimize the outcome. Owing to the coupling of medical advances with increasing financial and resource constraints, a trend to perform surgery in the ambulatory setting has emerged. Indeed, the percentage of all surgical procedures performed on an outpatient basis in the United States rose from 20% in 1982 to 60% in 1995, a phenomenon particularly relevant to the arthroscopic techniques of orthopedic surgery. Among the benefits of these developments has been the opportunity to move the preoperative medical evaluation to the outpatient arena. This change in practice allows time for discourse with the other physicians involved in the patient's care, for supplementary consultation and investigation, and, when necessary, for the institution of therapy directed at optimizing the patient's medical status before the contemplated surgery. Approached in this manner, the preoperative evaluation becomes a focal point of communication among all members of the medical team, enhancing the collaborative nature of the consultative process and, ultimately, the patient's care.

Although the efficacy of preoperative assessment has not been definitively established, the aging and increasing complexity of modern-day surgical patients justifies this clinical practice. Although no consensus exists regarding what constitutes the optimal preoperative medical evaluation, a growing literature pertaining to perioperative medicine supports various core principles that underlie effective medical consultation in this clinical setting.

ANESTHESIA IN THE ORTHOPEDIC PATIENT

Given the protean clinical features that accompany chronic arthritis and the connective tissue diseases, a variety of issues, including airway considerations, the surgical site (joint region), the anticipated duration of surgery, and comorbidities, are important determinants of the type of anesthesia to be used, whether invasive monitoring will be necessary, and the length of time the patient will require intensive monitoring after surgery.

General and regional anesthesia are commonly used in the orthopedic patient. General anesthesia with endotracheal intubation may present a particular danger in patients with rheumatoid arthritis or ankylosing spondylitis. Patients with cervical spine instability or a rigid airway may require fiberoptic intubation. Regional anesthesia may involve local anesthesia or peripheral nerve block for minor procedures or epidural/spinal anesthesia for total joint arthroplasty.

Although the debate concerning the relative merits of regional versus general anesthesia remains unresolved, many procedures, particularly orthopedic surgery, are well suited for regional anesthetic techniques. Advantages of regional anesthesia include a reduction in blood loss, deep vein thrombosis, pulmonary embolism, adverse postoperative respiratory events, and death. Further, postoperative pain, a significant problem for patients with a painful rheumatic disease, may be best managed with regional anesthetic approaches. For example, peripheral nerve blocks using longer-acting anesthetics and infusion methodologies are often employed because they provide excellent intraoperative anesthesia and postoperative pain relief.

A number of options exist for the control of postoperative pain (Chapter 29), including the traditional intravenous or intramuscular routes (systemic) versus the administration of epidural analgesia. Patient-controlled analgesia (PCA) via an epidural route of administration is an effective method of pain control after surgery. Further, PCA facilitates postoperative physical therapy, which is important for the restoration of range of motion in patients undergoing orthopedic procedures. PCA also reduces the systemic absorption of analgesics, thereby minimizing the problem of narcotic-induced respiratory depression. Parenterally administered nonsteroidal anti-inflammatory drugs (NSAIDs) are also useful and can reduce narcotic requirements after major surgery. However, the common contraindications to NSAID therapy, such as peptic ulcer, renal disease, and ischemic heart disease, should be observed in the postoperative setting.

SURGICAL MANAGEMENT

Surgical treatment of joint disease is focused primarily on the relief of pain; secondary objectives are improvement in joint motion and swelling, return to function, and prevention of continued cartilage destruction. Realizing that surgical treatment has limitations and complications, the decision to move forward must be individualized for each patient. Factors such as disease severity, the patient's desired activity level, and the anticipated longevity of the patient are all relevant to decision making. Typically, patients who are candidates for the surgical treatment of joint diseases have failed conservative measures (NSAIDs, physical therapy, intra-articular injections) and have daily pain that affects their quality of life.

ORTHOPEDIC PROCEDURES

Osteotomy

When a structural abnormality around a joint has led to mechanical overload, an osteotomy may be an option to correct alignment problems. The most common sites for osteotomy are the hip, to treat acetabular dysplasia, and the tibia, to realign the knee. In acetabular dysplasia, the hip socket is excessively shallow, leading to abnormal stresses on the articular cartilage and premature osteoarthritis. An acetabular osteotomy can be performed in patients in whom cartilage still remains. By rotating the pelvic bones, a deeper socket can be formed, reducing stresses on the cartilage and thereby slowing the arthritic process. With tibial osteotomy, the knee joint can be realigned to direct forces away from the region of cartilage damage. Usually, a varus (bowlegged) deformity indicates that the medial compartment of the knee is excessively worn, so a tibial osteotomy realigns the joint to direct forces to the uninvolved lateral compartment. Typically, osteotomy is considered an option for patients younger than 40 years; beyond this age, the extent of

cartilage loss generally means that total joint arthroplasty would achieve more beneficial results.

Arthroscopy

Arthroscopic surgery is performed by inserting a camera and specialized instruments into a joint via small, puncture-type incisions. Arthroscopic surgery is effective in the treatment of intra-articular pathology such as meniscal tears of the knee, labral tears of the hip, cartilage flaps, small chondral defects, and loose bodies. However, once the articular cartilage is significantly damaged, arthroscopic débridement is usually ineffective in the absence of mechanical symptoms such as locking and clicking. In some instances, underlying joint arthritis may lead to tears in the meniscus or labrum; if such a tear results in new mechanical symptoms, arthroscopic surgery may be helpful in selected cases. For osteoarthritis, arthroscopic knee surgery is no better than medical therapies.■

In the assessment of the hip, there has been an increased focus on the femoral head and neck architecture as a cause of osteoarthritis. In certain patients, the anatomy of the femoral head and neck may lead to impingement of the femoral neck on the acetabular rim, typically in flexion and internal rotation. This condition, known as *femoroacetabular impingement*, results in repetitive contact between the femoral neck and acetabular rim and is believed to cause labral tears, cartilage damage, and eventual arthritis. Thus, there is currently great interest in reshaping the bones of the femur and acetabulum by so-called osteochondroplasty. This technique is being performed as an open procedure or arthroscopically and provides good symptomatic relief in the short term. The long-term effects and the influence of the procedure on the development of arthritis have yet to be demonstrated.

Synovectomy

Synovectomy refers to removal of the synovial lining of the joint, via either an open or an arthroscopic approach. In conditions such as rheumatoid arthritis, where the disease process involves an actively inflamed synovium, debulking the pathologic tissue may reduce symptoms and slow the destruction of cartilage. In practice, synovectomy can be effective for relieving pain, as long as there is remaining cartilage. However, the procedure has not been predictable in terms of regaining joint motion. Further, once the cartilage is completely worn through, the joint deterioration is too advanced for synovectomy to be helpful. Therefore, synovectomy is generally performed in patients with rheumatoid arthritis (or other forms of inflammatory arthritis) who have active synovitis in the presence of relatively preserved articular cartilage. The most common joints that benefit from synovectomy are the knee and elbow. However, synovectomy should be considered a procedure that merely "buys time," because the synovium will reappear.

Arthrodesis

Arthrodesis, or fusion of a joint, achieves the goal of pain relief by creating a nonmobile joint. Rather than have the arthritic joint surfaces elicit pain with movement, a surgical fusion (arthrodesis) of the articulating bones creates a construct that can bear weight and is stable. This is achieved by removing the articular surfaces from the joint and immobilizing the bones such that they heal in a solid union. This procedure was formerly the treatment of choice for hip and knee arthritis in young, active laborers because of its durability and the avoidance of implants, with their propensity to wear. However, creating stiffness at one joint increases stresses on the joints above and below the fused joint.

Hip fusion may be performed in young patients to treat the sequelae of slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, post-septic arthritis, or osteonecrosis of the femoral head. Fusion surgery can achieve a painless, supportive joint that is capable of bearing heavy loads while avoiding artificial implants. However, the gait mechanics after fusion are altered, requiring more energy for ambulation. Further, the lack of motion at the hip increases stresses on the joints above and below it. Thus, the natural history of a hip fusion is the development of ipsilateral knee arthritis and low back pain after 20 to 25 years, necessitating conversion of the fused hip to a hip replacement (fusion takedown). Although hip arthrodesis is still a viable option in young arthritic patients, the desire to maintain hip mobility in order to sit and drive has made this largely a treatment of the past.

Fusion of the knee joint is performed less commonly than hip fusion. In addition to the lack of motion, which may make it difficult to sit or climb stairs, knee fusion cannot be successfully converted to total knee replacement. Thus, knee fusion is generally considered a salvage procedure, employed mainly when replacement is not possible (e.g., lack of muscle function or persistent infection).

Ankle fusion is still commonly performed as the treatment of choice for tibiotalar arthritis. Historically, the results of ankle replacement have not been durable; therefore, fusing the ankle is the best method of creating a pain-free joint. Further, the ability of the knee and the subtalar joints to compensate for a stiff ankle has made this procedure more tolerable.

Total Joint Arthroplasty

Joint arthroplasty refers to the re-creation of congruent joint surfaces, typically with artificial parts. In certain patients and in non-load-bearing joints such as the elbow, interpositional arthroplasty can be performed by placing a tissue graft between the arthritic surfaces. In the case of weight-bearing joints such as the hip and knee, however, metal and plastic materials produce the most durable results. In such circumstances, the articular surfaces are replaced by shaped materials designed to re-create the joint kinematics; thus, the procedures are commonly called *total hip, knee, and shoulder replacements*.

In general, once the articular cartilage is completely worn or destroyed on both sides of the joint, arthroplasty is the most predictable way to relieve pain. After total joint arthroplasty, it is advisable to reduce stresses on the joint to promote implant longevity. This includes weight loss and avoidance of impact activities; walking, cycling, and gliding-type activities are permitted, but in general, running and jumping should be avoided. Because a total joint arthroplasty involves artificial, moving components, the replaced joints are subject to the same wear and tear as native joints. Thus, they have a finite lifespan that is dependent on the patient's weight and activity level and the implant materials. Subsequent revisions of joint replacements can be difficult and less durable; thus, it is wise to defer joint arthroplasty until there are no other options.

Total hip replacement (THR) was first developed in the 1950s in the United Kingdom using metal and plastic components attached to the bone with cement. The early results were so beneficial and reproducible that the technique rapidly spread worldwide. The National Institutes of Health published a consensus statement in 1994, noting that THR "is one of the most successful surgical procedures and provides immediate and substantial improvement in a patient's pain, mobility, and quality of life. Compared to treatments for other chronic debilitating diseases, THR is highly cost effective."

THR is the treatment of choice for end-stage arthritis caused by any of the aforementioned pathobiologic processes. It involves exposure of the joint, removal of the arthritic femoral head at the level of the femoral neck, and removal of enough acetabular bone to place a prosthetic socket. The femoral implant is inserted into the intramedullary canal and anchored with bone-ingrowth techniques or bone cement. The choice of bearing material (metal, plastic, ceramic) is based on the patient's age and activity level and the surgeon's preference (Fig. 285-3).

FIGURE 285-3. Radiograph of a total hip replacement consisting of uncemented acetabular and femoral components. The articulating materials are a metal ball and a polyethylene liner.

FIGURE 285-4. Radiograph of a total knee replacement. The components are metal, with a polyethylene insert between the tibial and femoral components.

Using modern implant materials and surgical techniques, the implant survival rates are 90 to 95% at 15 years; however, longevity varies, depending on patient factors such as weight and activity. There have been cases in which THR implants lasted more than 30 years.

A major cause of failure of THR is wearing of the implant materials, coupled with the body's reaction to the particulate debris shed into the joint space over time. In the process of immunologic uptake of the debris, inflammatory cytokines are released, causing osteoclasts to resorb periprosthetic bone. The end result of this osteolytic process is that the implant attachments to bone may be compromised, causing loosening of the prosthesis and pain. The hope is that the current generation of implant materials will reduce the amount of particulate wear debris, extending longevity further.

Total knee replacement (TKR) was developed in the United States shortly after THR. The surgery involves removal of the arthritic surfaces of the tibia and femur, followed by their replacement with a metal femoral implant and a metal and/or polyethylene tibial component (Fig. 285-4). It is termed *total* knee replacement to distinguish it from a unicompartmental or *partial* knee replacement.

The recovery from TKR is more difficult than that from THR because of greater postoperative pain and the emphasis on regaining motion. Nonetheless, pain relief and function are usually excellent once recovery is complete. Current studies demonstrate modern implant survival to be 90 to 95% at 15 years, again depending on patient factors.

Although less commonly performed than hip and knee replacement, total shoulder replacement (TSR) is an excellent pain-relieving procedure for glenohumeral arthritis and is preferred over hemiarthroplasty. Developed from experience gained with THR and TKR, TSR uses a stemmed humeral implant with a metal ball and a metal and/or polyethylene glenoid socket. TSR requires an extensive rehabilitation protocol to regain range of motion and strength; however, at 1 year after surgery, 95% of patients have pain-free use of the shoulder.

In general, smaller joints such as the wrist and ankle are better treated with arthrodesis, because the implants necessary for arthroplasty in these joints have limited bone surfaces on which to attach the prosthesis. Additionally, the location of these joints allows the adjacent joints to compensate more effectively.

Surgical Innovations in Joint Arthroplasty

Minimally Invasive Surgery

As in all surgical subspecialties, there has been a movement toward "minimally invasive surgery." This may be a misnomer, because the actual work done inside the joint has not changed. Some surgeons have suggested that the terminology be changed to "smaller incision surgery" or "less invasive surgery." In any case, the idea is to use the smallest incision possible to perform the operation, resulting in less tissue trauma. The interest in this type of surgery has resulted in improvements in instrument design and surgical training. Typically, a hip replacement, until recently performed via a 10-inch incision, can now be done through a 4- to 5-inch incision. Similarly, knee replacement incisions are about half their former length. Despite these surgical advances, even larger benefits have resulted from the increased attention to various nonsurgical modalities directed at more rapid recovery. Examples include the increased use of peripheral nerve blocks and preemptive analgesia and a more expeditious approach to rehabilitation. Such approaches have reduced the average hospital stay to 2 to 3 days after THR and 3 to 4 days after TKR.

Improvements in Implant Technology

As the average age of patients undergoing hip and knee replacement decreases and their activity level increases, the number of revision surgeries is projected to grow. Therefore, much research is being performed to improve the longevity of implant materials. The "gold standard" of arthroplasty is to use a cobalt-chome (metal) implant against a polyethylene (plastic) surface. Unfortunately, the harder metal surface eventually wears away the softer plastic surface. Therefore, biomechanical engineers have developed a more resistant, highly cross-linked polyethylene that demonstrates greater wear resistance in laboratory simulators. Such highly cross-linked polyethylene has been in clinical use for about 7 years, and the early experience suggests significantly less wear compared with standard polyethylene. Other materials such as ceramics and metals are also being used in an attempt to improve longevity. Nonetheless, to date, there is no consensus concerning the optimal weight-bearing surfaces.

Bone-preserving implants have also been developed to provide more options when revision surgery becomes a necessity. Such procedures may require removal of the implant and placement of a new prosthetic device; thus, with more bone available, surgical options are enhanced. One such bone-preserving implant is the hip resurfacing device introduced in the United States in 2006 (discussed more fully later).

Unicompartmental knee replacement is a bone-preserving implant for the knee. As suggested by its name, it involves replacing only one of the three knee compartments with a prosthetic device (Fig. 285-5). Therefore, candidates for unicompartmental knee replacement must have arthritis limited to a single compartment. Because the surgical trauma and dissection are significantly reduced compared with TKR, the patient's recovery tends to be less painful and quicker. However, there is a higher failure rate for unicompartmental knee replacement than for TKR because of the possibility of developing arthritic changes elsewhere in the joint.

Resurfacing Arthroplasty

Hip resurfacing is quickly becoming an alternative treatment to THR in younger, more active patients. In countries where the procedure has been established for a decade or longer, it represents approximately 8% of all primary total hip arthroplasties. The main benefit is preservation of proximal femoral bone in the event that future (revision) surgery is necessary. Rather than removing the femoral head and a portion of the femoral neck, as in THR, the bone is sculpted to accept a metal resurfacing cap (like a tooth), preserving an additional 4 to 5 cm of bone (Fig. 285-6). Preservation of the proximal femoral bone raises an additional risk of failure (i.e., femoral neck fracture below the resurfacing implant), which is estimated to occur in 1% of cases. Although there are no defined age limits for hip resurfacing, the best candidates have been men younger than 55 years, probably because the bone quality in this group is the strongest and most robust. In this age group, the 7-year results of hip resurfacing in Australia have demonstrated a greater than 97% rate of implant survival (free of revision), which is comparable to THR. However, concerns regarding longevity, a greater short-term failure rate than THR, poorer results in women, and metal ion release have led to questions concerning the superiority of this procedure.

Computer Navigation

An orthopedic surgeon relies on visualization, instrument jigs, and experience to re-create the proper joint mechanics. Although the surgeon may know exactly how the artificial components are to be placed, it may be difficult to achieve perfect alignment in every operation. Computer navigation is a tool that can aid in the reproducible positioning of implants. Although some errors are inherent in the precision of computer navigation, such techniques have reliably diminished outlier results. It has yet to be determined whether the longevity of hip and knee replacements inserted with the aid of computer navigation differs from the longevity of those inserted by conventional approaches. For this reason, as well as the expense and time associated with its use, computer navigation is not universally practiced.

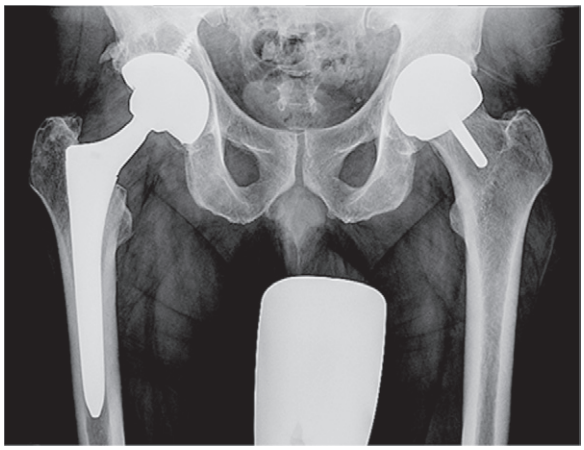

FIGURE 285-6. Radiograph of a patient with a right total hip replacement and a left hip resurfacing. The total hip replacement consists of a longer stem placed in the medullary canal of the femur. The hip resurfacing implant preserves the proximal femoral bone.

ORTHOPEDIC PROCEDURES ON OTHER JOINTS

Elbow, Ankle, Wrist, and Hand

The elbow, ankle, and wrist are less frequently replaced than the hip, knee, and shoulder. With the exception of the rheumatoid wrist, these joints are less commonly afflicted by chronic arthritis. Further, the smaller bones making up these joints translates to a diminished surface area for implant fixation, thus lowering the durability of surgical procedures. Although total joint arthroplasty can be successful at relieving pain in the short term, 10-year results do not approach those of THR or TKR. Synovectomy remains an effective surgical option in selected patients with inflammatory arthritis of the elbow, ankle, or wrist. Patients who develop dysfunctional hand deformities from rheumatoid arthritis may benefit from replacement of the metacarpophalangeal joints with Silastic prostheses and realignment of the small joints of the thumb and fingers with arthrodeses.

Spine

The spine consists of multiple levels of articulating bones, discs, and facets. Although not a "joint" in the typical sense of the word, various spinal segments may be differentially involved in chronic arthritis. Generally, the lumbar spine is most affected, although a similar process can occur in the cervical spine; more than 95% of patients older than 50 years exhibit degenerative changes in the lumbar spine. With aging, the nucleus pulposus of the intervertebral disc loses water content and elasticity, resulting in disc space collapse and increased forces across the vertebral facets. As a consequence of the increased pressure, bone spurs develop, leading to stenosis (narrowing) of the neural foramen. As a result of the degenerative process, or *spondylosis*, patients may experience mechanical back pain with bending, extending, and twisting. Pain, numbness, or weakness radiating down the extremities in a radicular distribution can result from the neural foraminal stenosis.

Mechanical back pain is the most common affliction of the spine. Unfortunately, this constellation of back symptoms is not reliably relieved by surgical intervention. Physical therapy and use of proper back mechanics are the mainstay of treating mechanical back pain.

The advanced sequelae of spinal arthritis is spinal stenosis, which can result in lower extremity pain and weakness. This disorder can reliably benefit from decompressive surgery with or without instrumented fusion. The spinal unit must be evaluated for stability to determine whether spinal fusion is necessary.

Newer surgical treatments, such as lumbar disc replacement, may be used in certain cases to treat spinal disorders. Whereas the "gold standard," vertebral fusion, eliminates painful motion at degenerative disc levels, disc replacement attempts to preserve motion of the spinal unit. As in hip and knee arthrodesis, fusion of the spinal unit increases forces at the levels above and below the fused segment, and further degeneration often occurs. Disc replacement surgery aims to eliminate the progression of arthritis at adjacent levels by retaining motion. Long-term studies comparing disc replacement and spinal fusion are not yet available.

MANAGEMENT ISSUES IN PATIENTS WITH ARTHRITIS UNDERGOING SURGERY

Prevention of Postoperative Infection

Efforts to prevent and detect any infectious processes pre- and postoperatively are of utmost importance. The skin and urinary tract are sites of specific concern, and infection can be ruled out by a careful physical examination and routine preoperative urine culture. In addition, dental consultation may be appropriate in patients with poor oral hygiene and dentition.

Prophylactic antibiotic therapy for total joint arthroplasty patients should begin less than 2 hours before surgery and continue for 24 hours. A common protocol involves cefazolin (Ancef) 1 g every 8 hours (total of three doses) or, in penicillin-allergic patients, vancomycin 1 g every 12 hours (total of two doses).

Peripheral Nerve Injuries

Peripheral nerve injuries arise more often after upper and lower extremity surgery because they generally result from excessive traction on the nerve or, alternatively, nerve compression resulting from prolonged positioning of the extremity during surgery or while in a cast. Early detection and intervention are critical. Patients with chronic neurologic conditions, such as neuropathies in the setting of diabetes or spinal stenosis, are at increased risk of nerve injury from surgery.

Venous Thromboembolism

Venous thromboembolic phenomena after orthopedic surgery are the most thoroughly studied postoperative complications, and pulmonary embolism remains an important cause of mortality (Chapter 98). The orthopedic literature has concentrated on lower extremity arthroplasty, although a recent study suggests that similar approaches should also be considered after total shoulder arthroplasty, where the risk of thromboembolism may be higher than generally appreciated.

After orthopedic surgery, a complicated balance exists between preventing a possibly life-threatening pulmonary embolus and reducing the potential for postoperative bleeding. Numerous protocols have documented the effectiveness of prophylaxis, which should begin at the time of the procedure. Short intraoperative time reduces the risk of deep vein thrombosis, as does the type of anesthesia. Epidural anesthesia reduces the risk of proximal deep vein thrombosis following THR by two- to three-fold and also reduces the overall risk of deep vein thrombosis by at least 20%. Other intraoperative interventions, such as hypotensive anesthesia and intraoperative heparin administration, further reduce thrombogenesis. Mechanical methods can also reduce the risk of thromboembolism. These include compression methodologies such as stockings and various pneumatic devices, foot flexion-extension exercises, and early ambulation. These are safe, effective approaches that do not increase the risk of bleeding.

The mainstay of prevention is prophylactic anticoagulation, which should begin immediately following surgery. Regimens include aspirin, warfarin, and low-molecular-weight heparin, often used in combination with various mechanical compression devices.

Fat Embolism Syndrome

Fat embolization, a well-described complication of skeletal trauma, can also occur after procedures involving instrumentation of the femoral medullary canal. Although the embolization of fat is believed to occur in almost all patients who sustain hip or femoral fractures, 1 to 3% of patients undergoing joint replacement surgery (particularly simultaneous bilateral procedures) develop fat embolism syndrome (FES).

The signs and symptoms of FES involve the respiratory, neurologic, and hematologic systems, as well as the skin. The time of onset is variable, with hemodynamic instability developing almost immediately in some patients or insidiously over the first 2 to 3 postoperative days in others. The latter patients gradually become hypoxemic, may be hypotensive, and are often confused. Transient thrombocytopenia is common. Respiratory signs are the most common manifestation. The majority of patients develop mild to moderate hypoxemia or radiographic changes (mainly bilateral alveolar infiltrates), but only a minority develop life-threatening adult respiratory distress syndrome. Neurologic manifestations range from mild drowsiness to acute confusional states to severe obtundation and coma, all consequences of the hypoxemia and the direct effect of fat embolization on the brain. The skin eruption, which is rare in total joint arthroplasty patients, takes the form of a petechial rash involving the conjunctiva and oral mucosa and may be distributed over the folds of the neck and axilla. Retinal edema and hemorrhage are also common.

Although patients suspected of having FES need to be closely monitored, in most cases, FES that develops after total joint arthroplasty is relatively benign. Treatment is supportive and includes the administration of oxygen and the prevention of pulmonary hypertension (by fluid restriction and the use of diuretics and venodilators). Corticosteroids are not effective. In the majority of patients, the condition resolves within 3 to 7 days, although in severe cases, the mortality rate is 5 to 15%, even with modern aggressive therapy.

Cervical Spine Involvement

In rheumatoid patients who exhibit advanced destructive disease, the presence of cervical spine instability should be ruled out before surgery with flexion-extension films. Patients with neck instability from rheumatoid arthritis may or may not exhibit symptoms such as neck pain, neck crepitus on range of motion testing, radicular symptoms, arm and/or leg weakness, or bladder and bowel dysfunction. Affected patients should wear a soft cervical collar to the operating room. When possible, epidural or spinal anesthesia should be used.

Conversely, in patients with ankylosing spondylitis, the rigid cervical spine may present technical challenges for the anesthesiologist during intubation. Fiberoptic methods are often employed in this clinical setting.

Immunosuppressive and Anti-inflammatory Therapy

The potential contributions of corticosteroids, disease-modifying antirheumatic drugs (DMARDs), and newer biological agents (Chapters 34 and 35) to the genesis of postoperative infection and wound dehiscence are well recognized by clinicians, although the debate concerning how to manage these medications in the perioperative setting is not settled. The primary challenge in this context is to achieve an optimal balance between maintaining control of the underlying disease and minimizing the risk of postoperative wound infection and/or wound breakdown.

Methotrexate is the most commonly used DMARD for the treatment of rheumatoid and other forms of inflammatory arthritis, so it is frequently seen in the perioperative setting. Given its importance in disease control, coupled with low rates of postoperative wound infection and dehiscence associated with its use, it appears to be safe—indeed, desirable—to continue methotrexate throughout the perioperative period.

With respect to the biological (anti–tumor necrosis factor) agents (etanercept, infliximab, adalimumab), recommendations formulated by international groups suggest that such agents be discontinued for short periods before surgery, generally 2 to 4 weeks. Some favor the longer 4-week interval for infliximab and adalimumab owing to the longer half-life of these agents. There is virtually no information concerning postoperative infection and wound healing with the newer agents such as anakinra, rituximab, and abatacept. Recommendations similar to those for the other biological agents must suffice until more data can be gathered.

The other important drugs commonly encountered in the perioperative setting are corticosteroids. In addition to problems related to the wound, there is concern about postoperative adrenal insufficiency. Traditionally, steroids have been shown to increase the rate of wound infection and dehiscence in surgical patients, although data derived from the orthopedic setting remain scant. Similarly, the published experience concerning postoperative adrenal insufficiency is scant. In contrast to methotrexate and the biological therapies, however, the question is not whether to stop corticosteroids before surgery, because this is generally not feasible. Rather, management considerations pertain to how much steroid augmentation (stress dosing) will be required, and for how long. In this regard, a nuanced approach, premised on patient-specific considerations, is required. For the patient managed with low doses of corticosteroid (≤7.5 mg/day) or on any dosage for less than 3 weeks, stress-dose steroid therapy is unnecessary, and maintenance of the patient's usual daily dosage should be sufficient. In contrast, for patients taking larger doses (≥20 mg/day) for longer periods (>3 weeks), it is prudent to assume that secondary adrenal suppression exists, justifying the use of stress-dose steroid therapy. For those taking intermediate doses (7.5 to 20 mg/day), decision making must be individualized. In addition to the dosage and duration of steroid therapy, other considerations include the presence of diabetes, the use of other immunosuppressive therapy, the presence of hypoalbuminemia, the patient's nutritional status, and the magnitude of the surgical procedure.

INTRODUCTION TO MICROBIAL DISEASE: HOST-PATHOGEN INTERACTIONS

W. MICHAEL SCHELD

Infectious diseases have profoundly influenced the course of human history. The "black death" (caused by *Yersinia pestis*) changed the social structure of medieval Europe, in the process eliminating approximately a third of the population. The outcomes of military campaigns have been altered by outbreaks of diseases such as dysentery and typhus. Examples include Napoleon's retreat from Russia, after typhus did more damage to his army than the opposition forces did; the decision by the French to sell the Louisiana Territory after French soldiers died from yellow fever in Cuba and the Gulf Coast; and the introduction of smallpox to the nonimmune population of the New World by Europeans, thus facilitating the "conquest" and the dawn of the colonial age. Malaria influenced the geographic and racial pattern and distribution of hemoglobins and erythrocyte antigens in Africa. The development of *Plasmodium falciparum* is inhibited by the presence of hemoglobin S, and Duffy blood group–negative erythrocytes are resistant to infection with *Plasmodium vivax.* Thus, populations with these erythrocyte factors are found in areas where malaria is common.

Infections are a major cause of morbidity and mortality in the world. Of the approximately 53 million deaths worldwide in 2009, at least a third were due to infectious diseases. In the United States, pneumonia is the fifth leading cause of death overall and the most common cause of death related to infection. In addition, invasive disease caused by *Streptococcus pneumoniae* and community-acquired pneumonia overall have increased in incidence over the past decade. Acquired immunodeficiency syndrome (AIDS) threatens to disrupt the social fabric in many countries of Africa and is severely distressing the health care system in the United States and other parts of the world. The year 2006 marked the 25th "anniversary" of the AIDS epidemic. Approximately 33 million people worldwide are currently infected with human immunodeficiency virus (HIV), and since 1981, approximately 25 million have died (≈ 600,000 in the United States alone). AIDS is now the leading cause of death in sub-Saharan Africa.

Infection can be defined as the multiplication of microbes (from viruses to multicellular parasites) in the tissues of the host. The host may or may not be symptomatic. For example, HIV infection may cause no overt signs or symptoms of illness for years. The definition of infection should also include the multiplication of microbes on the surface or in the lumen of the host that causes signs and symptoms of illness or disease. For example, toxin-producing strains of *Escherichia coli* may multiply in the gut and cause a diarrheal illness without invading tissues. Microbes can cause diseases without actually coming in contact with the host by virtue of toxin production. *Clostridium botulinum* may grow in certain improperly processed foods and produce a toxin that can be lethal on ingestion. A relatively trivial infection such as that caused by *Clostridium tetani* in a small puncture wound can cause devastating illness because of a toxin released from the organism growing in tissues. It has now become apparent that multiple virulence factors of microorganisms can be carried in tandem on so-called pathogenicity islands of the genome (the "virulome").

We live in a virtual sea of microorganisms, and all our body surfaces have indigenous bacterial flora. This normal flora actually protects us from infection. Reduction of gut colonization increases susceptibility to infection by pathogens such as *Salmonella enteritidis* serovar *typhimurium.* Bacteria that constitute the normal flora are thought to exert their protective effect by several mechanisms: (1) utilizing nutrients and occupying an ecologic niche, thus competing with pathogens; (2) producing antibacterial substances that inhibit the growth of pathogens; and (3) inducing host immunity that is cross-reactive and effective against pathogens. These conclusions appear to be oversimplistic, however. For example, colonization of the gastrointestinal tract with *Bacteroides fragilis* expressing an immunodominant bacterial polysaccharide, through dendritic cell activation and induction of a T_H1-mediated response, leads to a splenic response characterized by normal numbers of $CD4^+$ T cells, lymphoid architecture, and systemic lymphocytic expansion. Thus, a single bacterial molecule in our gut is necessary to make us "immunologically fit." In addition to the normal flora, transient colonization may be seen with known or potential pathogens. This may be a special problem in hospitalized patients because it can lead to nosocomial infection (Chapter 290).

Only a small proportion of microbial species can be considered primary or professional pathogens, and even among these species, a relatively small number of clones have been shown to cause disease. For example, epidemic meningococcal meningitis and meningococcemia are due to a small number of clones of *Neisseria meningitidis,* and the worldwide explosion of penicillin-resistant *S. pneumoniae* can be traced to a few clones originating in South Africa and Spain. This observation supports the concept that pathogenic organisms are highly adapted to the pathogenic state and have developed characteristics that enable them to be transmitted, attach to surfaces, invade tissue, avoid host defenses, and thus cause disease. In contrast, opportunistic pathogens cause disease principally in impaired hosts, and these organisms, which may be harmless members of normal flora in healthy persons, can act as virulent invaders in patients with severe defects in host defense mechanisms. Although opportunistic infection has traditionally been viewed as the exploitation of a weakened host through physiologic stress or immunocompromise (or both) by relatively "avirulent" pathogens, this is an oversimplification. For example, *Pseudomonas aeruginosa* recognizes host immune activation, specifically by binding interferon-γ to a cell surface protein OprF, which in turn, through a quorum-sensing signaling system, leads to the overexpression of virulence determinants such as PA-I (lecA) and pyocyanin. Thus, bacteria have developed a "contingency system" that recognizes immunologic perturbations in the host and counters this response by the expression of virulence factors.

Pathogenic organisms may be acquired by several routes. Direct contact has been implicated in the acquisition of staphylococcal disease. Airborne spread, usually by droplet nuclei, occurs in respiratory diseases such as influenza and in severe acute respiratory syndrome (SARS). Contaminated water is the usual vehicle in *Giardia* infection and typhoid fever. Food-borne toxic illnesses may be caused by extracellular toxins produced by *Clostridium perfringens* and *Staphylococcus aureus.* Blood and blood products may be vectors for transmitting hepatitis B and C viruses, as well as HIV. Sexual transmission is also important for these agents and for a variety of other pathogens, including *Treponema pallidum* (syphilis), *Neisseria gonorrhoeae* (gonorrhea), and *Chlamydia trachomatis* (nonspecific urethritis). The fetus may be infected in utero, and the infection may be devastating if the agent is rubella virus or cytomegalovirus. Arthropod vectors may be important, as illustrated by mosquitoes for malaria and dengue, ticks for Lyme disease and ehrlichiosis, and lice for typhus.

Pathogens are able to cause disease because of a finely tuned array of adaptations, including the ability to attach to appropriate cells, often mediated by specialized structures such as the pili on Gram-negative rods. Microbes such as *Shigella* species have the ability to invade cells and cause damage. Toxins may act at a distance or may intoxicate only infected cells. Pathogens have the ability to thwart host defenses by a variety of ingenious maneuvers. The antiphagocytic coat of the pneumococcus is an example. Organisms may change their surface antigen display at an astonishingly rapid rate to outmaneuver the host immune system. Examples include influenza virus and trypanosomes. Certain pathogens have the ability to inhibit the respiratory burst of phagocytes *(Toxoplasma gondii),* and others can destroy phagocytic cells that have engulfed them (e.g., *Streptococcus pyogenes*). The environment plays an important role in infection, both in transmission and in the host's ability to combat the invader. The humidity and temperature of air may affect the infectivity of airborne pathogens. The sanitary state of food and water, woefully lacking in many areas of the developing world, is an important factor in the acquisition of enteric pathogens, one of the major causes of mortality and morbidity, such as physical and mental developmental delay leading to poor performance in school and other consequences. The malaria associated with the "bad air" of swamps is, in fact, due to the mosquitoes there, but the environmental association was appropriate. The nutritional status of the host is clearly a significant factor in certain infectious diseases. It is likely that micronutrient deficiency contributes to the invasion and multiplication of certain pathogens. A new concept is the possibility that infectious diseases cause malnutrition through a vicious circle of diarrhea leading to dehydration and poor oral intake, resulting in secondary diarrhea with a propensity for "stunting" and delaying intellectual development. Establishment of infection is a complicated interplay of factors involving the microbe, the host, and the environment.

Host reaction to infection may result in illness. For example, previous infection with *Campylobacter jejuni* is responsible for about 40% of cases of Guillain-Barré syndrome. The mechanism is thought to be the production of antibodies against *C. jejuni* lipopolysaccharides that cross-react with gangliosides in peripheral nerves. Similarly, much of the damage resulting from meningitis is due to the host's response to invading bacterial pathogens.

With some exceptions, infectious diseases are often treatable and curable. Thus, it is important to make an accurate etiologic diagnosis and institute appropriate therapy promptly. In acute infections such as pneumonia, meningitis, or sepsis, rapid institution of therapy may be life-saving; thus, a presumptive etiologic diagnosis should be established before a definitive diagnosis. This presumptive diagnosis is based on the history, physical examination, epidemiology of illness in the community, and rapid techniques such as microscopic examination of appropriate Gram-stained specimens. Antimicrobial therapy can then be instituted for the presumptive etiologic agents, but it must be reevaluated as more definitive diagnostic information becomes available.

The study as well as the understanding of infectious diseases is a dynamic process. A number of factors or themes of current interest contribute to this conclusion, including the following:

EMERGING INFECTIONS. The most obvious is AIDS, but recent examples with a major impact on the public health in the United States include community-associated methicillin-resistant *S. aureus*, a hypervirulent strain of *Clostridium difficile*, and the 2009 H1N1 influenza. More than 300 new, emerging infectious diseases have been described in the last 70 years; approximately 60% are zoonoses associated with geographic "hotspots." Their emergence is driven largely by ecologic, socioeconomic, and environmental factors.

GENOMICS AND OTHER "OMICS." The exact sequence of the genome of more than 2000 microbes relevant to humans has been determined. This new information, in concert with genomic information from multicellular organisms such as the *Anopheles* mosquito, offers significant promise for the development of new therapies and vaccines. Careful analysis of the genomes of pathogens will continue to yield important information about the pathogenesis of infection. For example, genome sequencing of group A streptococci, collected over time with relevant robust clinical information, has detected the acquisition of new determinants (often by prophage) responsible for increased virulence and resulting in toxic shock syndrome, necrotizing fasciitis, or both. Proteomics, transcriptomics, metabolomics, and virulomics have transformed research on infectious diseases and promise significant improvements in diagnostics and therapeutics in the future.

GENETIC FACTORS ALTERING SUSCEPTIBILITY TO INFECTION AND THE RESPONSE TO INFECTIOUS DISEASES. This field promises new and significant information relevant to the wide variety of responses to infectious diseases in humans. For example, an overvigorous response, with generation of tumor necrosis factor-α, may accentuate the development of cerebral complications in falciparum malaria. Analysis of single-nucleotide polymorphisms of the human genome will lead to an enhanced understanding of two fundamental issues in infectious diseases: why invasive, overt disease develops in only a small fraction of individuals colonized with a given microbe, and why infections are more severe in some people than in others. Variants in genes that encode molecules that mediate attachment, pathogen recognition, inflammatory cytokine response, and innate and adaptive immunity are being identified at an astonishing rate.

INNATE IMMUNITY. This is the most active field in immunology. The identification of pattern recognition receptors (e.g., Toll-like receptors [TLRs] and nucleotide oligomerization domain [NOD]-like receptors) that recognize pathogen-associated molecular patterns, as well as endogenous substances reflecting tissue injury (e.g., alarmins), has revolutionized our understanding of the early host response to infection. Agonists or antagonists of TLRs have already entered clinical trials as adjuvant therapies (e.g., editoran for sepsis) or to improve the immunogenicity of vaccines. The other area that has exploded recently is the study of antimicrobial peptides (e.g., defensins, cathecidins, histatins, galectins) and their role in the early response to infectious disorders.

ANTIMICROBIAL RESISTANCE. The development of new antimicrobial agents has slowed despite the burgeoning problem of antimicrobial resistance. This disconnect has been the focus of meetings among the pharmaceutical industry, the Infectious Diseases Society of America, the Food and Drug Administration, and others. Multiresistant pneumococci, vancomycin resistance in *S. aureus,* vancomycin-resistant enterococci, and, perhaps most important, multidrug-resistant gram-negative bacilli (MDR-GNB) are just a few examples. Some MDR-GNB are susceptible to only a few agents of "last resort," such as colistin or tigecycline; others are truly untreatable (Chapter 313). Unfortunately, new agents active against these strains are years, if not decades, away from introduction.

THE ROLE OF INFECTIOUS AGENTS IN CHRONIC DISEASES. Many so-called idiopathic diseases may in fact have an infectious basis. Conditions for which there is some evidence (but not conclusive proof) of an infectious basis include diabetes, atherosclerosis, acute leukemia, collagen vascular diseases, and inflammatory bowel disease. Detection of "uncultivatable" microorganisms by newer techniques, such as 16S RNA analysis, may uncover agents responsible for "noninfectious" diseases or suggest a role in conditions that are considered infectious but in which the pathogen or pathogens are controversial (e.g., bacterial vaginosis). In addition, we know that hepatitis C virus, human papillomavirus, and *Helicobacter pylori* cause human cancers. Furthermore, changes in our own microbiome may lead to disease. Alterations in the gut microbiome are associated with obesity. Another recent example comes from experiments with mice lacking TLR5. These mice develop hyperphagia and hallmark features of the metabolic syndrome, including hyperlipidemia, hypertension, insulin resistance, and increased adiposity, associated with an altered gut microbiome. Further, transfer of this changed microbiota into germ-free wild-type mice induces most features of the metabolic syndrome in the recipients.

PRINCIPLES OF ANTI-INFECTIVE THERAPY

GEORGE M. ELIOPOULOS

Among the pharmaceutical agents used in the treatment of human disease, antimicrobial agents are distinctive because they target invading microorganisms rather than abnormal human cellular functions. As a result, to select an appropriate antimicrobial regimen, it is necessary to consider both the activity of the agent against the known or suspected pathogen and the effects that agent might have on the individual under treatment. Although the term *anti-infective agent* can be used more broadly to include substances that ameliorate infection by altering the virulence of the pathogen or modulating the host's response to infection, for purposes of this chapter, *anti-infective agent* and *antimicrobial agent* are used interchangeably to refer to drugs that inhibit the growth of microbial pathogens. This chapter focuses primarily on agents directed against bacterial pathogens, although many parallels can be drawn to the use of antimicrobial agents for the treatment of fungal, viral, or parasitic infections.

On the time scale of human history, the modern antibiotic era is short. Since the introduction of penicillin for general clinical use in the mid-1940s, the numerous antimicrobial agents developed for human use have saved countless lives and have led to amazing advances in cancer chemotherapy, organ transplantation, and implant surgery that have improved and extended the lives of many others. Unfortunately, over time, resistance to available antibiotics has become widespread among many common bacterial pathogens, making the selection of appropriate antimicrobial regimens ever more

challenging and threatening to thrust an unfortunate few into a situation resembling the pre-antibiotic era.

SELECTING ANTIMICROBIAL THERAPY TARGETING THE PATHOGEN

Empirical Antimicrobial Therapy

In most instances, selection of the initial antimicrobial therapy proceeds empirically, before a causative organism is identified or tested for susceptibility to antimicrobial agents. The clinician's first decision is whether a patient's symptoms are likely to represent infection. Fever may result from neoplastic, rheumatologic, or other noninfectious processes and does not necessarily imply the presence of infection. Noninfectious causes of fever, such as deep vein thrombophlebitis, drug reaction, or vasculitis, may pose just as great a risk to the patient as infection and must not be overlooked.

Additional symptoms, signs, and laboratory or radiographic data usually help define whether infection is likely and, if so, localize the organ systems involved. This information allows an initial prediction about the organisms likely to be involved. For example, if the initial data cause one to suspect a diagnosis of community-acquired pneumonia in a previously healthy person who does not have any unusual exposures, *Streptococcus pneumoniae* and atypical bacteria such as *Mycoplasma pneumoniae* or *Chlamydophila pneumoniae* would be prominent on the list of potential pathogens to be targeted when selecting antimicrobial therapy. Examination of a Gram-stained slide of expectorated sputum may provide valuable information. The prominent appearance of gram-positive cocci in clusters, for example, would alert the clinician to the possible presence of *Staphylococcus aureus,* many isolates of which are now methicillin resistant.

Guidance regarding the probable pathogens for site-specific infections and the susceptibility of these organisms to antimicrobial agents is available from a number of sources. In some cases, the susceptibility of suspected pathogens can be predicted with a high degree of certainty. For example, *Streptococcus pyogenes* remains uniformly susceptible to penicillin G. In other instances, resistance has emerged to antimicrobials previously considered to be highly active against a species. Resistance rates for a given organism may vary widely by region, by health care institution, or even by patient care area within a hospital. For this reason, access to periodically updated, cumulative antibiotic susceptibility profile data specific to an institution can be very important. Typically presented in tabular form, these "antibiograms" show the percentage of recently isolated bacterial pathogens that proved "susceptible" to the antibiotics tested and can help guide the selection of appropriate empirical regimens at that practice site.

There is mounting evidence that selection of an appropriate regimen (i.e., one that contains an antimicrobial that can be expected to inhibit the causative pathogen at the site of infection) and the prompt initiation of that empirical treatment result in improved clinical outcomes in those with serious infections. Published guidelines for the treatment of community-acquired pneumonia advise administration of the first dose of appropriate antimicrobial therapy while the patient is still in the emergency room.

Whenever possible, samples of purulent exudates, blood, or other body fluids suspected to be infected should be obtained for culture before starting antimicrobial therapy. Identification and susceptibility testing of the microorganisms detected can be used to direct subsequent definitive treatment. At times, however, this principle must be overridden. For example, when bacterial meningitis is suspected, antibiotic therapy (often with adjunctive corticosteroids) must not be delayed when a lumbar puncture cannot be performed promptly to obtain material for culture. In such instances, blood samples taken for culture before the administration of antibiotics often reveal the causative organism, or the pathogen may grow from spinal fluid even if lumbar puncture is delayed.

Definitive Antimicrobial Therapy

Identification of the causative microorganism and determination of its susceptibility to available drugs are the basis for optimizing definitive antimicrobial regimens. Often, the antibiotics used for empirical therapy are appropriate for definitive therapy and can be continued. At other times, the results allow one to switch to a narrower spectrum, better tolerated, or less expensive antimicrobial. In some instances, test results indicate the need to broaden the spectrum of an anti-infective regimen by adding or substituting agents active against pathogens inadequately targeted by the initial empirical regimen.

In almost all cases, it is desirable to test an infecting organism's susceptibility to antimicrobials that may be useful. To extend the example cited earlier, although it is not necessary to test the susceptibility of *S. pyogenes* to penicillin G, some isolates are resistant to macrolide antibiotics (e.g., erythromycin, azithromycin) and other drugs, so the testing of alternative agents might be useful for patients who are intolerant of β-lactam antibiotics. Even when the activity of certain antimicrobials can be predicted with great confidence, susceptibility testing is still useful. For example, surveillance studies examining hundreds of isolates have predicted that vancomycin or linezolid would inhibit virtually all *S. aureus* strains recovered from initial clinical specimens. Therefore, on statistical grounds, testing these agents would not seem warranted; however, rare isolates resistant to these agents have now been encountered, and it is advantageous to detect such isolates for both therapeutic and epidemiologic purposes. For most bacterial pathogens, resistance to commonly used agents is sufficiently frequent that testing of antimicrobials being considered for definitive therapy is essential. Organisms of the family Enterobacteriaceae that are resistant to multiple antibiotics are isolated often enough, even among outpatients, that susceptibility to agents previously considered broadly active, including third-generation cephalosporins, fluoroquinolones, and aminoglycosides, is no longer assured. Even more challenging problems of drug resistance are encountered among isolates of species such as *Pseudomonas aeruginosa, Acinetobacter baumannii,* and *Stenotrophomonas maltophilia.*

Susceptibility Testing

Several methods are available for determining the susceptibility of a bacterial isolate to antimicrobial agents being considered for therapy. Tests used in clinical microbiology laboratories today are variations of three methods: serial dilution, disc diffusion, and gradient diffusion. The minimal inhibitory concentration (MIC) represents the lowest concentration of an antimicrobial tested that inhibits growth of the microorganism in test media.

In the dilution method, the antimicrobial is diluted in broth or agar to span a range of (usually) two-fold decreasing concentrations, and the medium is then inoculated with a standardized number of organisms. After incubation for a specified period (usually 16 to 24 hours) at 35 to 37° C, the series of dilution tubes or microtiter wells (for broth dilution) or agar plates (for agar dilution) is examined for growth. The MIC is determined by direct inspection as the lowest concentration that prevents turbidity of the broth or colony formation on agar. Modifications of this method allow the automation of many steps in the process, permitting more efficient test performance in clinical laboratories.

In the disc diffusion method, paper discs impregnated with a standardized amount of the antimicrobial are placed on an agar plate, the surface of which has been seeded with the bacterium to be tested. During incubation, the antimicrobial diffuses from the disc into the surrounding agar and inhibits growth of the seeded organism. After a specified period of incubation, the zone of growth inhibition around the disc is measured. By this method, the MIC is not determined directly. Instead, relying on accumulated data correlating inhibition zones with MICs, the measured zone is used to predict the susceptibility of the organism to the drug tested.

The gradient diffusion method is similar to the disc diffusion method, except that instead of using a round paper disc impregnated with a single concentration of the antimicrobial, this test uses a strip impregnated with the antimicrobial applied in a concentration gradient along its length. The strip is laid on the surface of an agar plate that has been inoculated with a suspension of the organism to be tested, and the plate is then incubated. By visually inspecting where the zone of growth inhibition on the agar surface intersects the strip (which is marked at intervals corresponding to MIC equivalents), it is possible to determine the MIC value directly.

To perform and interpret the results of susceptibility studies, it is necessary to identify the organism to be tested. This knowledge allows the selection of appropriate interpretive criteria to determine whether an organism is "susceptible," "intermediate," or "resistant" to an antimicrobial based on measurement of the MIC or the inhibition zone diameter. To illustrate this point, consider that an enterococcus is determined to be susceptible to penicillin if the MIC is less than or equal to 8 μg/mL, whereas for viridans streptococci, the corresponding breakpoint for susceptibility to penicillin is a MIC of 0.12 μg/mL. Thus, knowledge that the MIC of a gram-positive coccus growing in short chains is 2 μg/mL does not allow the determination of whether it is susceptible to penicillin unless the organism has been identified.

Additional tests are sometimes required to fully assess susceptibility to an antimicrobial. For oxacillin-susceptible *S. aureus,* a test for penicillinase production is performed to assess susceptibility to penicillin G. For erythromycin-resistant, clindamycin-susceptible *S. aureus,* the laboratory may perform

a supplementary D-zone test before reporting the clindamycin result. A positive D-zone test (i.e., blunting of the inhibition zone around a clindamycin disc in proximity to an erythromycin disc) predicts the presence of *erm* genes. Their product, a ribosomal methylase, can confer resistance to clindamycin if expressed; however, clindamycin is a poor inducer of this resistance trait (in contrast to erythromycin, which is a good inducer). Mutants with constitutive production of methylase can be selected during treatment, resulting in the emergence of clindamycin resistance and an increased risk of clinical failure when this drug is used to treat serious staphylococcal infections caused by strains with the *erm* gene.

In principle, tests for the presence of resistance genes, their products, or both can be used in place of phenotypic resistance testing. Such methods have the potential to provide answers more rapidly than can be obtained with the usual susceptibility tests of growth inhibition, which generally require several hours of incubation. However, at present, these tests have not been widely adopted, with the exception of testing for methicillin resistance by detection of the *mecA* gene or its product, penicillin-binding protein 2a.

Bactericidal Activity

In some circumstances, an antimicrobial regimen that kills pathogenic microorganisms would be preferable to an alternative regimen that only inhibits growth of the pathogen. Bactericidal activity is desirable in the treatment of endocarditis or meningitis; in these infections, bacteriostatic agents have generally performed poorly, possibly because of inadequate host responses to infection at these sites. Tests to measure the bactericidal activity of an antibiotic in vitro have been developed. Bactericidal activity is usually defined as a 99.9% reduction in the number of viable colony-forming units relative to the inoculum density at a specified incubation time, which is usually 20 to 24 hours.

Despite the theoretical benefit of determining the bactericidal activity of an antibiotic or drug regimen, these tests are rarely used clinically because of several factors, including (1) the labor-intensive nature of the tests, (2) the potential for discordant results owing to the various methods and criteria for determining bactericidal activity, and (3) imperfect correlation between bactericidal activity measured in vitro and clinical outcomes observed.

SELECTING ANTIMICROBIAL THERAPY APPROPRIATE TO THE INFECTION AND PATIENT

Nature of the Infection

Determination that a pathogenic microorganism is susceptible to an antibiotic in vitro does not ensure that treatment with that drug will result in a successful clinical outcome. The antimicrobial must reach the site of infection in adequate concentration, which is generally assumed to be some multiple of the MIC, and it must demonstrate activity in the infection milieu. For some infections and antimicrobials, these requirements cannot easily be met.

A number of antimicrobials fail to penetrate into cerebrospinal fluid sufficiently well to permit their use for the treatment of bacterial meningitis in adults. First-generation cephalosporins or aminoglycosides given intravenously do not enter the subarachnoid space well enough to allow their use as primary agents for treatment of this disease. Aminoglycosides have been administered by intrathecal or intraventricular instillation when needed for the treatment of gram-negative meningitis, but the availability of newer β-lactams with broad activity, high potency, and reasonable penetration represents a major advance.

In other situations, antimicrobials may penetrate to the site of infection, only to be inactivated by local factors. For example, daptomycin is inactivated by interaction with pulmonary surfactant, so this antibiotic is not indicated for the treatment of bronchopneumonia, even though it is highly active against *S. pneumoniae* isolates in vitro. Antibiotics can also be inactivated by cellular debris or macromolecules present within abscesses, and some exhibit reduced potency at the low pH and reduced oxygen tensions prevailing at these sites. Finally, high densities of microorganisms within abscesses may elaborate sufficiently high concentrations of β-lactamases to inactivate some relatively labile β-lactam antibiotics. All these factors provide a rationale for the drainage of large abscesses as an adjunct to antimicrobial therapy.

Bacterial infections associated with foreign bodies such as artificial joints, cardiac pacemakers, or prosthetic heart valves can be particularly difficult to eradicate without removing the foreign material. The reasons are not completely understood, but they relate, at least in part, to the presence of biofilm, which is composed of bacteria embedded within extracellular material that is adherent to the foreign body. Bacteria recovered from biofilms are metabolically different from and less susceptible to antimicrobial agents than planktonic cells (i.e., those freely suspended in liquid medium) of the same organism. Rifampin is often added to antimicrobial regimens for the treatment of infections involving prosthetic material. This inhibitor of RNA polymerase rapidly penetrates into biofilms and demonstrates relatively similar activity against both biofilm-associated and planktonic cells of a susceptible organism. However, because resistance to rifampin emerges rapidly, it is not used as a single agent in these circumstances; rifampin must be combined with a second active drug to minimize the risk that resistance will emerge. Despite such approaches, many infections involving implanted devices prove refractory to antimicrobial therapy alone and require removal of the foreign material for eradication.

Host Factors

After considering the nature of the infection and the antimicrobials determined in vitro to be active against a bacterial isolate (or likely to be active against probable pathogens when an isolate is not yet available), the ultimate choice of an antimicrobial regimen must take into account a number of additional patient-specific factors, some examples of which are examined in the following paragraphs.

Allergies

It is imperative to obtain a history of previous allergic reactions to antimicrobial agents. Some reactions are by nature so severe and potentially life-threatening that one must avoid using the same agent or drugs within the same class for which cross-reactivity is likely to occur. Examples of such reactions include an immediate hypersensitivity reaction to penicillin (e.g., hives, lip swelling, laryngeal edema, circulatory collapse) or a mucocutaneous bullous eruption from a sulfonamide (e.g., Stevens-Johnson syndrome).

In cases in which the allergic reaction was mild, such as a faint, self-limited rash in a patient receiving penicillin, the clinician may elect to use a related antimicrobial, such as a cephalosporin, when the probability of cross-sensitivity and the risk for a severe adverse outcome if a reaction were to occur are both assessed to be low. In these instances, careful monitoring of the patient for adverse reactions is essential. Rarely, for patients with significant allergies to potentially life-saving antimicrobial agents for which no alternative exists, desensitization of the patient to the antimicrobial is attempted so that the agent can be used. For example, desensitization protocols are available for penicillin and for trimethoprim-sulfamethoxazole. Because of the risks involved, these procedures may need to be performed in intensive care unit settings.

Pregnancy

A number of antimicrobial agents have the potential to cause fetal harm if administered to a pregnant woman. For example, tetracyclines can cause tooth discoloration and hypoplasia of dental enamel and are thus avoided in pregnant women and young children. Streptomycin given during pregnancy can cross the placenta, and evidence of eighth nerve toxicity has been reported. A few other antimicrobials are labeled by the Food and Drug Administration (FDA) as pregnancy category D (evidence of human risk) or are contraindicated because of fetal harm (category X). Many more antimicrobials, however, are assigned to category C; for these drugs, the potential risk to the fetus is based on animal studies. When designing antimicrobial regimens, the possibility of pregnancy should be considered in any woman of childbearing age so that the risks of candidate agents can be individually reviewed and the safest possible therapy selected.

It should also be noted that many antibiotics used to treat lactating women can be found in breast milk. Thus, it may be necessary to suspend breastfeeding during treatment if exposure of the infant to the drug must be avoided.

Pregnant women may be particularly susceptible to certain antimicrobial-associated toxicities. Death resulting from hepatic failure has been described in pregnant women receiving large doses of tetracycline. Potentially life-threatening hepatic steatosis has been observed in patients treated with a combination of the antiretroviral agents didanosine plus stavudine; pregnant women may be especially vulnerable to this toxic effect.

Age

For reasons discussed earlier, tetracycline antibiotics are avoided in children during tooth development to prevent discoloration and enamel hypoplasia

of the permanent teeth. Because fluoroquinolone antimicrobials produce erosion of cartilage and arthropathy in juvenile animals, they are avoided in children when alternative agents are available. Recently, limited pediatric indications were added for ciprofloxacin (for complicated urinary tract infection and pyelonephritis and, along with levofloxacin, for treatment after inhalational exposure to anthrax). Musculoskeletal complaints appear to be more frequent in children treated with ciprofloxacin than with nonfluoroquinolone antimicrobials.

Pediatric dosing regimens differ from those appropriate for adults. Some agents, such as linezolid, are eliminated much more rapidly in young children (excluding preterm neonates) than in older children and adults, so higher doses are required. In premature infants and neonates, renal function has not yet reached full capacity, and drug elimination may be delayed. Similarly, hepatic clearance activity is not fully developed in the very young, which has led to cardiovascular collapse and fatalities from chloramphenicol treatment. Absorption of oral antimicrobials may also differ with age if their absorption is dependent on gastric pH. The gastric pH of young children is higher than that of adults, and achlorhydria resulting in higher gastric pH is more common in adults older than 60 years than in younger adults. Thus, in young children and older adults, the absorption of oral drugs that are unstable in acid, such as penicillin G, may be higher than that in younger adults. In contrast, antimicrobials such as ketoconazole require gastric acid for absorption and may be less bioavailable in persons with reduced gastric acid production.

A curious association between the appearance of a rash and the patient's age and sex was noted during development of the fluoroquinolone antimicrobial gemifloxacin. In clinical studies, rash was more common in young women than in men and older women, suggesting there may be hormonal influences on the risk of developing a rash.

Renal and Hepatic Function

Renal excretion and hepatobiliary excretion are the major routes of elimination for antimicrobial agents. Relatively few antibacterial agents can be administered without dosage adjustments in patients with renal dysfunction. Included among these drugs are nafcillin, ceftriaxone, doxycycline, azithromycin, and linezolid. Although linezolid exposure is not significantly altered, microbiologically inactive metabolites of the compound do accumulate in end-stage renal disease; what, if any, effect this has is unknown.

A number of antimicrobial agents require major dosage adjustments in the presence of renal dysfunction. The dosing interval for ceftazidime, usually administered every 8 hours in patients with normal renal function, is extended to once every 48 hours in persons with creatinine clearance below 10 mL/minute. Vancomycin is also administered at substantially increased dosing intervals or at smaller doses as renal function declines. Because of the increased efficiency of newer hemodialysis membranes in removing vancomycin, dosages are usually based on measured serum drug concentrations, and dosing may be required after each dialysis session.

In some instances, clearance of the antimicrobial agent is not affected by renal dysfunction, but excipients may accumulate, with the potential for toxic effects. For example, clearance of the antifungal agent voriconazole is not dependent on renal function. However, its intravenous preparation contains the solubilizing agent sulfobutyl ether β-cyclodextrin, which does accumulate in the presence of renal insufficiency. The intravenous preparation should not be used in those with renal dysfunction, but the oral formulation, which does not contain β-cyclodextrin, can be administered. A number of other antimicrobials may accumulate in the presence of severe liver disease, with the possibility of an increased risk for adverse events. Antimicrobials requiring dose adjustments for various levels of hepatic insufficiency include metronidazole, chloramphenicol, tigecycline, caspofungin, and voriconazole. For ceftriaxone, dosage adjustments or careful monitoring may be required in patients with both hepatic and renal dysfunction. Several of the newer antimicrobials, such as daptomycin, linezolid, and micafungin, have not been studied sufficiently to determine whether dosing modifications are required in patients with severe liver disease.

Drug-Drug Interactions

One of the most important considerations in the selection of an appropriate antimicrobial regimen is to determine whether the drug or drugs will interact with other medications the patient is taking. Some drug-drug interactions can have severe or even fatal consequences. There are too many potential interactions to list comprehensively, but some examples are provided in this section. Fortunately, resources are now available that allow the clinician to check for potential drug-drug interactions when an antimicrobial agent is ordered.

A large number of antimicrobials are eliminated via cytochrome P-450 pathways. As a result, they may interfere with the elimination of other drugs cleared by these pathways, leading to their accumulation to potentially dangerous levels. Several macrolide antibacterials, some fluoroquinolones, and human immunodeficiency virus (HIV) protease inhibitors are among the most likely antimicrobials to inhibit the clearance of other drugs. For example, use of the protease inhibitor nelfinavir is contraindicated with several drugs, including the antiarrhythmics amiodarone and quinidine, ergot derivatives, the neuroleptic drug pimozide, and certain sedative-hypnotic agents. Macrolides may result in increased levels of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, which can lead to rhabdomyolysis. Although quinupristin-dalfopristin is not eliminated by the cytochrome P-450 system, this drug inhibits the elimination of various agents cleared by this pathway, including cyclosporine, midazolam, nifedipine, and others.

In contrast, administration of rifampin induces the cytochrome P-450 system and may enhance the clearance of other drugs, some of which have narrow therapeutic windows. This may result in a number of important effects, including reduced effectiveness of oral contraceptives and increased warfarin requirements to maintain desired levels of anticoagulation. It is very important to consider these potential interactions not only when starting rifampin therapy but also when *stopping* treatment. When rifampin is stopped, unless the previously increased dose of warfarin is adjusted downward accordingly, excessive anticoagulation and possibly serious bleeding can occur.

A number of other drug interactions have been described. Linezolid has weak monoamine oxidase inhibitor activity. As such, it has the potential to enhance the hypertensive effect of adrenergic agonists and has been associated with the development of serotonin syndrome in patients taking selective serotonin re-uptake inhibitors (SSRIs). Patients with this syndrome can exhibit a number of signs and symptoms, including fever, tachycardia, tremulousness, agitation, confusion, and clonus, occasionally with fatal results. Serotonin syndrome (Chapter 442) has been described in patients taking linezolid together with drugs other than SSRIs; in principle, it could occur when linezolid is combined with any of a large number of agents that increase serotonin concentrations in the central nervous system.

Other Host Factors

Several additional host factors may influence the choice of a suitable antimicrobial regimen. Some antimicrobials have the potential to induce hemolysis in persons with glucose-6-phosphate dehydrogenase deficiency (Chapter 164). Among the drugs that should be avoided in these individuals are primaquine, nitrofurantoin, and various sulfonamides.

Coexisting diseases should also be taken into account. Use of fluoroquinolones has been associated with abnormalities in glucose homeostasis. Hyperkalemia has been observed in patients with renal insufficiency during treatment with trimethoprim-sulfamethoxazole because trimethoprim blocks the renal excretion of potassium in the distal tubule.

In some cases, the patient's occupation might play a role in the selection of a treatment regimen. Antibiotics that can cause transient (minocycline) or permanent (streptomycin) dizziness or unsteadiness may create hazardous situations in those whose occupations require excellent balance. Antimicrobial agents with the potential to cause photosensitivity, such as tetracyclines, fluoroquinolones, trimethoprim, and sulfonamides, may be problematic in persons with significant sun exposure during outdoor employment or other activities.

ANTIMICROBIAL COMBINATIONS

It is very common for hospitalized patients to receive more than one antimicrobial agent simultaneously. The rationale for using antimicrobials in combination is not always clearly defined, and there are a number of potential disadvantages to combination therapy. The basis for using combination therapy is considered in this section.

Reasons to Use Combination Antimicrobial Therapy

The clinical indications for using combination antimicrobial therapy can be divided into five categories. Two of these categories (empirical therapy and polymicrobial infections) relate to maximizing the likelihood that at least one agent in the combination will be active against known or suspected pathogens. The other three reasons (minimizing toxicity, preventing the emergence of resistance, and obtaining synergistic inhibition or killing) attempt to exploit the unique advantages of combinations versus any component drug alone.

Provide Broad Coverage during Empirical Therapy

A common reason for using more than one antimicrobial in hospitalized patients is to provide broad coverage against potential pathogens and to maximize the likelihood of delivering an active antimicrobial agent as quickly as possible to seriously ill patients. When the pathogen is unknown, the antimicrobial regimen often includes an agent broadly active against gram-positive bacteria, including methicillin-resistant *S. aureus* (MRSA), such as vancomycin, as well as an agent active against aerobic or facultative gram-negative bacteria. Selection of the latter is strongly influenced by local patterns of antimicrobial resistance specific to the institution and might include an extended-spectrum cephalosporin, an aminoglycoside, a fluoroquinolone, a β-lactam–β-lactamase inhibitor drug, or a carbapenem. The latter two choices also provide activity against gram-negative anaerobes. Alternatively, one could add an agent such as metronidazole to provide anaerobic activity. Because of the high frequency of antibiotic resistance in *Pseudomonas aeruginosa* isolates, in settings in which that pathogen is encountered frequently, empirical use of two agents with antipseudomonal activity may be justified to maximize the likelihood that at least one of the agents will inhibit the organism.

Combination therapy is widely used in the initial treatment of hospitalized patients with community-acquired pneumonia. Commonly used regimens include a third-generation cephalosporin such as ceftriaxone with a macrolide or fluoroquinolone. The cephalosporin provides antimicrobial activity against *S. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis,* and several other "typical" bacterial pathogens associated with community-acquired pneumonia, with the notable exception of MRSA. The macrolide azithromycin is commonly used, or a fluoroquinolone that inhibits "atypical" bacteria that cause pneumonia, including *M. pneumoniae, C. pneumoniae,* and *Legionella* species. Although fluoroquinolones approved for respiratory tract infections are likely to cover most or all of the organisms targeted by the cephalosporin, isolates of *S. pneumoniae* resistant to fluoroquinolones do exist, so guidelines recommend combination therapy in patients with severe pneumonia requiring hospitalization.

Treat Documented Polymicrobial Infections

For many infections from which two or more pathogens are recovered, it is possible to provide adequate coverage with a single, broadly active antimicrobial agent. Switching to a single agent reduces the patient's exposure to potential antibiotic toxicities, is usually more convenient for nursing staff, and may be less expensive. For some patients, susceptibility profiles or allergies to broad-spectrum agents justify the use of antibiotic combinations for the treatment of polymicrobial infections.

Attempt to Reduce Toxicity

It is theoretically possible to use two or more drugs of different classes with additive antimicrobial activities and independent toxicities, each at relatively low doses, to achieve sufficient potency while avoiding toxicity. However, there are no situations in which the approach of using submaximal doses of multiple agents is predictably effective in accomplishing this goal. This does not exclude the possibility that, in isolated instances, a successful response might be attained when drugs with marginal activities are combined.

Prevent the Emergence of Drug Resistance

The treatment of tuberculosis provides the paradigm for using combinations of drugs in an attempt to prevent the emergence of resistance to any one agent. The basis for this approach is that if resistance to two different agents occurs by independent mechanisms, the probability of resistance developing to both drugs is the product of the probability of resistance developing to each drug, which is likely to be very low, so resistance should not emerge. Similar reasoning has justified the use of combination regimens when rifampin is required for the treatment of nonmycobacterial infections. Rifampin is not used alone (with rare exceptions, such as brief courses for the eradication of meningococcal carriage) because resistance to this agent emerges quickly. As mentioned earlier, rifampin is particularly useful in the treatment of infections related to foreign devices because of its activity against biofilm-associated bacteria. In such cases, it is combined with another active antimicrobial, such as vancomycin for coagulase-negative staphylococcal prosthetic valve endocarditis (usually with a brief course of gentamicin as well, to reduce the bacterial inoculum further at the beginning of therapy) or a fluoroquinolone for orthopedic device–related infections.

It has been difficult to show unequivocally that combination therapy protects against the emergence of resistance to antimicrobial drugs in other situations, including infections caused by *P. aeruginosa* or *Enterobacter* species. There are two plausible explanations of why combinations do not prevent resistance predictably. First, there may be differential penetration of the two antimicrobials at an infected site or differences in activity at the site of infection. Thus, a more readily penetrating agent may be left relatively unprotected in a privileged site of infection. Second, for many commonly encountered bacteria, resistance mechanisms against unrelated antimicrobial classes may not be truly independent. Some bacterial efflux pumps recognize chemically unrelated substrates, so upregulation of pump activity may confer resistance to several classes of antimicrobials. In other instances, there may be coordinated upregulation of efflux mechanisms and downregulation of outer membrane protein channels (porins), again potentially conferring resistance simultaneously to two or more antimicrobial classes.

Attain Synergism

Decades ago, the surprising benefits of using penicillin and streptomycin together for the treatment of enterococcal endocarditis were discovered empirically. Penicillin alone usually inhibits but does not kill enterococci, and failure rates were high when penicillin G was used alone to treat enterococcal endocarditis. Streptomycin has no significant activity against enterococci at clinically relevant concentrations. However, the combination results in bactericidal synergism in vitro and high cure rates in patients with enterococcal endocarditis. Detailed studies of this phenomenon demonstrated that in the presence of a cell wall–active antibiotic, uptake of the aminoglycoside into the bacterial cell increases substantially. Unfortunately, increasing rates of high-level resistance to streptomycin (MIC > 2000 μg/mL), gentamicin (MIC > 500 μg/mL), or both have nullified the benefit of such combinations against a substantial number of enterococcal isolates today. An example of bactericidal synergism between vancomycin and gentamicin against an *Enterococcus* isolate is illustrated in Figure 287-1A.

Combinations of cell wall–active agents plus aminoglycosides have been shown to achieve synergistic killing against a broad range of gram-positive and gram-negative bacteria when tested in vitro. Modest clinical benefits were shown when short courses of gentamicin were added to nafcillin for the

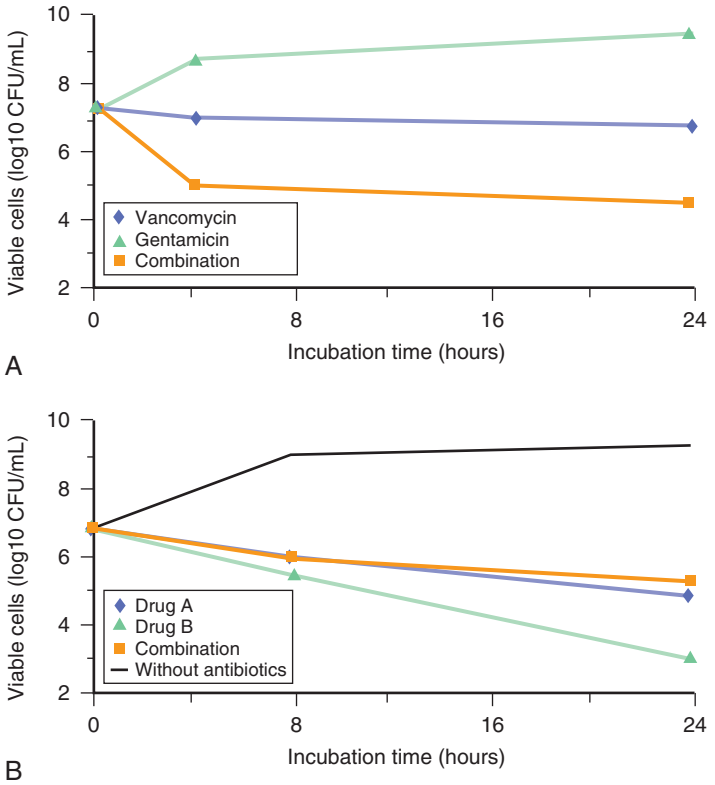

FIGURE 287-1. Bactericidal synergism and antagonism. A, Bactericidal synergism between vancomycin and gentamicin against an isolate of *Enterococcus* species. Killing by the combination of drugs is substantially greater than that by each agent alone. **B,** Antagonism of the bactericidal activity of drug B by the more slowly bactericidal drug A. Killing by the combination of drugs is less than that by drug B alone. Growth in the absence of antibiotics is also shown. CFU = colony-forming unit.

treatment of *S. aureus* endocarditis, but at the cost of added nephrotoxicity. Against strains of viridans streptococci that are relatively insensitive to penicillin, the addition of an aminoglycoside for the first 2 weeks of a 4-week course of penicillin G is believed to result in a higher likelihood of cure.

Although it was once considered important in the treatment of gram-negative bacterial infections, especially in immunocompromised (e.g., neutropenic) patients, the clinical value of a synergistic combination of a cell wall–active agent and an aminoglycoside has been difficult to prove in recent experience. To a large extent, the introduction of agents with very potent activity against gram-negative bacteria has diminished the perceived value of synergistic combinations. Nevertheless, there is some evidence that administering two or more active drugs for empirical therapy may achieve a better outcome than is possible with a single active agent for *P. aeruginosa* infections, especially in neutropenic patients. The major value of combination therapy in this setting is to ensure that at least one active agent is administered promptly (Chapter 289). The combination of sulfamethoxazole and trimethoprim, agents that block sequential steps in folic acid synthesis, can also achieve bactericidal (or bacteriostatic) synergism against a number of important gram-positive and gram-negative pathogens. Quinupristin and dalfopristin are streptogramin antibiotics that display inhibitory activity against gram-positive organisms. Combining these two agents, as is done in the commercial formulation, results in bactericidal synergism against organisms susceptible to both.

β-Lactam–β-lactamase inhibitor antimicrobials represent another example of synergistic combinations. Four drugs in this category are currently marketed in the United States: amoxicillin-clavulanate, ampicillin-sulbactam, ticarcillin-clavulanate, and piperacillin-tazobactam. The β-lactamase inhibitors themselves, clavulanic acid, sulbactam, and tazobactam, are devoid of significant antimicrobial activity, with rare exceptions. However, by inhibiting common β-lactamases that are sensitive to these agents, the inhibitors restore the activity of the hydrolyzable companion penicillins against many target pathogens elaborating these enzymes.

Antagonism

Antibiotic combinations can sometimes result in microbiologic antagonism, such that the combination may have *reduced* activity when compared with the most active single agent of the treatment regimen. Time-kill curves illustrating in vitro antagonism are shown in Figure 287-1B. In this example, the more slowly bactericidal drug A antagonizes the killing effect of the intrinsically more bactericidal drug B. Antagonistic interactions against *S. aureus* between less bactericidal (linezolid) and more bactericidal (vancomycin) antimicrobials have also been demonstrated in vivo in experimental endocarditis. In vitro antagonism can be demonstrated when certain β-lactams are tested in combination against gram-negative bacteria with inducible β-lactamases. Here, exposure to one β-lactam can de-repress the synthesis of inducible β-lactamases, which then degrade the second antibiotic.

It is uncommon to encounter clinically apparent antagonism between antibiotics in the patient care setting, in part because offending combinations are not likely to be used in routine clinical care today. However, if unusual antimicrobial combinations are used, in desperation, against isolates exhibiting multiple drug resistance, it is possible that clinically relevant antagonism will be encountered more often in the future. Antagonism of bactericidal activities may also be difficult to detect in clinical practice because most common infections (with the exception of endocarditis and meningitis) do not unequivocally benefit from bactericidal therapy. As long as one agent maintains inhibitory activity, it is unlikely that failure resulting from antagonism will be observed.

CONSIDERATIONS IN ANTIMICROBIAL ADMINISTRATION

Route of Administration

In almost all instances, antimicrobial therapy for infections of mild to moderate severity that are treated in the outpatient setting can be undertaken with oral agents. There are notable exceptions, such as the use of intramuscular injections of benzathine penicillin for the treatment of syphilis or ceftriaxone for the treatment of otitis media or gonorrhea caused by strains resistant to oral agents.

Drugs such as levofloxacin and linezolid demonstrate virtually complete bioavailability when administered by the oral route in persons with normally functioning gastrointestinal tracts, and they can be used as an alternative to intravenous therapy in many patients with more serious infections. Even for these well-absorbed antimicrobials, however, treatment of seriously ill patients in the hospital is often initiated with intravenous formulations because of the uncertainty of gastrointestinal tract function under conditions of hemodynamic instability.

Antimicrobial therapy can be administered by other routes, including topical administration for the treatment of infected skin lesions (e.g., mupirocin ointment) and intravaginal administration for candidiasis (e.g., azole creams) or for bacterial vaginosis (e.g., metronidazole gel). Topical administration *onto* the eye is used to treat conjunctivitis or as adjunctive therapy for deeper infections; administration *into* the globe itself is a component of regimens for the treatment of endophthalmitis. Infections associated with peritoneal dialysis are frequently treated by intraperitoneal instillation of antimicrobials admixed with the dialysis solution. Rarely, direct administration into the thecal space or into the cerebral ventricles is necessary for the treatment of meningitis when the required antimicrobials do not achieve adequate concentrations in cerebrospinal fluid after systemic administration. Vancomycin is almost always given orally, but it is occasionally administered directly into the intestine for the intraluminal treatment of *Clostridium difficile*–associated diarrhea.

The availability of protocols for the outpatient use of long venous catheters, whether inserted centrally or peripherally, has made it possible to administer antimicrobial agents that are not well absorbed orally. Thus, many patients who require long-term antibiotic treatment for infections such as endocarditis, osteomyelitis, neuroborreliosis, and other conditions can be treated as outpatients after an initial period of hospitalization for a full assessment of the infection, initiation of therapy, and stabilization of the medical condition. In addition to monitoring for adverse effects from the antibiotic itself, patients treated via indwelling intravenous devices require close observation for complications related to the catheter, such as thrombophlebitis, entry site infections, or line-related blood stream infections.

Pharmacodynamic Considerations

In recent years, the scientific basis for selecting a dosing regimen has extended well beyond empirical dosing strategies based primarily on the pharmacokinetic characteristics of antimicrobial agents. Pharmacodynamics relate the time course of antibiotic concentrations after dosing, the observed antimicrobial effects against likely pathogens, and the potential adverse effects of the agent.

Studies of the pharmacokinetic and pharmacodynamic properties of antimicrobial agents allow the prediction of their activities with various dosing regimens. For β-lactam antibiotics, the time during which the concentration of free drug (i.e., the non-protein-bound fraction) exceeds the MIC of the pathogen best relates to antimicrobial effectiveness in animal models. This provides the rationale for the frequent dosing schedules of β-lactams with short half-lives, such as penicillin G and the antistaphylococcal penicillins.

In contrast, the aminoglycosides and fluoroquinolones demonstrate concentration-dependent killing of bacteria. For these drugs, animal models show that the ratio of either peak concentration to MIC or the area under the 24-hour drug concentration curve to MIC better predicts effectiveness. With these agents, less frequent, higher dosing would be optimal. For the aminoglycosides, less frequent dosing may also allow more time for washout of the drug from the kidney, thus potentially minimizing the risk for nephrotoxicity; however, the advantages of this approach are not striking.

For daptomycin, the adoption of once-daily dosing largely mitigated the muscle toxicity that had been seen with more frequent dosing and allowed the use of this agent for serious gram-positive infections.

MONITORING ANTIMICROBIAL CONCENTRATIONS

From a practical point of view, there are few situations in which assays to determine concentrations of antimicrobials in blood or body fluids are readily available. Commercial assays for the measurement of serum aminoglycoside concentrations are available and, because of these agents' great potential for toxicity, are used frequently. Commercial assays to measure vancomycin concentrations are also widely available. It may be prudent to monitor serum concentrations of vancomycin in patients with unstable renal function, those undergoing hemodialysis, patients at the extremes of body composition, or those with particularly serious infections in which high concentrations may be desirable. In some young adults, clearance of vancomycin may be so great that unexpectedly low concentrations result with the usual dosing regimens.

ADMINISTRATIVE ASPECTS OF ANTIMICROBIAL THERAPY

Formularies

In most practice settings today, the choice of antimicrobials is constrained in some way. For example, in hospitals and other facilities, institutional formularies may limit the choice of antimicrobial agents available, require special approval for the use of selected agents, or both. Such policies can, in principle, enhance efficiency by avoiding the need to stock and dispense multiple agents with very similar antimicrobial activities, minimize costs by allowing purchase of the most cost-effective alternatives, and potentially increase patient safety by encouraging clinical personnel to become familiar with a manageable number of agents. In the outpatient setting, it is common practice for health insurers to assign oral drugs to various tiers of coverage and copayment; as a result, there may be dramatic financial benefits or disincentives for the patient to receive specific agents. In both health care settings, the practitioner must be familiar with the options available to patients under these constraints.

Interchangeability

It is important to remember that although two drugs may have antimicrobial spectra that are so similar that only one need be included on a formulary, it is not always safe to assume that the activity of either agent can be predicted perfectly by susceptibility to the other. For example, for most bacterial species, the percentage of isolates susceptible to meropenem and imipenem will be roughly comparable. However, there are differences in mechanisms of resistance to these two carbapenems, so it is possible that a specific strain will be susceptible to one but resistant to the other. For serious infections, even when two drugs are considered interchangeable, one should determine susceptibility to the specific antimicrobial used.

Impact on the Institutional Environment

In contrast to other medications, which almost always affect only the patient receiving them, antimicrobial use can have a significant impact on the institutional environment as well. As a result, it is sometimes necessary or desirable to manage the use of antimicrobial agents on an administrative level to avoid selective pressure leading to the spread of antibiotic resistance. Within institutions, antimicrobial-resistant organisms not only threaten the patient treated with the antimicrobial but can also be transmitted to other vulnerable persons, including those who have not been exposed to the drug.

APPROACH TO FEVER OR SUSPECTED INFECTION IN THE NORMAL HOST

JAMES LEGGETT

We are constantly exposed to microorganisms via our skin or mucous membranes. Most microorganisms are adapted to niches in the environment that make them avirulent to humans. Pathogens in a normal host are relatively few, and most of the time, exposure results in only transient or stable colonization. Infection can be defined as invasion of a pathogen that triggers an immune response, whether the infection is asymptomatic or symptomatic. Manifestations of infection are protean and are due as much to our immune response as to the attributes of the particular pathogen.

The inflammatory response that accompanies infection is usually marked by fever. Fever is a tightly controlled elevation in body temperature above the normal range in response to a central nervous system change in the set point. Defining normal body temperature is somewhat problematic because it is dependent on both physiology and the method of measurement. Normal oral temperature in 99% of the population ranges from 36.0 to 37.7° C, with a circadian variation of 1° C or more between the morning nadir and the evening peak. Mean oral temperature in healthy adults is 36.8 ± 0.4° C, with women exhibiting slightly higher values than men (36.9 vs. 36.7° C). In menstruating women, the morning temperature may rise by 0.6° C with ovulation and remain higher until menses occur. Measured rectal temperatures are 0.4° C higher than oral and 0.8° C higher than aural (tympanic membrane) temperatures. However, considerable individual variability exists. Clinicians generally define significant fever as a temperature higher than 38.3° C (101.0° F). Despite historical claims, fever patterns are not especially helpful in establishing a specific diagnosis.

The vast majority of acute febrile illnesses lasting less than 2 weeks have an infectious cause. These infections occur predominantly where body surfaces interact with the environment, such as the upper and lower respiratory tracts, gastrointestinal and genitourinary systems, and skin. The majority of acute respiratory and gastrointestinal infections are viral in nature. As the duration of the febrile illness lengthens beyond 3 weeks, other inflammatory illnesses become more prominent in the differential diagnosis. Most chronic febrile illnesses are not caused by infection.

PATHOBIOLOGY OF INFECTION AND FEVER

Infection ensues only when a pathogen overcomes both nonspecific innate and specific adaptive humoral and cellular immune responses. The normal indigenous microflora, host physical barriers (e.g., skin, mucous membranes, cilia), and soluble factors (e.g., cytokines, complement) provide important barricades to pathogen invasion. Disruption of these barriers, which provide a first line of defense, permits the invasion of pathogens. The acute phase response triggered by such disruption provides direct antimicrobial activity and prompts the development of adaptive immunity mediated by lymphocytes and macrophages. This inflammatory response plays an important role in containing infection. Unfortunately, an exaggerated response may worsen the clinical condition. It is the neutrophil response that causes the damage seen in septic arthritis, and it is the unchecked immune response that precipitates the systemic inflammatory response syndrome.

Body temperature is regulated both physiologically and behaviorally. Basal metabolic processes, governed especially by thyroid hormones but also by catecholamines and growth hormone, are responsible for the normal resting body temperature. Thermogenesis may be increased up to 80% by hyperthyroidism and decreased as much as 50% by hypothyroidism. Moderate activity increases thermogenesis and results in a transiently increased temperature until heat-dissipating processes are engaged. Each 1° F increase in temperature results in a 7% increase in the basal metabolic rate. Vaporization from the lungs and skin accounts for a third of basal body heat loss and for as much as all heat loss at ambient dry temperatures above 36° C. The elderly have a decrease in basal metabolism, as well as blunted responses to thermogenetic stimuli, but they have the same average core temperature as young people.

The hypothalamus contains temperature-sensitive neurons that have receptors for pro-inflammatory and anti-inflammatory cytokines, which are continuously balanced to maintain a homeothermic set point. When body temperature becomes elevated, cutaneous vasodilation and sweating occur, and people may reduce activity and seek a cooler environment. In contrast, low body temperature is increased by shivering, piloerection, cutaneous vasoconstriction, adding clothes, and seeking a warmer environment. In a febrile illness, symptoms may be due to the underlying disease or to the fever itself. Malaise is the rule, and many febrile patients experience myalgia secondary to the muscle contractions used to generate temperature elevation. Although it was once thought that the back and thigh pain related to rigors suggests bacteremia, any febrile stimulus can produce such symptoms. The chill associated with rigors may be related to the surface vasoconstriction that accompanies the increase in core temperature.

Fever is a complex physiologic process involving metabolic and immunologic responses (Fig. 288-1). Exogenous pyrogens cause fever largely mediated by endogenous pro-inflammatory pyrogenic cytokines produced by

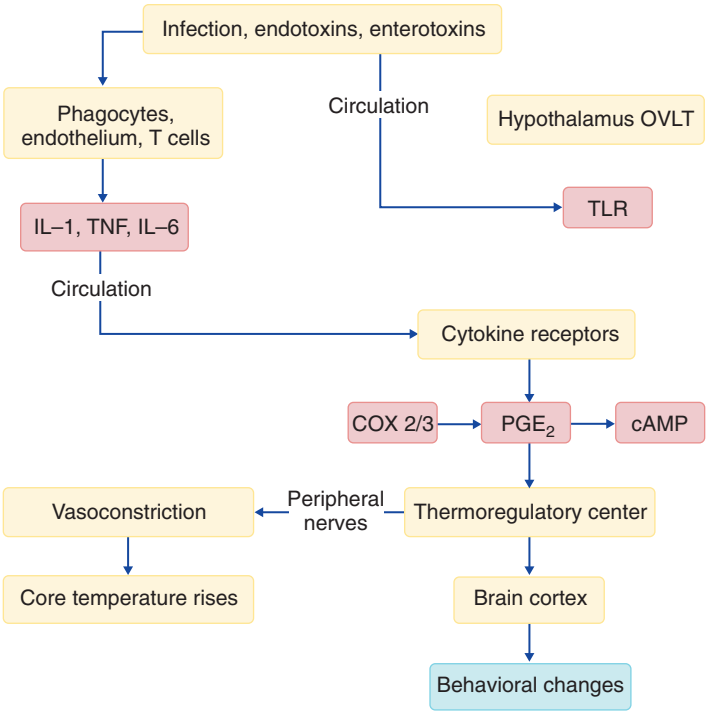

FIGURE 288-1. Pathways leading to the production of fever in bacterial infection, whether local or systemic. Bacteria release cell wall products such as peptidoglycans and endotoxin, as well as enterotoxins, which bind to Toll-like receptors (TLRs) on phagocytes (neutrophils, macrophages) and endothelial cells. As a result, pyrogenic cytokines such as interleukin (IL)-1 and IL-6 or tumor necrosis factor (TNF)-α are released into the circulation and bind to cytokine receptors in the hypothalamic organum vasculosum of lamina terminalis (OVLT). Bacterial products may also directly bind to TLRs on the OVLT. Activation of TLRs and cytokine receptors induces cyclooxygenase 2 (COX2), which leads to the production of prostaglandin E_2 (PGE_2) and elevates cyclic adenosine monophosphate (cAMP) in the brain. This, in turn, triggers neurons in the thermoregulatory center to raise the hypothalamic thermostatic set point. In addition, neuronal signals to the cortex prompt behavioral changes to conserve heat (e.g., posturing, adding clothing). The hypothalamus also triggers sympathetic peripheral efferent nerves that constrict peripheral blood vessels and conserve central heat until hypothalamic PGE_2 levels fall.

phagocytic leukocytes, including interleukin (IL)-1, IL-2, IL-6, tumor necrosis factor-α, and interferon-γ. These cytokines stimulate the immune responses of T and B cells, macrophages, and polymorphonuclear leukocytes. They appear to act via a common mechanism involving the induction of prostaglandin synthesis. Feedback inhibitory responses are mediated by adrenocorticotropic hormone, arginine vasopressin, serotonin, dopamine, and other homeostatic mechanisms, thus emphasizing the orchestrated nature of fever production and response to infection. These thermoregulatory mechanisms rarely allow fevers to exceed 41° C (106° F). Temperatures exceeding 41° C are often due to a drug-induced imbalance in these mechanisms and may cause direct cellular damage.

Failure of fever to develop during severe bacterial infection has, in some studies, been associated with higher morbidity and mortality. Whether this is due to the absence of fever per se or to associated conditions such as chronic renal failure or corticosteroid use has not been determined. Favorable effects of fever on host-microbe interactions are suggested by inhibited multiplication of some pathogens such as *Streptococcus pneumoniae* and *Treponema pallidum,* reduced proliferation of pathogens in the presence of hypoferremia, augmented complement-mediated lysis, and increased neutrophil entry into inflammatory sites. Temperature-pulse dissociation, in which there is relative bradycardia compared with the usual increase of about 10 beats/minute/1° F, has been described in typhoid fever, leptospirosis, rickettsiosis, dengue, legionellosis, and babesiosis, for unclear reasons.

No laboratory abnormalities accompany typical benign acute viral infections. Leukocytosis (Chapter 170) of various lineages is usually seen in other infections in immunocompetent adults. Neutrophilia is the norm in most acute infections, whatever the cause. The elderly, though not mounting a neutrophilic response, generally display bandemia during an acute bacterial infection. Neutropenia (Chapter 170) may be seen in rickettsial, severe viral, and overwhelming bacterial infections. Eosinophilia (Chapter 173) is typical

TABLE 288-1 SELECTED EXAMPLES OF FEVER ASSOCIATED WITH RECENT TRAVEL

	Incubation Period

of invasive helminthic and some protozoal infections. Lymphocytosis may accompany many viral and rickettsial infections and is common during convalescence from acute bacterial infection. Monocytosis may be seen in tuberculosis. Virtually all infections have an impact on the erythroid system, but given the long half-life of erythrocytes, usually only chronic infections or other inflammatory diseases result in anemia (Chapter 161). Few acute infections rapidly produce anemia. For instance, *Helicobacter pylori* may induce a bleeding ulcer, *Plasmodium falciparum* may directly lyse erythrocytes, overwhelming clostridial and other bacterial infections associated with disseminated intravascular coagulopathy may cause hemolytic anemia, and *Mycoplasma pneumoniae* may induce immunologically mediated hemolysis.

APPROACH TO FEBRILE ILLNESS IN OUTPATIENTS AND INPATIENTS

Infectious disease epidemiology depends on the interaction among pathogens, susceptible hosts, and environmental conditions allowing exposure. Most infections are transmitted horizontally between people via contact (e.g., hands, fomites), a common vehicle (e.g., food, water), air (e.g., tuberculosis), or vectors (e.g., mosquitoes). Evaluation of a patient with a known or possible infection should determine whether the condition might be due to a transmissible agent and its source; whether the patient has done any recent traveling; whether there are secondary causes; and what measures need to be taken to contact health department officials and prevent additional infections.

The age of a patient influences which illnesses should be considered. Natural exposure or immunization generally limits certain illnesses, such as rubeola, rubella, or varicella. Waning of immunity may likewise lead to pertussis in young adults or reactivation of tuberculosis in the elderly. Other physiologic effects of aging, such as impaired bladder emptying, lead to increased rates of urinary tract infection in the elderly.

A patient's occupation and travel history should be noted. An abattoir worker is more likely to have been exposed to *Brucella* (Chapter 318) than someone with another occupation. Indiana residents are more likely be infected with histoplasmosis (Chapter 340), whereas those from the Southwest desert may have coccidioidomycosis (Chapter 341), despite having a similar febrile illness. Many other illnesses are likewise directly related to specific geographic exposure, with varying incubation times before their onset (Chapter 294). Typhoid fever should manifest within a few weeks, whereas amebic liver abscess might not cause symptoms until months after a traveler's return from an endemic area (Table 288-1). The Centers for Disease Control and Prevention website and many others provide more specific information about prevalent infections in all parts of the world (see *http://www.cdc.gov*).

Many travelers return home with fever after a variable incubation time, generally with other symptoms and signs as well. The first consideration in evaluating such a patient is that an infection unrelated to travel is more likely

to be the cause of the illness. Once such routine infections have been ruled out, the differential diagnosis should include infections related to travel, whether within a region of the United States (e.g., ehrlichiosis, Colorado tick fever, hantavirus) or abroad (e.g., visceral leishmaniasis, tick-borne encephalitis in Europe) (Chapter 294). For example, prompt evaluation of a patient who has traveled to a malaria-endemic area should be undertaken and blood tests performed to determine the presence of parasites.

The setting in which a febrile illness occurs influences both the diagnostic approach and the differential diagnosis. In the ambulatory arena, with a generally healthy febrile patient, the clinician should not necessarily pursue a diagnosis as aggressively as with a hospitalized or chronically ill patient. Empirical treatment of a presumed urinary tract infection is warranted for an outpatient, where the cost of a culture is often more than that of the antibiotic. However, the cost of a urine culture in a hospital setting is minimal in comparison to the daily cost of care, and accurately identifying the pathogen may speed hospital discharge. Likewise, the pathogens commonly causing febrile illness in health care facilities, including nursing homes, may differ from those seen in ambulatory settings. Most patients in the ambulatory setting have noncritical, self-limited infections.

Higher temperatures are usually due to invasive visceral disease such as community-acquired pneumonia or pyelonephritis. Common viral respiratory infections and gastroenteritis, as well as some cases of subacute bacterial endocarditis, are accompanied by fevers below 102° F. Moreover, many infections may not be associated with fever, such as Lyme disease, osteomyelitis, and most sexually transmitted diseases. The clinician must always keep in mind that certain infections, such as sexually transmitted diseases (Chapter 293) or herpes zoster, occur normally in immunocompetent hosts and may signal a higher risk for infection with human immunodeficiency virus (HIV) or an already established immunodeficiency.

FEVER IN OUTPATIENTS. In the ambulatory setting, an acutely febrile patient represents a common problem and only infrequently presents an enigmatic diagnostic challenge. In most instances, a febrile illness is accompanied by localizing symptoms and signs suggesting a specific diagnosis. For instance, leg erythema, pain, and fever in a patient with tinea pedis or a saphenous vein graft incision immediately suggests streptococcal cellulitis. If the patient has had a gradual onset and does not appear toxic, only clinical observation and follow-up are required. If the patient appears toxic, with tachypnea and apprehension or confusion accompanying localized findings, clinically focused diagnostic studies should be performed immediately, and hospitalization should be considered. When a patient has fever and only nonspecific constitutional symptoms, it may be more difficult to address the problem in a single ambulatory clinic visit, requiring a balance between observation and investigation.

FEVER IN INPATIENTS. Fever and leukocytosis are probably the main clinical parameters for evaluating potential infections in hospitalized patients. However, about 10% of nosocomial bacteremias occur without fever, and health care–associated infections occur without fever in a substantial proportion of patients who are elderly or have significant comorbid conditions. Most cases of hospital-associated fever represent nosocomial infection, which typically involves the lower respiratory tract, urinary tract, or surgical wounds (Table 288-2). Some important causes of nosocomial fever may not exhibit easily discernible localizing symptoms or signs. Antibiotic-induced colitis secondary to *Clostridium difficile* (Chapter 304) is increasing in prevalence and may be characterized by little or no diarrhea. It is probably the most common cause of a leukemoid reaction in hospitalized patients. Other intra-abdominal processes involving the hepatobiliary system, bowel infarction, viscus perforation, or abscesses may have little in the way of localizing symptoms or signs.

Given the greater severity of illness and comorbid conditions in intensive care unit (ICU) patients, it is logical that fever and infection are more frequent in the ICU than elsewhere. Infection was recently found to be present in more than 80% of febrile ICU patients, although both infectious and noninfectious causes of fever may coexist. Indeed, ischemia or devitalization of tissue provokes an inflammatory response similar to that prompted by infection. About half of patients with acute myocardial infarction have a temperature between 38.0 and 38.5° C within 2 to 3 days of their infarction. Similarly, about half of patients with deep vein thrombosis and pulmonary embolism have a temperature in the same range, most commonly in the first 3 days after diagnosis. A third or more of patients with stroke demonstrate fever, which is also a common consequence of subarachnoid hemorrhage and subdural hematoma, especially within 72 hours of onset. The fever in such cases may result from damage to the hypothalamus or pulmonary aspiration secondary to obtundation. Iatrogenic causes of fever should be considered. Fever and chills may be seen in up to a quarter of patients receiving platelet transfusions, although the frequency is much less with other blood products.

TABLE 288-2 SELECTED CAUSES OF HOSPITAL-ASSOCIATED FEVER

COMMON	LESS COMMON
Infectious	**Infectious**
Clostridium difficile enterocolitis	Biliary tract disease
Pneumonia	Endometritis
Surgical wound	Intra-abdominal abscess
Urinary tract	Mediastinitis
Vascular catheter	Sinusitis
Noninfectious	**Noninfectious**
Drug-induced fever	Adrenal insufficiency
Hematoma	Gout
Immediate postoperative state	Myocardial infarction
Transfusion reaction	Organ infarction
Venous thromboembolism	Pancreatitis

SYNDROMIC APPROACH: FEVER AND RASH

A syndromic approach is valuable to narrow the many possible causes of a suspected infection. Two approaches must be juxtaposed in this evaluation, and both are key in recognizing patterns. The clinician must be aware of (1) the differential diagnosis of the particular type of lesion observed and (2) the constellation of findings produced by individual pathogens. Because of the variety of possible manifestations and the often overlapping symptoms and signs, both elements are key in arriving at a probable diagnosis. Moreover, fever and associated findings such as exanthem, lymphadenopathy, or jaundice may be due to noninfectious systemic diseases as well as infectious ones. For instance, leukocytoclastic vasculitis and fever may be found in meningococcemia, Rocky Mountain spotted fever, and hepatitis C, but they are also seen in noninfectious inflammatory diseases. Likewise, fever and adenopathy may be due to lymphoma or to cat-scratch disease.

A recognizable exanthem may lead to the immediate recognition of a particular pathogen (Chapter 449), but often a larger differential diagnosis must be entertained. The clinician must recognize the type or types of skin lesions present, the distribution of the exanthem, and the chronologic progression with respect to the onset of fever and other symptoms (Table 288-3). Morphologic variations in skin lesions help in the differential diagnosis. Maculopapular exanthems are frequently seen in viral illness, hypersensitivity drug reactions, and immune complex–mediated diseases. Some of the most common viral causes include the many enteroviruses, but similar lesions may also be seen with hepatitis B and West Nile viruses. Erythema multiforme, a subset of maculopapular exanthem, can result from various viral infections or drug eruptions (Chapter 448). It may have a spectrum of disease that ranges from benign to the life-threatening Stevens-Johnson syndrome/toxic epidermal necrolysis complex. Herpes simplex virus is perhaps the most common cause of erythema multiforme. Although drugs, especially antibiotics, are the major precipitating factor in the Stevens-Johnson syndrome/toxic epidermal necrolysis complex, *M. pneumoniae* has been associated with it as well. Evolution of the cutaneous findings over time may give clues to the cause; for example, the initial blanching, erythematous, maculopapular lesions may later evolve into petechiae, as seen in meningococcemia, Rocky Mountain spotted fever, and dengue. Secondary syphilis may manifest with a multitude of morphologic skin lesions. Sometimes, many different manifestations occur simultaneously in the same patient. Most vesiculobullous skin exanthems are immunologically mediated. The few infections associated with these eruptions include herpes simplex and varicella-zoster viruses and enteroviruses such as echovirus and coxsackievirus. The poxviruses, which can also cause such exanthems, are much rarer or are associated with bioterrorism. Pustules, or vesicles containing leukocytes, are usually associated with psoriasis or infections with *Pseudomonas, Staphylococcus,* or *Neisseria.* Bullous exanthems in the presence of sepsis suggest severe streptococcal cellulitis or necrotizing fasciitis, staphylococcal impetigo, or *Vibrio* infections.

Herpes	
Lymphogranuloma venereum	
Syphilis (primary)	

Petechial and purpuric eruptions are due to the extravasation of red blood cells and should always lead to consideration of a potentially serious illness. Pathogens creating such lesions most commonly include *Neisseria meningitidis, Rickettsia,* and *Capnocytophaga canimorsus,* but these eruptions may be seen with a variety of other pathogens, including *Staphylococcus aureus,* group B streptococci, and other gram-negative bacilli. A petechial exanthem may also be seen with enteroviruses and viral hemorrhagic fevers. The most common causes of petechiae not attributable to infections include thrombocytopenia and vasculitis.

The presence of fever and rash involving the palms and soles allows considerable narrowing of the differential diagnosis (Table 288-4). In addition to the diffuse erythema associated with toxic shock syndrome, illnesses such as Rocky Mountain spotted fever, secondary syphilis, hand-foot-and-mouth disease, *Neisseria* infections, and rat-bite fever should be considered in patients with maculopapular exanthems involving these areas.

Nodular skin lesions may be either noninfectious, as seen in malignancy or with certain drugs (e.g., sulfonamides), or infectious, as seen in a variety of inflammatory diseases. Atypical mycobacteria and disseminated fungi often produce skin nodules. The tender nodules of erythema nodosum usually occur in crops located pretibially, but they may be solitary or occur on other parts of the body. They do not typically suppurate, and they heal without scarring. Infectious agents are the most likely cause of erythema nodosum. Diffuse erythema may be seen with scarlet fever, toxic shock syndrome, Kawasaki disease, Stevens-Johnson syndrome, and toxic epidermal necrolysis, with desquamation occurring late in all these syndromes. Sweet's syndrome, a febrile neutrophilic dermatosis, represents a hypersensitivity reaction often preceded by an upper respiratory tract infection.

SYNDROMIC APPROACH: FEVER AND MUSCULOSKELETAL COMPLAINTS

Fever and localized tenderness, swelling, or erythema generally accompany septic arthritis and often accompany osteomyelitis (Chapter 280). Septic bacterial arthritis in adults usually manifests acutely and involves a single large joint such as the knee, hip, or shoulder, unless the infection is directly inoculated by trauma or surgery. Septic oligoarthritis may be seen with endocarditis and rat-bite fever. Disseminated gonococcal disease is the usual cause of arthritis involving small joints of the wrist, ankle, and digits, often with tenosynovitis. Acute or subacute polyarthritis may be seen in several viral diseases, including parvovirus B19 and hepatitis B, and in Lyme disease, but it is more typical of immunologic disorders. Rheumatologic diseases generally have more subacute manifestations, with more symmetrical polyarthritis. Hematogenous osteomyelitis in adults frequently involves the vertebrae and is almost always initiated by discitis with symmetrical involvement of adjacent vertebrae (as opposed to malignant metastasis, which is asymmetrical and does not involve the disc).

Myositis secondary to clostridia, streptococci, *Aeromonas,* or mixed aerobic-anaerobic infections usually causes an acutely septic picture with painful, edematous involvement of the limb or torso. Pyomyositis frequently involves deep muscles such as the psoas or gluteus and is usually due to *S. aureus*. Diffuse myositis may be seen with leptospirosis or toxoplasmosis, and rhabdomyolysis occurs with a variety of viral infections and legionellosis.

SYNDROMIC APPROACH: FEVER AND LYMPHADENOPATHY OR HEPATOSPLENOMEGALY

Fever and lymphadenopathy may suggest a variety of illnesses, both infectious and noninfectious (Table 288-5). Lymphadenopathy (Chapter 171) may be regional or generalized. Local enlargement can occur with either a local infection or some systemic illnesses (e.g., posterior cervical lymphadenopathy with Epstein-Barr virus and other viral illnesses). Generalized lymphadenopathy usually suggests a systemic disorder, which may itself be either infectious or noninfectious. Although the combination of fever and lymphadenopathy secondary to infection is especially common during childhood, it is also frequently seen in adults. As in other syndromes, acute versus chronic adenopathy tilts the diagnosis toward different broad categories of illness. In the latter, histopathologic evaluation of enlarged lymph nodes may point to a particular diagnosis. For instance, toxoplasmosis or cat-scratch disease can be easily differentiated from mycobacterial disease or sarcoidosis.

Fever and hepatosplenomegaly (Chapter 171) may provide an important clue to the cause of a febrile illness, which is typically either an infection or

a malignancy arising from bone marrow or the reticuloendothelial system. Jaundice may also limit the differential diagnosis (Table 288-6). Aside from the viral hepatitides and other diseases affecting primarily the liver, many pathogens producing sepsis can cause hyperbilirubinemia.

APPROACH TO FEVER OF UNKNOWN ORIGIN

The majority of febrile illnesses are short-lived, but fever may be prolonged for weeks or months as part of an infectious disease, inflammatory disorder, or occult neoplasm. When fever is caused by infection, the site is an area not easily controlled by host defenses, leading to the continued release of inflammatory cytokines. Likewise, macrophage and lymphocyte involvement in inflammatory disorders causes persistent cytokine production, as do certain neoplasms. Given this final common pathway, it is easy to understand why the majority of cases of classic fever of unknown origin (FUO), loosely defined as lasting longer than 3 weeks despite routine investigation, are found in these three broad categories. Two other categories round out the bulk of FUO cases: miscellaneous illnesses and cases in which the fever remains undiagnosed (Table 288-7). The proportion of patients in each category varies by geographic locale, age, duration of fever, and immune status. As more effective methods of diagnosing viral and bacterial infections have become available, and with improved serologic studies to detect connective tissue disorders and better imaging techniques to detect occult malignancies, the proportion of patients with FUO in the miscellaneous and undiagnosed categories has increased to about a third of the total in developed countries. The longer a febrile illness persists without a diagnosis or appropriate therapy, the less likely it is to be due to an infection. In one study, only 6% of patients who had persistent FUO beyond 6 months were found to have infection. Most such cases resolve spontaneously, with a mortality rate of less than 3% at 5 years.

Bacterial species, particularly *Mycobacterium tuberculosis,* make up the largest category of infections that cause prolonged FUO. *M. tuberculosis* and other bacterial pathogens causing FUO have adapted to survive intracellularly or frequently change their surface antigens so that they are not readily eradicated by host defenses. Other infections causing FUO are localized in cryptic abscesses, especially intra-abdominally, or reside on heart valves, where the inflammatory response is blunted. Persistent viral infections constitute a small and shrinking subset of patients with FUO because modern techniques can more readily detect infection with Epstein-Barr virus, cytomegalovirus, and others. Among the pathogens likely to be characterized initially by fever alone, cytomegalovirus is the most common cause of mononucleosis in adults, and malaria is a common cause of fever in returning travelers. Malignancy may result in persistent fever owing to the production of inflammatory cytokines, necrosis, or the presence of a complicating infection. The most common malignancies manifesting as FUO are lymphomas, leukemias, and solid tumors with metastases to the liver. Connective tissue disorders may lead to tissue inflammation, which produces fever as a prominent feature of the illness. In a recent series, adult Still's disease (Chapter 269) was the leading rheumatologic disorder manifesting as FUO. Temporal arteritis and polymyalgia rheumatica (Chapter 279) are seen almost exclusively in patients older than 50 years. Systemic lupus erythematosus (Chapter 274) is an occasional cause of FUO, especially if it manifests in an atypical fashion.

The miscellaneous category of FUO includes several disparate groups of diseases. Granulomatous diseases such as granulomatous hepatitis, Crohn's disease, or sarcoidosis may incite cellular immune responses that result in fever. Granulomatous hepatitis was present in up to 6% of National Institutes of Health cases with fever lasting longer than 6 months. Chronic pancreatitis may occasionally cause FUO, as may recurrent pulmonary embolism.

Drug-induced fever (Table 288-8) may be the only manifestation of an adverse drug event in up to 5% of cases of drug hypersensitivity. Recognizing drug-induced fever is important to avoid extra tests, additional therapy, and prolonged hospitalization. The mechanisms by which drugs incite fever are not well understood in many cases. These events may result from hypersensitivity reactions, altered thermoregulatory homeostasis directly related to either drug administration or the drug's pharmacologic action, or idiosyncratic reactions. Hypersensitivity reactions are usually accompanied by an exanthem or enanthem and hepatic, renal, or pulmonary dysfunction, in addition to fever. Antimicrobial agents appear to be the most common cause of drug-induced fever and are responsible for approximately a third of episodes in some studies. β-Lactams and sulfonamides account for most cases because they are among the most frequently administered antimicrobials. Anticonvulsants are also common causes of drug-induced fever secondary to hypersensitivity reactions. Altered thermoregulation is possible with a variety of drugs, including those with anticholinergic activity such as phenothiazines and tricyclic antidepressants. Sympathomimetic agents such as amphetamines and cocaine may also cause fever. Drug administration itself may cause fever if the vehicle of the drug is contaminated with exogenous pyrogens or chemical phlebitis occurs. Some drugs appear to have intrinsic pyrogenic properties, such as amphotericin B and bleomycin. Others cause fever as a result of their pharmacologic activity, such as interferon-α or IL-2. With antibiotics, drug-induced fever occurs with the rapid lysis of spirochetes or other bacteria, known as the Jarisch-Herxheimer reaction. Idiosyncratic drug-induced febrile reactions include malignant hyperthermia, neuroleptic malignant syndrome, and serotonin syndrome. Drugs implicated in these reactions are inhaled anesthetic agents, central nervous system dopamine-depleting agents, and serotonin re-uptake inhibitors, among others. Drug-induced fever is usually a diagnosis of exclusion. The duration of drug exposure before the onset of fever, the clinical appearance of the patient, and the pattern of the fever are not particularly useful. Elimination of a single drug at a time, beginning with the one most likely to be implicated, is the usual means of identifying the causative agent. The fever abates once the drug has been eliminated from the body, usually within 3 to 4 days of discontinuing use of the drug.

Laboratory evaluation and diagnostic imaging studies should be chosen according to information derived from a detailed history and physical examination. These may initially include a complete blood count and blood chemistry determinations, erythrocyte sedimentation rate, blood cultures, and antibody tests (antinuclear antibody, cytomegalovirus, Epstein-Barr virus, HIV), as well as a chest radiograph and computed tomography of the abdomen. Despite the recent focus on "emerging" infectious diseases, the cause of FUO is still more likely to be a common pathogen presenting atypically.

examination reveal diagnostic clues and may guide decisions about additional studies or therapy. More difficult to diagnose is a fever that occurs without localizing symptoms or is accompanied only by nonspecific symptoms such as malaise or anorexia. Fortunately, most such acute, undifferentiated febrile illnesses are benign and resolve spontaneously within 1 or 2 weeks without a specific diagnosis being made. In such cases, no further evaluation beyond the initial visit is warranted. If symptoms persist, the history and physical examination should be repeated, looking for previously unsought clues and new physical findings. Laboratory studies might be required.

In patients with a cough illness of less than 3 weeks' duration, the evaluation should focus on ruling out serious illness. Normal vital signs and a normal chest examination effectively rule out most cases of pneumonia. Such cough illnesses are caused by viral pathogens in more than 90% of cases. Antibiotics are ineffective in such patients, and antimicrobial therapy does not prevent bacterial complications such as pneumonia. The presence of sputum and its characteristics are not helpful in distinguishing bacterial from viral infections. Adults with prolonged coughing lasting longer than 3 weeks or with recurrent episodes should be evaluated for reactive airway disease, gastroesophageal reflux, and other illnesses. Infections rarely causing prolonged cough include *Bordetella pertussis, M. pneumoniae,* and *Chlamydia pneumoniae.* Clinicians in this case should obtain a chest radiograph; treat for exacerbation of chronic obstructive pulmonary disease (fever, leukocytosis, purulent sputum), if present; treat a confirmed bacterial infection; and direct therapy to a specific underlying cause or other causes.

Symptoms and signs of pharyngitis include fever, tonsillar exudates, tender anterior cervical lymph nodes, and absence of cough. If fewer than two of these criteria are present, the patient should be managed as though viral pharyngitis were the cause. With two or more of these criteria, one should consider obtaining a rapid streptococcal antigen test. Because of the low incidence of streptococcal infection and acute rheumatic fever in adults, a negative rapid test alone is sufficient to rule out infection with *Streptococcus pyogenes.* If the antigen test is positive, the patient can be managed with a β-lactam antibiotic if not allergic. Ninety percent of cases of pharyngitis in adults are viral in origin. In a patient with symptoms of upper respiratory tract infection and a mucopurulent nasal discharge of less than 10 days' duration, it is important to remember that purulent nasal secretions do not predict bacterial infection. Most cases of acute rhinosinusitis seen in the outpatient setting are caused by uncomplicated upper respiratory viral infection. If symptoms have been present for more than 10 days without improvement, or if there are specific symptoms of sinusitis of any duration (purulent nasal discharge lasting 3 to 4 days, unilateral facial pain and pressure, maxillary toothache, or worsening of symptoms after initial improvement), amoxicillin or another β-lactam should be considered, with other antimicrobial classes used in penicillin-allergic patients.

Community-acquired pneumonia (Chapter 97) should be suspected in a patient with cough, sputum production, or dyspnea, especially if accompanied by fever and altered breath sounds. A chest radiograph should be performed to confirm the diagnosis. Determining where to care for the patient is the most important immediate decision. Outpatient care generally suffices for patients younger than 50 years with no cardiopulmonary disease, no comorbid conditions (including malignancy, heart failure, diabetes, hospitalization within the last year), and no physical examination findings such as altered mental status, pulse of 125 beats/minute or greater, or respiratory rate of 30/minute or greater. Recent guidelines developed by the American Thoracic Society and the Infectious Diseases Society of America suggest a β-lactam, macrolide, or doxycycline. Fluoroquinolones should be used for outpatients only when the patient has failed first-line therapy, has a significant comorbidity, or has a known allergy to a first-line agent.

Skin and soft tissue infections are caused, for the most part, by streptococci; a minority are due to *S. aureus* and, rarely, other bacteria whose presence may be suggested by epidemiologic considerations (e.g., swimming in fresh water, where *Aeromonas* may be the pathogen). Pain may be present for 12 hours or more before skin discoloration is noted. A furuncle or abscess formation should prompt consideration of *S. aureus* and, rarely, *Streptococcus milleri.* Incision and drainage may be sufficient for a skin abscess, although the rapidly expanding, virulent, community-acquired methicillin-resistant *S. aureus* phenotype may require antimicrobial therapy. Septic bursitis is nearly always due to *S. aureus,* and the infected bursa should be aspirated and drained, in addition to using antibiotics.

Gastrointestinal infections may be due to ingested toxins, viruses, or, less commonly, bacteria, with or without associated toxin production. The appropriate approach depends on the epidemiologic setting, such as improper food storage, travel abroad, or contact with another ill person. Symptoms of cystitis in a young, sexually active woman can be treated with empirical antibiotics, but when fever and flank pain are present and the patient is nauseated, consideration of a brief hospital admission or an initial intravenous dose of antibiotics may be necessary. The possibility of pelvic inflammatory disease should also be entertained.

In the initial evaluation of a patient with a more chronic, persistent fever, a careful history and physical examination provide important diagnostic clues, directing further investigation. The initial goal is to characterize the illness accurately, in addition to eliciting important host and epidemiologic factors. A careful review of systems is necessary to understand the extent of involvement of various organ systems, as well as to note previous medical conditions. The examination should be broader than for an acute febrile illness with localizing symptoms and signs. Laboratory tests may also play a more important role in guiding further investigation. Repeat evaluations are the norm rather than the exception in these cases. Blindly initiating empirical therapy in febrile patients with no imminent risk of serious clinical harm or death should be discouraged because it may impede a timely diagnosis affording definitive care.

INITIAL MANAGEMENT OF SUSPECTED NOSOCOMIAL INFECTION

Determination of the nature of a febrile illness in a hospitalized patient must take into account the host, the setting, and the timing of recent trauma or type and duration of surgery, in addition to the general approach taken for ambulatory patients. A classic mnemonic—the six Ws—may help guide the evaluation: wind, water, wound, walk, wonder drug, and what we did. "Wind" refers to fever within the first 24 hours of surgery, when it is unusual to have an infection. A fever at this time is often thought to be related to the anesthetic agent or to surgical trauma. The only bacteria believed to cause significant infections within 24 hours of surgery are *S. pyogenes* and *Clostridium* species, both of which are unusual in the typical hospital patient. "Water" refers to a urinary tract infection occurring after the third day of urinary tract catheterization. Because nearly all nosocomial urinary tract infections occur in patients with indwelling urinary catheters or in those who have undergone urologic instrumentation, urinalysis or culture (or both) should be performed routinely only in febrile patients with such risk factors. There is a high prevalence of bacteriuria in patients who have been catheterized for 3 days or longer, and there is a relatively low incidence of true infection attributable to bacteriuria. "Wound" infections commonly occur about 5 to 7 days postoperatively, whether they are surface wounds or complications of dehiscence of gastrointestinal anastomoses. Some of the highest rates of skin and soft tissue infections in the National Nosocomial Infection Surveillance database are seen with gastrointestinal procedures. Toxin-producing *C. difficile* is the only significant nosocomial gastrointestinal infection seen in hospitalized patients, so a routine bacterial culture is not necessary. "Walk" refers to possible deep vein thrombosis or pulmonary embolism in someone who has not received appropriate prophylaxis or who is otherwise at risk for thrombosis.

Fever induced by a "wonder drug" is typically seen after approximately 7 to 10 days of use if the patient does not already have an allergy to that medication, in which case it recurs immediately. An exception to this rule is sulfamethoxazole, in which approximately half of hypersensitivity reactions occur within 3 days of initiation. Finally, "what we did" alerts the clinician to the possibility of an iatrogenic infection, such as intravenous catheter–related bacteremia.

CONCLUSION

The initial management of patients with febrile illnesses requires three major considerations. First, is the illness more likely to be infectious or more likely to be related to some other process? Excessive antibiotic use when not warranted, such as for viral infections or collagen vascular disease, may cause an adverse reaction, in addition to contributing to the worldwide increase in antimicrobial resistance. However, an empirical antibiotic is appropriate in many cases of fever and localizing signs of bacterial infection. Second, the clinician must rapidly assess the severity of the illness and determine whether it is likely to cause significant organ damage or even death. In a febrile patient with signs of sepsis, the clinician must quickly decide which specific therapy is indicated, because a delay in initiating antimicrobial therapy is correlated with increased morbidity and mortality. Finally, the clinician needs to determine whether supportive care alone, including antipyretic therapy, is warranted.

The nearly universal prevalence of febrile adaptive responses to microbial challenge suggests that fever has a net benefit to the host. In addition to clinical studies correlating elevated core temperature and improved prognosis during infection, investigations of principal endogenous mediators have provided evidence of a protective effect of pyrogenic cytokines. Although the use of antipyretic medications is a long-established and widespread practice, the actual benefit of temperature reduction in febrile patients is uncertain. Antipyretic therapy does not protect against the recurrence of childhood febrile seizures, nor has its risk-benefit ratio been determined in patients with cardiopulmonary and other underlying disorders. In summary, fever is usually not harmful, and antipyretics may confuse the clinical picture by dampening it, although their anti-inflammatory effects are often beneficial.

APPROACH TO FEVER AND SUSPECTED INFECTION IN THE COMPROMISED HOST

KIEREN A. MARR

DEFINITION

This chapter focuses on the approach to suspected infection and fever in compromised hosts. There are multiple states (e.g., burns, intensive care unit hospitalization) that can fulfill the general definition of *compromised*, specifically with consideration of heightened risks for infection, but focus here will be placed on the immunocompromised host who has acquired defects in immune function, secondary to medical therapies. Examples include treatment of conditions such as neoplastic diseases (particularly hematologic disorders such as leukemia and lymphoma), organ transplantation, and treatment of collagen vascular or autoimmune diseases. Management of people with the acquired immunodeficiency syndrome (AIDS) is discussed in Chapters 392 through 402.

APPROACH TO THE PATIENT

The approach to the immunosuppressed patient requires detailed knowledge of the type of immune defect and related risks. Table 289-1 is an attempt to outline general defects in host responses with the types of agents or conditions that characterize the three general groups of "medically immunosuppressed" patients discussed in the context of this chapter (treatment of neoplastic diseases, transplantation, and treatment of autoimmune and collagen vascular diseases).

Patients with Malignancy

In patients with neoplastic diseases, particularly hematologic malignancies, the underlying condition plays a role in dictating infectious risks. For instance, the absolute number of phagocytic cells belonging to the polymorphonuclear leukocyte series may be reduced or the function of those cells impaired in the setting of specific malignancies (e.g., acute or chronic leukemias). In conditions such as acute leukemia, in which the cells are abnormal in morphology and function, and only a small proportion of normally functioning cells circulate, risks for bacterial infections are enhanced, even in the absence of administered cytotoxic therapies. In certain conditions, such as in the setting of chronic lymphocytic leukemia, there may be quantitative defects in humoral factors that are critical in host defense, such as circulating immunoglobulin G (IgG) and IgM antibodies, secretory IgA antibodies, and components of the complement cascade that can directly lyse some bacteria and viruses. Another component of the population of phagocytic cells includes circulating monocytes and tissue macrophages and the fixed mononuclear cells of the reticuloendothelial system. These cells collaborate with helper T cells in defense against pathogens that can survive intracellularly, such as mycobacteria, fungi, and some viruses and parasites. The spectrum of infectious risks is further enhanced and prolonged after treatment with cytotoxic drugs (Chapter 182). These therapies affect other organ functions that are critical to defense, especially the integrity of the gastrointestinal tract mucosal barrier and airway innate clearance mechanisms, posing additional innate susceptibilities to bacterial and fungal pathogens. In this manner, the neoplastic disorder itself, as well as the specific therapies used to treat it, combine to define both acute and chronic risks for infection.

Transplant Recipients

Hematopoietic stem cell transplantation (HSCT) (Chapter 181) posits additional risks to the patient as a result of the agents used for conditioning therapy in preparation for the stem cell transplantation, variable rate and magnitude of cellular engraftment, and, in recipients of allogeneic HSCT, administration of additional agents to modulate risks for and treatment of graft-versus-host disease (GVHD). Thus, risks for specific infections can be roughly divided on a time scale relative to engraftment. Organ dysfunction, loss of natural barriers (skin and gut), and neutropenia dictate enhanced early risks for bacteria and fungi that inhabit the gastrointestinal tract; impaired humoral and secondary immunity enhance late risks for infections caused by viruses, fungi, and encapsulated bacteria, especially in people treated aggressively for GVHD.

Immunodeficiency in solid organ transplant recipients (Chapter 48) is largely related to the acute initiation and chronic maintenance requirements of therapies to suppress T- and B-cell function in order to minimize impact of allosensitization and decrease risks for early and late graft rejection. Therapies have evolved over time, with increased use of targeted biologic therapies, but in general, risks are largely related to those associated with acute and chronic cellular and humoral dysfunction. Type and amount of therapy differ according to immunologic risk of recipients. Additional variables modulating overall risks for infection include the altered anatomy, surgical intervention, and potential of infection transmitted from the graft itself (i.e., donor derived).

Transplant recipients have increased risks both for acute infection and for reactivation of latent infections after initiation of immunosuppression. Hence, pretransplantation evaluation should be focused on detection of latent herpes viruses (e.g., cytomegalovirus [CMV]) and other pathogens (e.g., *Mycobacterium tuberculosis*) that can be transferred or reactivated with transplantation and immunosuppression.

Two important concepts regarding immunosuppression that have emerged from the field of transplantation include observations of the

TABLE 289-1 CONDITIONS, INTERVENTIONS, AND IMMUNE DEFECTS TYPICALLY ENCOUNTERED IN THREE GROUPS OF COMPROMISED HOSTS

UNDERLYING CONDITION	INTERVENTION	TYPE OF DEFECT
Treatment of neoplastic diseases (particularly hematologic malignancies)	Cytotoxic chemotherapies	Bone marrow suppression. Defects in primary and secondary humoral and cellular immunity. Breach in mucosal barriers (skin, gut). Impairment in mucociliary clearance. Defects in other organ function (e.g., kidney, liver)
Transplantation: hematopoietic stem cell transplantation (HSCT)	Underlying disease (e.g., hematologic malignancies)	Defects in primary and secondary humoral and cellular immunity. Defects in phagocytic cell quantity and function
	Cytotoxic conditioning therapy (± total body irradiation)	Bone marrow suppression. Defects in primary and secondary humoral and cellular immunity. Breach in mucosal barriers. Defects in organ function
	Stem cell manipulation (e.g., T-cell depletion)	Delay in cellular engraftment
	Prophylaxis and treatment of graft-versus-host disease (e.g., corticosteroids, calcineurin inhibitors, antimetabolites, TNF-α antagonists)	Defective function in phagocytic cells and dysfunction of primary and secondary humoral and cellular immunity
Solid organ transplantation (SOT)	Underlying disease (e.g., diabetes, end-stage liver disease)	Organ dysfunction and miscellaneous immune dysfunction
	Induction therapies (e.g., corticosteroids, antilymphocyte globulin, splenectomy, anti-IL-2 Ab, anti-CD52 Ab, calcineurin inhibitors	Depletion and impairment in primary and secondary cellular and humoral immunity
	Surgical intervention and altered anatomy	Breach in mucosal barriers. Defects in organ function.
	Acute and chronic rejection prophylaxis and treatment (e.g., corticosteroids, calcineurin inhibitors, antimetabolites and alkylating agents, plasmapheresis, antithymocyte globulin, monoclonal antibodies to B and T cells, anticytokine therapies, T-cell costimulation blockers)	Defective function in phagocytic cells, primary and secondary humoral and cellular immunity
Treatment of collagen vascular and autoimmune diseases	Anti-inflammatory and immunosuppressive agents (corticosteroids, nonsteroidal anti-inflammatory drugs, calcineurin inhibitors, sirolimus, mycophenolate mofetil)	Defective function in phagocytic cells, primary and secondary humoral and cellular immunity
	Antimetabolite and alkylating agents	Bone marrow suppression, defects in primary and secondary humoral and cellular immunity
	Biologic immune response modifiers (e.g., antithymocyte globulin, monoclonal antibodies to B and T cells, anticytokine therapies, T-cell costimulation blockers)	Defective function in primary and secondary humoral and cellular immunity

Ab = antibody; TNF = tumor necrosis factor.

immunomodulatory effects of viral reactivation and infection, and the "net state of immunosuppression." It was long ago noted that viral infections (both reactivation and disease) and, in many models, seropositivity alone enhance risks for other infections. This has been particularly well documented for CMV (Chapter 384), which is recognized as a risk for other infections in both recipients of hematopoietic stem cell and solid organ transplant grafts. Overall risks for infection are largely related to epidemiologic exposures and the net state of immunosuppression, dictated by multiple host, donor, and medical variables. This net state is variable both in quantity and changes in character over time, largely influenced by therapies to prevent rejection or GVHD, and other complications, such as viral reactivation. This concept, which originated toward an understanding of solid organ transplantation, can perhaps be applied to the care of all immunosuppressed patients in general.

Patients Treated for Autoimmune Disease

Table 289-1 also outlines the types of immunosuppressive therapies frequently administered to patients for the control of connective tissue diseases and autoimmune conditions. This is detailed here in order to emphasize that this group of patients is growing in importance in both hospitalized and outpatient populations, with increased use of biologic immune response modifiers (Chapters 34 and 35) enhancing risks for both reactivation of latent infection (e.g., *M. tuberculosis*) and severe manifestations of acute infection. Infectious risks should be considered when balancing need for these therapies, designing preventative regimens, and creating differential diagnoses of suspected infection.

FEVER DURING NEUTROPENIA: CONSIDERATIONS AND DIAGNOSTIC EVALUATION

The onset of fever in a compromised patient can be an ominous development, and depending on the nature and magnitude of the impaired host defenses, a febrile response can herald the onset of a life-threatening systemic infection. If fever occurs in the setting of chemotherapy-induced neutropenia, the risk for bacterial infection increases proportionally with the decline in neutrophil count, especially with prolonged durations of significant neutropenia. Early pivotal studies documented that infection rates increase with neutrophil levels lower than 1000 cells/mm^3, progressively increasing as counts decline to less than 100 cells/mm^3. The duration of significant neutropenia is also an important determinant of the type of infection most likely to occur, with the risk for bacterial and fungal infections increasing with each successive week in which leukocyte counts are less than 500 cells/mm^3. In these studies, neutropenia and lymphopenia played significant roles in influencing infection rates in the setting of acute leukemia; however, neutropenia alone was more important than lymphopenia alone. This study marked some of the earliest efforts that laid the foundation for our current approach to treatment of fever during neutropenia.

Historically, the most common causes of fever during neutropenia were gram-negative bacteria arising from the gastrointestinal tract. These observations drove establishment of empirical and prophylactic antibiotic practices designed to prevent primary development and to treat unrecognized infection caused by the most common predicted pathogens. In the 1990s, concurrent with increased use of prophylactic and empirical antibiotics, especially quinolones and extended spectrum β-lactams, reported rates of gram-negative bacteremias declined, with proportional increases in the numbers of bacteremias caused by gram-positive organisms. The precise reason, such a change in epidemiology occurred, is a matter of debate and likely multifactorial; in addition to increased use of effective preventive antibacterials, there has likely been a role played by increased use of indwelling intravascular devices. It has also been recognized that fever that persists despite administration of broad-spectrum antibacterial therapy may herald the onset or presence of undiagnosed invasive fungal infections.

The importance of mucositis in influencing both the occurrence of primary inflammation and the development of bacterial or fungal infection through mucosal barrier injury cannot be overemphasized in patients administered

TABLE 289-2 APPROACH TO FEVER DURING CHEMOTHERAPY-INDUCED NEUTROPENIA

PAST AND CURRENT CLINICAL CONSIDERATIONS
What is the type and duration of immunologic deficiency?
Does the patient have any organ dysfunction that would predispose to particular infection?
Does the patient have any unique environmental or epidemiologic exposures?
What are the patient's prior infections and colonizing organisms?
What are the current and recently administered antimicrobial agents?
Are there any specific presenting signs or symptoms that suggest a particular type of infection or syndrome?

TABLE 289-3 MULTINATIONAL ASSOCIATION OF SUPPORTIVE CARE IN CANCER (MASCC) RISK SCORING INDEX FOR IDENTIFICATION OF LOW-RISK PATIENTS WITH FEBRILE NEUTROPENIA

cytotoxic therapy for treatment of malignancies or HSCT. Studies have shown that mucositis can produce inflammation adequate to drive development of fever. It is also likely that a reasonable percentage of patients develop fever due to transient seeding of the blood stream with colonizing bacterial or fungal pathogens. Some of these infections may be caused by organisms that are less well adapted toward growth using standard microbiologic methods. These concepts support liberal use of empirical antimicrobials in the febrile neutropenic setting, with the focus on administering a compound that is active against the most likely pathogens, considering the patients' epidemiologic exposures and colonizing organisms and the hospital environment.

Table 289-2 lists multiple questions and considerations that the clinician should entertain when approaching fever in the neutropenic patient. The differential diagnosis of fever in the setting of chemotherapy-induced neutropenia is influenced by local and hospital exposure and the type of preventive antibiotics administered to the patient, which serve to alter microbial epidemiology within the gastrointestinal tract (see Table 289-2). Importantly, the type and the duration of immunodeficiency can alter overall risks, with "latent" infections presenting at development of first fever. Specific organ dysfunction, such as underlying pulmonary disease or renal impairment, can predispose to unique infectious syndromes (see later). Epidemiologic exposures should be thoroughly solicited; for instance, diagnostic evaluation should consider whether the patient previously or currently resides in areas endemic for *M. tuberculosis* or other infections that become latent (e.g., histoplasmosis). Current and previously administered antimicrobial drugs both affect risks for specific infections and can alter host microbial epidemiology. With this in mind, it is useful to have some information on colonizing organisms that may display complex resistance profiles, such as vancomycin-resistant enterococci and bacteria that express extended spectrum β-lactamases. Knowledge of recent colonization with these organisms should tailor initial antibiotic management, especially in patients who present severely ill.

One early consideration in treatment of fever during neutropenia is whether the patient requires hospitalization for therapy. Risk assessment is an integral part of early evaluation to determine whether outpatient therapy is feasible. Two risk-assessment systems have been developed, with the Multinational Association of Supportive Care in Cancer (MASCC) score validated to serve as a useful predictor of outcome, potentially assisting in identifying patients who can be treated with oral antibiotics and close monitoring rather than inpatient therapy (Table 289-3). In this model, a calculated index of more than 21 identifies low-risk patients who have a less than 5% risk for complications. Although the score is useful as a general guide to risk stratification, other variables that are important to consider when making risk assessment are underlying disease (e.g., lymphoma vs. leukemia), past and anticipated duration of neutropenia, symptoms and signs of infection foci, other comorbidities, and perhaps most importantly, whether the patient has access to immediate and reliable medical attention if discharged from the medical facility.

The onset of fever should trigger a prompt and thorough bedside evaluation of the patient. Beginning with examination of the head and neck, there should be a specific examination for evidence of central nervous system (CNS) infection as well as a general evaluation of mental status. The oropharynx must be examined for evidence of pharyngitis and focal tenderness. Sinus membranes should be evaluated for the presence of erythema or necrosis. Complete examination of the heart, lung fields, and abdomen is critical, with attention to the potential presence of new murmurs, pneumonia, and intra-abdominal tenderness. The perirectal area and the entire integument should be examined. Intravenous catheter exit sites and tunnels should be carefully examined, and blood should be drawn through all catheter channels for culture. Because catheter exit sites and tunnels can be infected in neutropenic patients without showing early signs of inflammation and erythema and with classic signs of infection presenting only after return of neutrophils, examination should be performed daily and with close scrutiny for evolving localized infection that may necessitate catheter removal.

Laboratory studies should be undertaken, with emphasis placed on procedures that can yield prompt results, such as Gram stain of body fluids, exudates, or aspirates. Routine blood work should include a complete blood count with differential, serum creatinine, and screening liver function studies. A chest radiograph should be part of the initial evaluation, as should routine urinalysis. Because routine radiographs are insensitive for detection of small nodular lesions, especially those caused by filamentous fungi, computed tomography (CT) should be performed when evaluating persistent fever, especially in the presence of airway symptoms.

Although fever is the hallmark of infection, it is not specific for the presence of an infectious process. The development of fever may be a result of multiple causes, including medications, reaction to blood components, and GVHD. The fundamental principle is that infection should be suspected as the most likely cause of fever in a compromised host, and therapy should be applied empirically, even as diagnostic tests are being performed. Multiple episodes of fever during prolonged hospitalization and neutropenia are not uncommon; each episode requires comprehensive assessment. After a documented infection, it should not be assumed that a subsequent episode of fever is caused by the same recrudescent pathogen; the law of diagnostic parsimony tends to be less reliable in immunosuppressed patients.

FEVER DURING NEUTROPENIA: MANAGEMENT

Progression of infection can occur rapidly in neutropenic hosts. Observation of very high mortality rates associated with bacteremia, especially those caused by gram-negative bacteria, triggered the introduction of routine empirical therapies (i.e., treatment of fever before diagnosis of infection). There are now many options for initial antibiotic therapy; choice should be tailored according to patient and institutional variables, as outlined in Table 289-1 and Figure 289-1. The first therapeutic distinction is whether a patient is at high risk, warranting inpatient management and intravenous antibiotic therapy, or low risk, potentially treated with oral regimens as an outpatient. In low-risk patients, the combination of a fluoroquinolone such as ciprofloxacin with amoxicillin-clavulanate, or levofloxacin alone, has been shown to be effective. In high-risk patients, admission for treatment and prompt administration of a broad-spectrum antibiotic regimen is necessary. Early studies demonstrated that the combination of an antipseudomonal β-lactam and an aminoglycoside is effective. Extended-spectrum agents, such as third- and fourth-generation cephalosporins and carbapenems, were then shown to be effective options administered as monotherapy. Meta-analyses have now shown that the routine use of an aminoglycoside in combination may result in more toxicities and no better outcomes.

One major choice in early therapy involves the decision to use vancomycin initially in high-risk patients. Advocates point to the risk for gram-positive infections that may carry a higher morbidity in neutropenic patients, including those caused by *Staphylococcus aureus* and viridans streptococci. However,

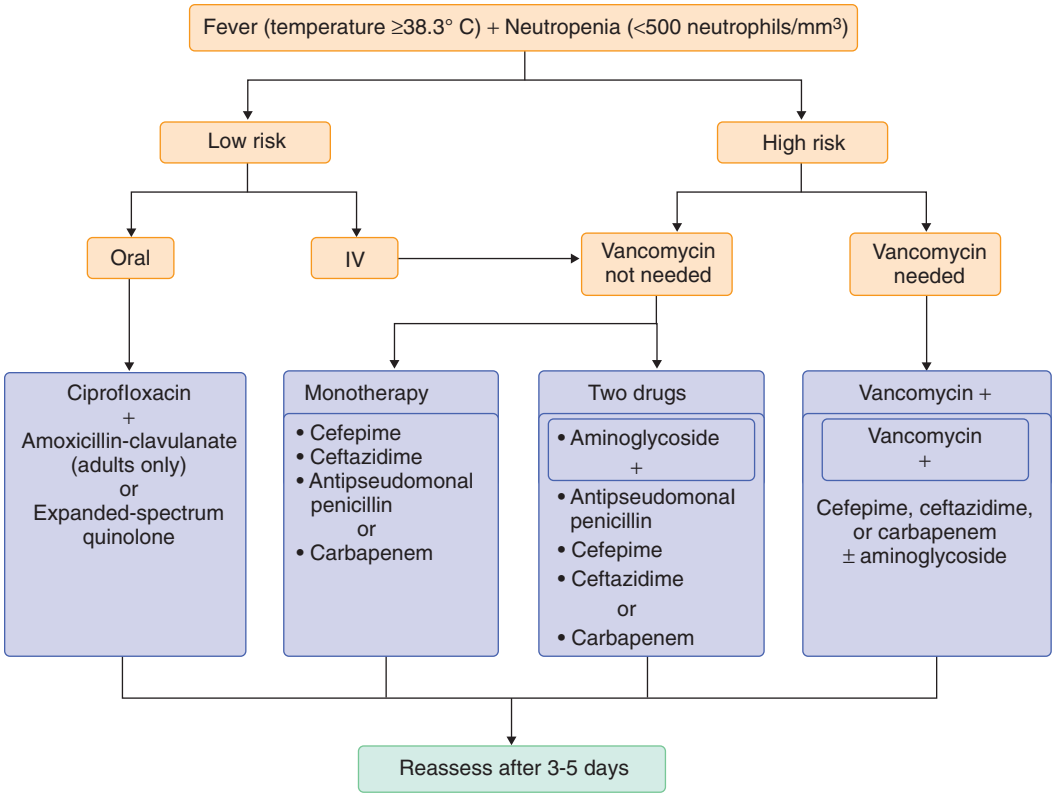

FIGURE 289-1. Algorithm for the initial management of febrile neutropenic patients. Risk assessment discussed in text and summarized in Table 289-3. "Vancomycin needed" is also discussed in text. (Modified from Hughes WT, Armstrong D, Bodey GP, et al. 2002 Guidelines for the use of antimicrobial agents in neutropenic patients with cancer. *Clin Infect Dis*. 2002;34:730-751.)

because initiation of vancomycin with fever does not affect outcomes except in the case of treating breakthrough viridans streptococcal infection, general guidelines for initiation of vancomycin include documented or suspected catheter-related infection, colonization with penicillin and cephalosporin-resistant pneumococci or methicillin-resistant *S. aureus*, positive blood cultures for gram-positive bacteria, and hemodynamic instability. A meta-analysis of randomized controlled trials showed that addition of a glycopeptide to an initial empirical regimen did not result in improved treatment success, and adverse effects, including nephrotoxicity, were more common.[2] These observations, combined with increased use of broad-spectrum empirical agents, support a strategy of applying glycopeptides with persistent fever or in select situations of high risk for gram-positive infections, as described previously.

The median time to defervescence is shorter (2 days) in low-risk patients and longer (5 to 7 days) in high-risk patients. Clinical response to the first few days of therapy is a critical determinant of the course of extended antimicrobial therapy. Therapy should be tailored to the diagnostic findings. If patients are stable yet still febrile during a period of prolonged and severe neutropenia, clinical judgment must be used in deciding whether to maintain the initial regimen or switch to an alternative regimen. If patients become afebrile after 3 to 5 days of antibacterial treatment but cultures are negative, some authorities recommend continuing the broad-spectrum intravenous coverage until recovery of the neutrophil count. This, however, may not be practical for patients with leukemia in blast crisis or refractory aplastic anemia, in whom periods of aplasia lasting weeks or more are common. Others believe that a switch to oral treatment is justifiable (e.g., a fluoroquinolone possibly paired with a ß-lactam) if the patient becomes afebrile and appears to be clinically stable. If the patient remains afebrile, there is rapid improvement in the underlying condition, such as with recovery of the circulating neutrophil count to higher than 500 cells/mm^3, and no focus of infection is identified, discontinuation of treatment is an option. If the neutrophil count recovers to above 500 cells/mm^3 and fever persists, clinical judgment must be used to define needs for antimicrobial therapy while a search for the cause of the fever is continued. If the patient was initially treated with vancomycin and no confirmatory cultures supporting continued vancomycin use are obtained after 3 days (e.g., no coagulase-negative staphylococci from blood or methicillin-resistant *S. aureus*), intravenous vancomycin therapy should be discontinued.

Clinical deterioration should trigger consideration of infections resistant to the empirical regimen. Classic examples include breakthrough streptococcal bacteremia in patients not receiving vancomycin, breakthrough extended-spectrum β-lactamase–producing gram-negative bacteria in patients taking single-agent β-lactams, *Stenotrophomonas* species infections occurring in the setting of carbapenem monotherapy, and, especially more recently, infections with multidrug-resistant pathogens, such as *Acinetobacter* species and organisms that produce carbapenemases.

There are many causes of persistent fever, both noninfectious and infectious. Noninfectious causes include hematomas, drug reactions, transfusion reactions, pulmonary emboli, splenic infarcts, and the underlying malignancy. The possibility of infection caused by nonbacterial pathogens, such as fungi (especially *Candida* and *Aspergillus* species) prompted evaluation and widespread adoption of routine antifungal empirical therapies in the setting of fever that persists more than 4 to 7 days. Many drugs have been evaluated and shown to be effective in this setting, including azole drugs, echinocandins, and polyenes.[3,4] Choice should be tailored to current antifungal prophylaxis, diagnostic findings, suspicion of *Candida* versus *Aspergillus* infection, and organ function.

There are no hard and fast rules for duration of therapies; the simplest recommendation is to treat documented pathogens until the signs and symptoms of infection subside. On the other hand, persistently compromised hosts may remain febrile for weeks without identification of the cause. For a patient with persistent fever in whom no pathogen is identified, the duration of therapy must be based on integration of clinical data and the best estimate of the direction of the host's status. As mentioned previously, therapy can be discontinued in stable, afebrile patients, assuming that the absolute neutrophil count exceeds 500 cells/mm^3. Clearly, if broad-spectrum antibacterial therapy is to be discontinued, the patient must be monitored carefully thereafter. For patients whose neutrophil counts remain at levels less than 500 cells/mm^3, particularly the subset with severe profound neutropenia of less than 100 cells/mm^3, it is prudent to continue empirical antibacterial and antifungal therapy, with reappraisal of all diagnostic measures. The decision to stop therapy at whatever arbitrary interval may be justified if the patient's condition is stable.

The use of granulocyte colony-stimulating factors (G-CSFs) for the prevention of febrile neutropenia is discussed in Chapter 170. For the management of established fever in neutropenic patients, evidence-based guidelines have been published by the American Society of Clinical Oncology[5] and by the Infectious Disease Society of America. The guidelines generally agree, and they support the use of CSFs in similar circumstances that indicate high risk for infection-associated complications and poor clinical outcomes, such as in patients with anticipated long and profound durations of neutropenia,

TABLE 289-4 INFECTIOUS AND NONINFECTIOUS SYNDROMES IN IMMUNOCOMPROMISED HOSTS

age greater than 65 years, uncontrolled primary disease, pneumonia, hemodynamic compromise, and invasive fungal infections.

The remainder of this chapter discusses diagnosis and evaluation of specific syndromes that are common in neutropenic hosts and individuals who are immunocompromised because of other therapies, including transplantation. Table 289-4 summarizes some of the most common infectious and noninfectious syndromes that involve the skin, lungs, gastrointestinal tract, and nervous system, as discussed later.

CUTANEOUS SYNDROMES

Cutaneous abnormalities can provide a clue to bacteremia, and aspiration and culture of suspicious lesions can be as valuable as a blood culture. Ascending streptococcal or staphylococcal cellulitis can occur in both immunocompromised and normal patients. Metastatic abscesses are a well-recognized part of the *S. aureus* bacteremia syndrome. Necrotizing vasculitis is classically associated with *Pseudomonas aeruginosa* infections (the cutaneous lesion of ecthyma gangrenosum is an erythematous, indurated target or "bull's eye" lesion with an area of central necrosis that can appear in crops) (Fig. 289-2). However, other gram-negative endotoxin-producing bacteria have been associated with similar cutaneous lesions.

In the neutropenic host, disseminated fungal infections may be initially recognized by characteristic cutaneous lesions. Disseminated candidiasis in neutropenic patients can present with diffuse maculopapular, erythematous, and sometimes tender lesions. Disseminated infections caused by filamentous organisms such as *Aspergillus* species cause similar lesions, but usually fewer in number and more often with some component of central necrosis. Other filamentous fungi, namely those with which infection is characterized by a high fungal burden, such as *Fusarium* species, typically cause more skin lesions in multiple stages of evolution, ranging from papules to larger erythematous lesions with central necrosis. Multiple filamentous fungi such as *Aspergillus* species and Zygomycetes can also cause primary cutaneous lesions, especially with a breech in skin integrity, associated with catheter sites, trauma, and surgery. Infection with *Cryptococcus neoformans* can be accompanied with cutaneous involvement, with manifestations ranging from molluscum-like lesions to primary cutaneous cellulitis, which may be especially common in solid organ transplant recipients. Cutaneous lesions are an opportunity to establish diagnosis through aspiration, biopsy, and culture.

Morbilliform eruptions or maculopapular exanthems are frequent in neutropenic patients and transplant recipients, and they can be caused by drug reactions, GVHD, and numerous viral infections. Primary infection and reactivation with herpes viruses such as CMV and Epstein-Barr virus (EBV) can be accompanied by rashes, and diagnostics should be considered in the appropriate context. Human herpesvirus-6 (HHV-6), the primary cause of roseola infantum in childhood, leads to latency and can cause disease in immunocompromised hosts both by reactivation and primary infection. Disease can be accompanied by fever, rash, myelosuppression, and involve other organ systems (e.g., CNS). In immunocompromised patients, adenovirus can be both primarily acquired, usually through the respiratory tract, and reactivated, and it causes fever, rash, and potentially disease involving multiple organ systems (lungs, gastrointestinal tract, kidneys, liver, CNS). In HSCT recipients, the constellation of fever, rash, diarrhea, and hepatitis may be confused for severe GVHD. Parvovirus B19 infection can be severe in immunocompromised hosts and associated with fever, rash, and manifestations of hemophagocytosis, although there are other infectious causes of hemophagocytic syndromes as well. The characteristic vesicular rashes of varicella reactivation are frequent in stem cell and solid organ transplant recipients with chronic T-cell deficiencies, especially in the absence of antiviral prophylaxis; an important therapeutic consideration is to recognize and aggressively treat disease that involves viscera because disseminated disease is associated with high mortality rates. Antivirals administered as prophylaxis in high-risk HSCT and solid organ transplant recipients can decrease both early morbidity and late mortality associated with herpes simplex virus (HSV), varicella-zoster virus (VZV), and CMV disease, although drug-related toxicities need to be measured in risk-benefit calculations.[6,7]

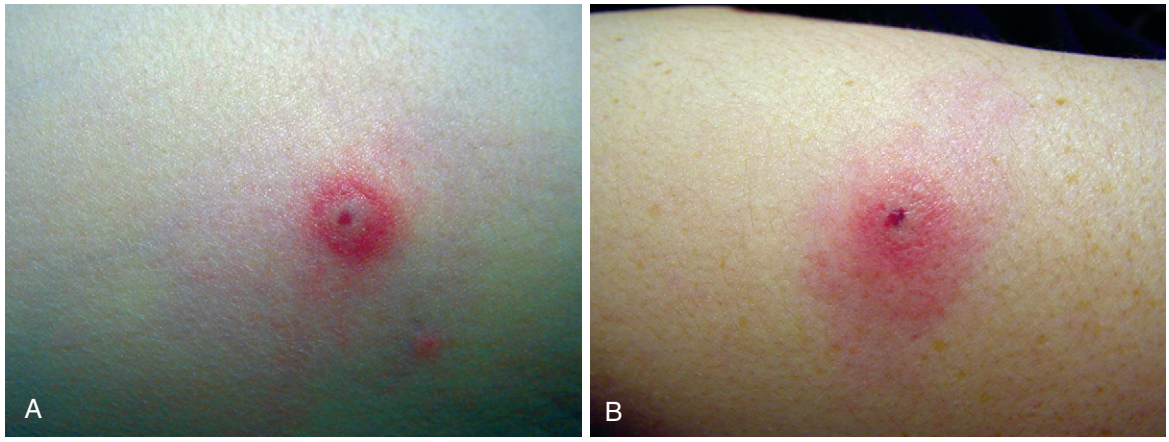

FIGURE 289-2. Ecthyma gangrenosum. A 28-year-old woman with fever and neutropenia while on chemotherapy for acute leukemia developed several tender edematous papules on her thighs. **A,** Central crust and surrounding erythema are shown. **B,** The papula becomes necrotic over 1 to 2 days, with the formation of black, well-demarcated eschar. Cultures from blood and the necrotic eschar grew *Pseudomonas aeruginosa*. (© DermAtlas; http://www.DermAtlas.org.)

There are numerous noninfectious causes of skin rashes and lesions that are common in immunocompromised individuals. Drug-induced hypersensitivity syndromes can be both mild and severe, potentially associated with life-threatening toxic epidermal necrolysis. As in other populations, antimicrobial agents are frequently implicated as causative agents. GVHD, especially during the acute phase, frequently presents as suspected infection, with fever, nonspecific skin rashes, and frequently, disease involving the gastrointestinal tract (diarrhea, hepatitis).

Sweet's syndrome, or acute febrile neutrophilic dermatosis, is characterized by skin lesions with neutrophilic infiltration in the dermis (see Fig. 448-22 in Chapter 448). This presents a diagnostic dilemma in neutropenic patients and has been described in the setting of impending neutrophil recovery or treatment with G-CSF. It is also associated with numerous drugs and can appear as a paraneoplastic phenomenon. Biopsy with appropriate microbial stains and culture is essential to distinguish these lesions from infectious causes of ecthyma gangrenosum and other disseminated infections such as those caused by fungi.

RESPIRATORY SYNDROMES

The lungs are a challenging site in evaluating fever in a compromised patient because detection of abnormalities is easy but obtaining lung secretions or infected tissues can be difficult. Pneumonia should be suspected in a patient who has respiratory symptoms as manifested by cough, shortness of breath, chest pain, and hypoxia. In the early stages of pneumonitis, routine chest radiographs may be negative, whereas more expensive imaging procedures such as computed axial tomography can reveal pulmonary infiltrates or abscesses. Both community-acquired pathogens such as pneumococci and *Haemophilus influenzae* can cause lobar or diffuse pneumonia. Gram-negative bacilli can cause pneumonia of a necrotizing type in severely neutropenic patients. All patients who are receiving ventilator support are at risk for secondary gram-negative bacillary pneumonia or staphylococcal pneumonia. Clusters of outbreaks of *Legionella pneumophila* infection have occurred in immunocompromised patients maintained in dialysis, transplant, or intensive care units; these outbreaks reflect institutional environmental contamination. Pulmonary involvement is primary with tuberculosis but may be secondary with nontuberculous mycobacteria such as *Mycobacterium avium,* which usually originates from the gastrointestinal tract.

Opportunistic fungi have been increasingly recognized as causes of lung infection in compromised neutropenic patients and transplant recipients. A travel history is essential in a compromised patient who has evidence of lung disease; epidemic mycoses such as blastomycosis, coccidioidomycosis, and histoplasmosis may present as acute pneumonia after recent exposure (although more typically, initial exposure in a normal host leads to containment in an initial focus of fungal lung disease). After immune suppression, the primary focus can be the source of reactivated disease. *Candida* species, in contrast, are uncommon primary lung pathogens. Although *Candida* species commonly colonize indwelling vascular and urinary catheters, candidal pneumonia is unusual in the absence of systemic candidiasis. Systemic candidiasis usually originates from the gastrointestinal or genitourinary tract if not secondary to vascular catheter dissemination. Although traditionally associated with an "interstitial pattern" of lung infiltration, *Pneumocystis* species pneumonia can be manifested as local consolidation or pulmonary nodules, frequently exhibiting granulomatous inflammation on pathology. Filamentous fungi, which include *Aspergillus,* Zygomycetes, and less frequently diagnosed *Fusarium* species and *Scedosporium* species, are difficult to treat. These infections may be accompanied by chest pain and occasionally hemoptysis. From an initial focus, *Aspergillus* infection can spread through the pulmonary vasculature, which sets the stage for localized hemorrhage, creating a halo sign on CT scan, and infarction and necrosis, which can progress to cavitary lesions. Non-neutropenic hosts frequently also develop less specific radiographic findings, such as bronchopneumonia. These organisms can also cause primary airway disease, presenting with features typical of tracheobronchitis, with or without findings apparent on CT scan. This infection is particularly well described in lung transplant recipients, who may also have involvement of the bronchial anastomosis.

Recently, attention has been drawn to the high risks for severe pulmonary infection caused by reactivation *M. tuberculosis* in people who are treated with biologic immune response modifiers (Chapter 35) in the setting of autoimmune or other inflammatory diseases, such as with rheumatoid arthritis, psoriasis, and inflammatory bowel diseases. High risks are particularly well described in the setting of treatment with tumor necrosis factor antagonists, justifying enhanced vigilance, including routine screening for prior infection, and consideration of preventive chemotherapy. These patients are also at increased risk for invasive fungal infections, including reactivation of endemic infections such as histoplasmosis, warranting enhanced screening and high suspicion for disease.

Viral infections that involve the lung are difficult to diagnose in immunocompromised patients. Particularly common concerns are reactivation pneumonitis caused by members of the herpesvirus family, especially CMV, which occur most frequently in the setting of chronic T-cell depression associated with transplantation. Respiratory viruses, which infect immunocompromised hosts with the same frequency as in the general population, cause lower tract disease and pneumonitis more frequently in hosts with suppressed cellular immunity. Essentially any respiratory virus can cause upper and lower tract disease, depending on geographic and seasonal epidemiology; most frequently recognized are respiratory syncytial virus, parainfluenza viruses, influenza viruses, and adenoviruses. Patients who have defects in cellular immunity typically exhibit higher viral loads and prolonged shedding, presenting considerations with regard to enhanced therapy, emergence of antiviral resistance, and infection control. The transplant population has served as a sentinel population in recognizing multiple emerging viral pathogens, including human metapneumovirus, bocavirus, and the KI and WU polyomaviruses.

There are numerous recognized noninfectious causes of pulmonary infiltrates in immunosuppressed hosts. These include early complications of chemotherapy administration, such as diffuse alveolar damage and hemorrhage, as well as late complications of GVHD and organ rejection (e.g., bronchiolitis obliterans syndromes). Certain drugs that are frequently administered in these patient populations can cause direct lung toxicity; classic examples include the proliferation signal inhibitor sirolimus.

GASTROINTESTINAL SYNDROMES

There are multiple causes of diarrhea in a compromised host, including conventional enteric pathogens such as *Salmonella* (Chapter 316), *Shigella* (Chapter 317), and *Campylobacter* (Chapter 311). In patients who have been in the hospital and have been receiving multiple courses of antibiotic treatment, *C. difficile* (Chapter 304) is a common occurrence, and colitis can be both severe and persistent in immunosuppressed hosts. Two acid-fast staining parasites are *Isospora belli* and *Cryptosporidium* species, and they are associated with predisposing impairments in cell-mediated immunity. More recently recognized are the microsporidians. *Giardia lamblia* is classically associated with hypogammaglobulinemia. Individuals who have received long courses of chemotherapy, radiation, and antibiotics commonly experience *Candida* mucosal overgrowth in the mouth and esophagus. HSV and CMV can cause symptoms identical to those of *Candida* esophagitis. In severely neutropenic patients, anaerobic streptococci and gram-negative pathogens such as *P. aeruginosa* can cause severe mucositis and pharyngitis. In cancer patients, these organisms take advantage of the cytotoxic effects of chemotherapy, which promotes sloughing of mucosal surfaces and subsequently predisposes to infection.

Neutropenic patients may develop enterocolitis that can be of mixed anaerobic and aerobic bacterial origin. Neutropenic enterocolitis, also known as typhlitis or ileocecal syndrome, results from chemotherapeutic damage to the intestinal mucosa in the setting of neutropenia. Presentation usually includes fever, abdominal pain, nausea, vomiting, and diarrhea. Because neutropenic enterocolitis can rapidly progress to intestinal perforation, sepsis, and multisystem organ failure, prompt diagnosis and aggressive medical or surgical intervention are required.

CMV colitis can be focal or diffuse; in some solid organ transplant recipients, disease can be present without demonstration of a positive blood polymerase chain reaction for CMV, so endoscopy is required for diagnosis. Norovirus gastroenteritis can be severe and protracted and is frequently misdiagnosed as gastrointestinal GVHD in allogeneic HSCT recipients. Because the differential diagnosis of colitis and diarrhea is broad and includes multiple infections, focal EBV-associated post-transplantation lymphoproliferative disorder, GVHD, and drug-induced toxicities such as that caused by mycophenolate mofetil, these patients should be evaluated with endoscopy to reach definitive diagnosis.

NEUROLOGIC SYNDROMES

Both gram-positive and gram-negative bacteria (including anaerobes) can cause brain abscess or meningitis. *Listeria monocytogenes* is a common cause of meningitis in a compromised host. This pathogen is a gram-positive pleomorphic bacillus that may be difficult to identify on routine Gram stain of cerebrospinal fluid. Encapsulated bacteria such as pneumococci and staphylococci can cause metastatic CNS disease and meningitis. In patients with impaired cell-mediated immunity, *C. neoformans* is also a leading cause of CNS infection. Other fungal pathogens such as *Aspergillus* and other molds can invade the CNS, both by direct sinus invasion and by hematogenous spread. Focal brain lesions and meningoencephalitis in individuals who have chronic deficiency in cellular immunity can be caused by reactivation or acute severe infection by typically latent organisms such as *Toxoplasma gondii*, *M. tuberculosis,* and *Histoplasma capsulatum*. Reactivated or quiescent CNS syphilis should also be considered in patients with severe immunologic impairment.

There are numerous viral causes of meningoencephalitis; similar to other populations, one needs to consider enteroviruses, measles, and, neurotropic herpesviruses (HSV-1, CMV, VZV). HHV-6 is a common cause of encephalitis and post-transplantation acute limbic encephalitis in transplant recipients, characterized by seizures, anterograde amnesia, and neuroimaging abnormalities involving the temporal lobes. Progressive multifocal leukoencephalopathy caused by JC polyomavirus occurs in patients with chronic CD4 deficiency, such as with human immunodeficiency virus type 1 (HIV-1) infection. Recent studies have emphasized that solid organ transplant recipients are at increased risk for meningoencephalitis caused by West Nile virus compared with the general population. Anyone presenting early after transplantation should be considered at risk for potentially severe infections acquired from the donor; West Nile virus, rabies, HIV, HSV, and multiple other viruses have been documented to be transmitted through organ donation.

There are multiple noninfectious causes of neurological symptoms, which include drug toxicities and immunologic disorders, such as paraneoplastic syndromes and Guillain-Barré syndrome. Particularly relevant in the transplant recipient, patients with autoimmune diseases, and recipients of high-doses of cancer chemotherapy is the posterior reversible encephalopathy syndrome (PRES). The classic presentation of PRES encompasses a sudden onset of severe "thunderclap" headache, seizures, confusion, and visual disturbance, accompanied by a CT or magnetic resonance imaging pattern of predominantly posterior cerebral edema and angiographic evidence of reversible vasoconstriction. It may be caused by endothelial injury, vasospasm, or edema associated with drugs such as calcineurin inhibitors (cyclosporine, tacrolimus).

CONCLUSION

Infections are a major cause of mortality in immunocompromised hosts. The approach to fever and suspected infection requires knowledge of specific risks inherent to the type and duration of immunodeficiency, diagnostic diligence, and tailored therapeutics designed to avoid rapid progression and poor outcomes.

290 PREVENTION AND CONTROL OF HEALTH CARE–ASSOCIATED INFECTIONS

NEIL FISHMAN AND DAVID P. CALFEE

Health care–associated infections, often referred to as *nosocomial* (from the Greek word *nosocomium,* meaning hospital), have been traditionally defined as infections that occur after hospital admission and that were neither present nor incubating at the time of admission. Because the site of health care delivery and management has increasingly shifted to the ambulatory setting, the relevance of traditional "hospital-associated" infections has diminished. An increasing number of patients are intermittently exposed to the health care environment and may become colonized or infected with health care–associated pathogens without ever being admitted to the hospital and thus may acquire health care–associated infections before admission. For example, patients may receive ablative chemotherapy for a stem cell transplantation and then be seen only as outpatients until substantial medical problems occur, including infections. Similarly, an increasing number of patients who have malignancies are being treated in "day hospital" settings and may never get admitted unless problems occur with respect to their care, including health care–associated infections.

Additionally, some health care–associated infections become manifested after hospital discharge. Delayed manifestations of these infections usually occur within days of discharge but may occasionally not become clinically apparent for months or even years. Development of these infections is dependent on the incubation period of the particular pathogen, the individual immunologic response to the infection, and the various specific risk factors for the infection. For example, operative insertion of prosthetic devices (such as joints) can impair the immune response to infection and allow an insidious infection to continue developing and finally be manifested months after insertion of the device. Similarly, hepatitis B or C infection acquired during surgery often does not become evident for weeks to months after discharge. Health care–related infections are associated with increased patient morbidity and mortality, substantial inconvenience for the patient and institution, and striking increases in the cost of care that are primarily absorbed by the institution in which they occur.

HISTORY

The earliest European hospitals were established in the Middle Ages and bore little resemblance to modern hospitals in either form or function. These primitive institutions were generally thought of as places where patients who had intractable diseases could be cared for until they died. Because most patients in that era died of infections, many of which were transmissible, contagion occurred commonly in hospitals. Crowding was so extreme in these institutions that hospital beds were sometimes used for multiple patients, and beds often had to be used in shifts. Such intense physical proximity allowed for effective transmission of organisms between patients and resulted in high rates of infection among those who did not die rapidly of their underlying diseases. According to some 19th century reports, surgery was almost always followed by infection, and 60% of limb amputations resulted in fatal infections. These squalid conditions led to early hospitals being called "pest houses."

The discovery plus clinical application of antibacterial agents such as sulfonamides and penicillin during the 1930s and 1940s was heralded as a medical miracle and resulted in lower rates of surgical infection. These momentous discoveries were followed, however, by the development of antimicrobial resistance to these new agents and the subsequent development of health care–associated infections caused by bacteria resistant to the new antibiotics. The first isolate of penicillin-resistant *Staphylococcus aureus* (PRSA) was noted at the time of discovery of penicillin, even before its widespread clinical use. Within a relatively short period, some hospitals reached epidemic rates of PRSA, thus rendering the new wonder drug powerless. Giving penicillin to patients who had penicillin-resistant infections had no effect. A pandemic of PRSA nosocomial infections led to national and international meetings, which in turn led to a consensus that required the creation of hospital infection control programs. The absence of effective antimicrobial therapy led to the realization that such infections might not always be curable and that prevention might thus be a more important intervention.

Other life-saving medical advancements were similarly associated with new types of lethal infections, such as catheter-related blood stream infection, prosthetic valve infection (endocarditis), and ventilator-associated pneumonia. In the 1970s, gram-negative bacillary infection became a somewhat more common cause of health care–associated infection, but infection with gram-positive cocci became predominant again in the 1980s. In the 1980s, *S. aureus* and coagulase-negative staphylococci displayed increasing frequencies of resistance to new agents that had been developed to combat resistance, such as methicillin and other β-lactam antibiotics. In the 1990s, vancomycin-resistant enterococci (VRE) emerged as a frequent cause of health care–associated infection, particularly in seriously immunocompromised patients. In the past decade, multidrug-resistant gram-negative bacillary organisms have emerged as significant health care–associated pathogens. Advancements in medical science during these decades allowed prolongation of life for patients who had sustained severe trauma and other severe illnesses. Advances in chemotherapy and immunosuppression permitted successful and life-prolonging therapy for previously untreatable neoplastic and autoimmune diseases; however, impairment of the immune system resulting from these aggressive therapies also made these patients highly susceptible to common and uncommon health care–associated infections.

IMPORTANCE OF HEALTH CARE–ASSOCIATED INFECTIONS

The literature from the 1970s suggests that six to eight health care–associated infections occurred for every 100 patients admitted to the hospital. During the 1990s, the total number of health care–associated infections remained essentially unchanged, but because there was a decrease in hospital admissions, the rate of health care–associated infections actually increased. The number and rates of these infections increased in great measure because the most severely ill patients continued to be admitted. Because of both their underlying disease states and the aggressive and invasive therapies used to manage their illnesses, seriously ill patients often have the highest risks for health care–associated infections. For a variety of reasons, discussed in more detail later, the numbers and types of antimicrobial-resistant organisms continued to increase, and these antibiotic-resistant infections have spread with facility throughout health care institutions. During the 1990s, the Centers for Disease Control and Prevention (CDC) estimated that the number of deaths directly or indirectly related to health care–associated infections increased from 80,000 to 88,000 annually.

Health care–associated infections are important because they cause additional inconvenience, suffering, and mortality for patients. Furthermore, these infections prolong hospitalization and significantly increase the cost of care, thus having a significant adverse effect on the health care system. The CDC has estimated the annual cost of health care–associated infections to be 28.4 to 45 billion dollars. Both the mildest (e.g., urinary tract infections) and the most severe (e.g., septic shock) infections are associated with unnecessary increases in cost and inconvenience for patients. Moreover, in the era of prospective payment plans, third-party payers will not reimburse for approximately 95% of the cost of nosocomial infections. For a variety of reasons, then, health care institutions must focus on prevention of these infections not only to increase patient survival and satisfaction but also to save money.

The attributable cost of nosocomial infections relates in part to prolonged duration of intensive care unit (ICU) or total hospital stays and in part to costs associated with the management of specific infections (e.g., additional diagnostic tests, antimicrobial therapy, personal protective equipment for isolation, and sometimes surgery). Studies have demonstrated that nosocomial blood stream infections result on the average in a 7-day prolongation of hospitalization associated with $40,890 in additional cost for surviving ICU patients and an attributable mortality rate as high as 30%. Generally, surgical site infections result in prolongation of hospitalization for an additional week. Health care–associated pneumonia usually occurs in patients who have been receiving mechanical ventilation and often results in 7 or more excess days in the hospital, frequently in the ICU. These patients often require ventilator support and expensive antimicrobial agents. Cases of health care–associated pneumonia result in increases in cost similar to those incurred by blood stream and surgical site infections (Table 290-1).

Urinary tract infection, the most frequent and least severe health care–related infection, has been associated with a 3-day increase in length of stay in two large case-control studies from different countries. A recent economic

TABLE 290-1 RATE AND IMPACT OF NOSOCOMIAL INFECTIONS IN ACUTE CARE HOSPITALS

SITE	NO. OF INFECTIONS PER 100 ADMISSIONS	% OF ALL NI	DIRECT COD	EXTRA DAYS	% OF NI EXTRA DAYS
Urinary tract	2.5	30	<1%	1-3	15
Surgical site	1.4	15	1-2%	7	23
Lung	1.4	15	5-10%	7	23
Blood stream					
Primary	1.4	15	3%	7	23
Secondary	0.3	3	25%	10	5
Others	2.2	24	<1%	2	11

TABLE 290-2 ANTIBIOTIC DISCOVERY AND DEVELOPMENT OF RESISTANCE

ANTIBIOTIC	DISCOVERY	CLINICAL USE	RESISTANCE IDENTIFIED
Penicillin	1940	1943	1940
Streptomycin	1944	1947	1947
Tetracycline	1948	1952	1956
Erythromycin	1952	1955	1956
Vancomycin	1956	1972	1987
Gentamicin	1963	1967	1970

analysis estimated the cost per catheter-associated urinary tract infection to be $749 to $1007 (in 2007 U.S. dollars). Although urinary tract infections are generally milder infections, they can cause more severe illness when infection ascends to the kidney or when secondary blood stream infection occurs. Blood stream infection secondary to urinary tract infection is associated with a crude case-fatality rate of 13 to 30%.

RESERVOIRS AND TRANSMISSION OF HEALTH CARE–ASSOCIATED INFECTIONS

Health care–associated infections occur for a wide variety of reasons and are caused by a broad spectrum of pathogens. In some cases (particularly in instances in which patients are severely immunocompromised by disease or treatment), a microbe that would rarely produce an infection may colonize and ultimately infect a hospitalized patient. Hospitalization and the diagnostic and therapeutic interventions associated with hospitalization may provide access to some normally protected parts of the body (e.g., insertion of a percutaneous catheter through the skin provides a portal of entry into the blood stream). Other pathogens that cause these infections are not present in or on the host at the time of hospital admission but colonize the host after admission (frequently after spending just 24 hours in the hospital). After variable periods of colonization, these health care–associated pathogens may produce active infections. Because many patients become colonized or infected with health care–associated pathogens, spread from one patient to another in a health care institution may occur by direct contact between patients, by contact with contaminated environmental surfaces, and perhaps most commonly by the contaminated hands, clothing, or equipment of health care providers. Health care workers move from patient to patient and, in the absence of appropriate hand hygiene, may easily transmit hospital pathogens. Studies have found that health care workers, on average, follow hand hygiene recommendations after only 40% of patient contacts that should prompt the use of hand hygiene. Nurses and allied health professionals comply more often than physicians, but no category of health care provider achieves rates of compliance greater than 70%. Poorest compliance has been observed in areas at highest risk for transmission, such as the ICU, where the number, types, and immediacy of invasive interventions are the highest and where, unfortunately, patients at the highest risk for adverse outcomes of these infections are often housed. Nevertheless, in recent years, substantial efforts have been made in many health care facilities to improve adherence to hand hygiene recommendations among health care personnel.

ANTIBIOTIC-RESISTANT INFECTIONS

No discussion of health care–associated infections would be complete without a thorough discussion of infections caused by antibiotic-resistant microorganisms as well as strategies to prevent transmission of these organisms. Resistant microorganisms became a significant problem in health care institutions within only a few years after the introduction of antibiotics for clinical therapy. Infections caused by antibiotic-resistant organisms are important because they are generally associated with prolonged illnesses, longer hospital stays, increased risk for death, and greater cost to the health care system than infections caused by antibiotic-susceptible strains of the same species. Antimicrobial resistance to new agents occurs rapidly and is often identified within months of the introduction of a new antimicrobial agent into the pharmacologic armamentarium (Table 290-2). Resistance is often first identified in hospitals and later in the general community. PRSA emerged in just this fashion at the time of discovery of penicillin, even before its widespread clinical use. For some antibiotics (e.g., vancomycin), resistance did not appear until three decades after its introduction. VRE first appeared in the mid-1980s. The organism appears to have different origins in the United States and Europe. In the United States, emergence of resistance is thought to be due to clinical overuse of vancomycin, but in Europe, it is attributed to the use of a related compound (avoparcin) as a nutritional supplement and growth enhancer in farm animals.

Two predominant risk factors have been identified for infection with antibiotic-resistant pathogens in hospitals: the volume of antimicrobial agents (especially broad-spectrum agents) used in the institution and spread from patient to patient in an institution (frequently by health care personnel). The reason that the prevalence of antibiotic-resistant pathogens has grown so rapidly in hospitals was perhaps most clearly explained by Charles Darwin, who noted that nature selects the strain or species most suited to survive within each environment. Because up to half of all patients in U.S. hospitals and almost all patients in ICUs receive antibiotics, a microbe that is resistant to currently administered antimicrobials has a selective advantage to survive, proliferate, and spread. For some combinations of microbe and antibiotic, the probability of a spontaneous mutation to resistance to that particular drug is so high that giving that drug alone for infections caused by that microbe invariably results in antimicrobial resistance. Two prime examples of the risk for development of resistance when using a single agent are tuberculosis and human immunodeficiency virus (HIV) infection.

For example, the risk for mutation to isoniazid resistance among *Mycobacterium tuberculosis* isolates is so high that monotherapy for active tuberculosis with isoniazid results in the development of resistance in 70% of patients. For other combinations of microbes and antibiotics, however, the probability of a spontaneous mutation to resistance is much lower, and administration of that drug alone does not result in an increased risk for resistance of that microbe to that drug. The latter pattern is true for combinations such as enterococci and vancomycin or *S. aureus* and methicillin, which correspond to two of the most frequent antibiotic-resistant infections in U.S. hospitals. In these two examples, antimicrobial resistance is due to acquisition of a genetic resistance determinant (e.g., the *vanA* and *mecA* genes, respectively) rather than spontaneous mutation within the organisms' genome. The pattern mentioned earlier (i.e., that large proportions of hospital patients are taking antibiotics and that microbes are routinely transported from patient to patient) has resulted in a steadily growing prevalence of antibiotic-resistant pathogens such as methicillin-resistant *S. aureus* (MRSA), VRE, and multidrug-resistant gram-negative bacilli inside U.S. hospitals (Table 290-3).

Widespread and sometimes injudicious use of antibiotics along with the ready transmission of bacteria between patients in the hospital has resulted in an alarming trend in the emergence of antimicrobial-resistant organisms. Table 290-3 illustrates the most recent data reported by the CDC's National Healthcare Safety Network (NHSN), formerly known as the National Nosocomial Infection Surveillance (NNIS) system. Not only are both gram-positive and gram-negative organisms becoming increasingly resistant to available agents, but many bacteria are also acquiring multiple genes that render them resistant to multiple antibiotics (i.e., multidrug-resistant organisms).

TABLE 290-3 ANTIMICROBIAL RESISTANCE AMONG PATHOGENS CAUSING HEALTH CARE–ASSOCIATED INFECTIONS IN U.S. HOSPITALS, 2006-2007

		Percentage of Isolates Resistant to Antimicrobial			
ORGANISM	**ANTIMICROBIAL AGENT**	**CLABSI**	**CAUTI**	**VAP**	**SSI**
Staphylococcus aureus	Oxacillin	56.8	65.2	54.4	49.2
Enterococcus faecium	Vancomycin	78.9	81.0	NR	56.5
Escherichia coli	Ceftriaxone or ceftazidime	8.1	5.5	11.0	5.3
	Fluoroquinolones	30.8	24.8	22.7	22.7
Klebsiella pneumoniae	Ceftriaxone or ceftazidime	27.1	21.2	23.7	14.8
	Carbapenems	10.8	10.1	3.6	5.2
Pseudomonas aeruginosa	Fluoroquinolones	30.5	33.8	27.8	15.9
	Piperacillin or piperacillin-tazobactam	20.2	17.1	17.0	7.9
	Cefepime	12.6	10.8	11.1	5.7
	Carbapenems	23	25.1	26.4	11.8
Acinetobacter baumannii	Carbapenems	29.2	25.6	36.8	30.6

CLABSI = central line–associated blood stream infection; CAUTI = catheter-associated urinary tract infection; SSI = surgical site infection; VAP = ventilator-associated pneumonia.
From Hidron AI, Edwards JR, Patel J, et al. Antimicrobial-resistant pathogens associated with healthcare-associated infections: annual summary of data reported to the National Healthcare Safety Network at the Centers for Disease Control and Prevention, 2006-2007. *Infect Control Hosp Epidemiol*. 2008;29:996-1011.

GENERAL STRATEGIES EFFECTIVE IN PREVENTING SPREAD OF RESISTANCE IN HOSPITALS

Antibiotic Stewardship

Many experts believe that improving or shortening the duration of antibiotic use (or both) may be among the most cost-effective means of controlling antibiotic-resistant infections. Bacteria naturally acquire chromosomal mutations or, in other instances, acquire genetic material from other bacteria that confer resistance to antibacterial drugs. Subsequent survival of the resistant organisms depends on a number of factors. Extensive use of antimicrobial agents can promote selective pressure for the survival of resistant pathogens. The risk for emergence of antimicrobial resistance increases markedly after the administration of antibiotics for just 7 days. Thus, inappropriate or unnecessarily prolonged use of antimicrobial agents can select for antimicrobial-resistant isolates. Such strains can colonize and cause infection and can be transmitted between patients.

Several prospective studies have documented a clear association between the use of antimicrobial agents and colonization or infection with resistant organisms in health care institutions, including an association with the use of broad-spectrum agents. In many studies, other interventions were implemented at the same time as restriction of antibiotic use, thus making interpretation of the relative importance of antibiotic restriction problematic. Antibiotic stewardship may be a more effective means of preventing the emergence of resistance in certain organisms (such as gram-negative bacteria), whereas prevention of transmission may be the more important intervention for others (such as MRSA).

Hand Hygiene

Proper use of hand hygiene clearly reduces nosocomial transmission of resistant organisms. Adherence to hand hygiene recommendations is associated with a reduced risk for health care cross-contamination, and failure to perform appropriate hand hygiene is generally considered to be the leading cause of patient-to-staff-to-patient transmission of health care–associated infections. Hands that are visibly dirty or contaminated should be washed with soap and water, and hands that are not visibly soiled should be decontaminated with an alcohol-based hand rub before contacting patients or engaging in clinical procedures. Similarly, health care workers should use an alcohol-based rub after contacting patients' intact or nonintact skin, mucous membranes, or body fluids. Finally, hand hygiene should be used after removing gloves and after any contact with inanimate objects or medical equipment in the vicinity of patients. Alcohol-based hand hygiene products have been demonstrated to be superior to soap and water for general hand hygiene. These products are rapidly bactericidal, are easier to use, do not require a sink, save time, and are less irritating to the skin than handwashing with soap and water. However, soap and water appears to be the preferable mode of hand hygiene when providing care for patients with *Clostridium difficile* infection because *C. difficile* spores are not reliably killed by alcohol.

Staffing Strategies

Cohorting care means having staff dedicated solely to providing care for patients known to be infected or colonized with resistant pathogens. When cohorting, staff do not cross-cover both infected or colonized and noncolonized patients. In an outbreak setting, keeping infected and colonized patients separate from uninfected and uncolonized patients, as well as managing them with separate staff, provides a powerful mechanism to prevent transmission. Understaffing clearly contributes to the spread of resistant organisms, particularly in epidemic settings. An association among understaffing, patient overcrowding, and the spread of infectious diseases has been established in several studies.

Decreasing Hospital and Intensive Care Unit Stay

Decreasing the length or the frequency of hospital stay, or both, as well as the length and frequency of stay in critical care units, has been suggested to be an effective mechanism to decrease the risk for spread of resistant organisms, and the results from a number of clinical studies provide support for this concept. Several studies conducted over the past 10 years provide evidence that shortening the hospital or ICU stay decreases rates of infection with resistant organisms.

Microbiologic Surveillance

Although interventions aimed at controlling institutional use of antimicrobials have been associated with modest control of resistance, their success has been far from uniform. Some experts argue for aggressively identifying colonized patients (i.e., an important reservoir for institutional spread) by performing prospective surveillance cultures and then implementing contact isolation precautions to limit opportunity for transmission. This latter strategy has been shown to decrease the spread of resistant pathogens, in some instances even in the absence of antibiotic control measures. The relative efficacy of these interventions—antimicrobial stewardship versus aggressive identification and isolation—probably varies from organism to organism, if not from institution to institution.

A controversial issue in the health care epidemiology community is whether to use aggressive microbiologic surveillance (called active surveillance) as an intervention in an attempt to minimize transmission of resistant microorganisms. By microbiologically screening all patients admitted to a health care setting, one can prospectively identify those who are colonized or infected with these organisms. Such patients can then be managed aggressively with isolation precautions, cohorting, or even attempts at decolonization. Active surveillance is labor-intensive and costly, and from a practical standpoint only specific organisms can be targeted. Conversely, active surveillance is likely to identify problematic pathogens sooner and thus enable measures to be taken to prevent their spread within the health care environment. Many experts believe that tight control is reasonably important to prevent cross-contamination with multiply resistant organisms. To date, no studies have definitively demonstrated the efficacy of this strategy as an independent intervention. Similar to the investigations of antimicrobial

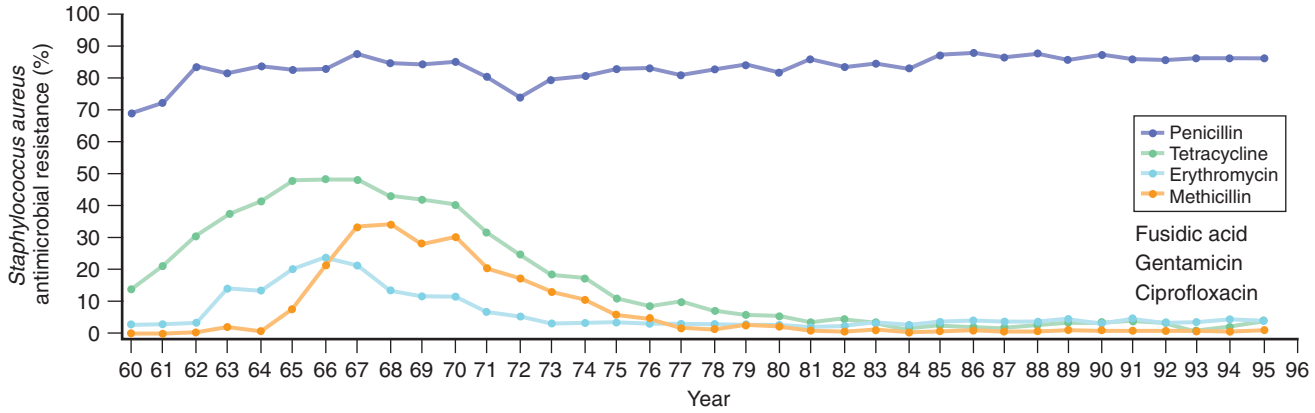

FIGURE 290-1. Percentage of *Staphylococcus aureus* bacteremias caused by strains resistant to antimicrobials in Danish hospitals from 1960 to 1995. (From Bager F, ed. DANMAP 98—Consumption of Antimicrobial Agents and Occurrence of Antimicrobial Resistance in Bacteria from Food Animals, Food, and Humans in Denmark. Copenhagen: Danish Zoonosis Centre; 1999.)

stewardship interventions, although many studies have demonstrated a benefit of prospective surveillance cultures, most of them introduced several infection control interventions simultaneously. Because of the simultaneous use of several strategies, one cannot determine the individual contribution of any single intervention. Some European and Scandinavian countries have implemented policies of restrictive antibiotic use and aggressive surveillance. The Netherlands uses an aggressive surveillance approach for the prevention of MRSA transmission as well as a policy of restrictive antibiotic use. In the Netherlands, prospective surveillance cultures of all admissions are performed, strict barrier precautions are required for patients who carry the identified resistant organisms, temporary furloughs are provided for colonized health care workers, and hospital wards—and sometimes even entire institutions—are closed when the prevalence starts to rise. As an example of the efficacy of this approach, the prevalence of staphylococcal isolates resistant to methicillin and causing infection in the Netherlands is currently less than 2%. Similar approaches have been used in Denmark (Fig. 290-1) and other Scandinavian countries. Many U.S. hospitals have not implemented the aggressive surveillance approach because of the cost of both the microbiologic procedures and the requisite isolation gear.

Contact Isolation

Most major infection control guidelines for multiply resistant organisms recommend some kind of isolation for patients who harbor these organisms; the category of isolation most frequently used is contact isolation. In studies in which contact isolation has been used as part of a program designed to limit the spread of resistant pathogens, the overall approach has been reasonably effective. One report described a 16-fold reduction in MRSA transmission associated with the use of contact precautions. However, as previously discussed, contact isolation has typically been implemented concurrently with other (usually several) infection control measures. Therefore, determining the benefits of any single intervention is often not possible. Using contact isolation as an infection control strategy does have the potential for unintended, adverse consequences. Some recent studies have found that isolated patients were more likely to experience adverse events during their hospitalizations and were less likely to have narrative notes from physicians or nurses in their charts. Additionally, isolated patients in this study were substantially more likely than controls to experience failure of supportive care, including falls, pressure ulcers, and fluid and electrolyte imbalances. Because these adverse outcomes appear to be due to changes in health care worker activities and behavior, health care personnel must make a conscious effort to ensure that their patients in isolation receive the same level of care as those who are not in isolation. Similarly, the potential benefits associated with the use of isolation in an attempt to limit spread of resistant pathogens must be evaluated in the context of the potential adverse impact on patient care.

Antibiotic Cycling

Antibiotic cycling—that is, rotating or cycling the use of different antimicrobials or antimicrobial combinations over time—has been advocated as a possible approach to limiting resistance in health care institutions. To date, the data are quite limited and somewhat contradictory about this approach. Furthermore, this approach has been studied only in the ICU setting and may not be generalizable throughout the health care institution. In short, the verdict is not yet in concerning the relative efficacy of this approach.

Combinations of Strategies

Based on mathematical modeling, strategies that might be expected to be effective in preventing or reducing the prevalence of resistant bacteria in hospitals include reducing antibiotic use, decreasing the length of hospital stays (i.e., increasing patient turnover), and instituting infection control measures to disrupt the spread of bacteria. These infection control measures include restriction of contact between patients and health care workers carrying resistant bacteria, improved hand hygiene, and the use of personal protective equipment (e.g., gloves, masks, protective eyewear or face shields, and gowns). These models also suggest that an important byproduct of these interventions is that interdictions that reduce transmission of all bacteria within a hospital will disproportionately reduce the prevalence of colonization with resistant bacteria. These interventional strategies based on mathematical models need to be subjected to empirical testing to confirm their veracity and utility in clinical settings.

At a more pragmatic level, educating the staff about the epidemiology, pathogenesis, and general routes of transmission of resistant bacteria within the hospital environment, as well as the role that antibiotic use plays in the emergence and spread of bacterial resistance, is of paramount importance. Staff knowledge is required both to understand the rationale for interventions and to encourage compliance with infection control measures.

CATEGORIES OF HEALTH CARE–ASSOCIATED INFECTIONS

Urinary Tract Infections

Nosocomial urinary tract infection usually follows instrumentation of the urinary tract, most often with a catheter. Infection occurs in about 1% of individuals who undergo a single in-and-out catheterization. For patients who have an indwelling urinary catheter, the risk for infection remains relatively constant at about 3 to 6% per catheter day (higher for female than for male patients and increased by manipulation of the catheter). After 10 to 14 days, about half of catheterized patients have bacteriuria. Thus, infection develops at some point in virtually all patients who have long-dwelling urinary catheters. Because enteric flora are the usual cause of urinary tract infection and because diarrhea predisposes to contamination of the catheter-urethra interface, diarrhea is an independent risk factor for catheter-associated urinary tract infection. Urinary tract infections (Chapter 292) account for between 30 and 40% of all health care–associated infections.

According to data from the CDC's NHSN, the pathogens most frequently responsible for health care–associated, catheter-associated urinary tract infections are (in order of decreasing relative frequency) *Escherichia coli, Candida* species, *Enterococcus* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae, Enterobacter* species, coagulase-negative staphylococci, *S. aureus, Acinetobacter baumannii*, and *Klebsiella oxytoca*. Recommended measures for the prevention of catheter-associated urinary tract infections include the use of indwelling urinary catheters only for appropriate indications and durations,[1] aseptic insertion and maintenance techniques, securing the catheter,

and keeping the collection system below the level of the bladder. Device technology that has been associated with preventing catheter-associated urinary tract infections includes closed drainage systems and antiseptic-impregnated (e.g., silver alloy) urinary catheters.

Pneumonia

Infection of the pulmonary parenchyma can occur after the aspiration of either microbe-laden secretions from the upper respiratory tract or regurgitated gastric contents. Infection at a distant site in the body, such as *S. aureus* infection of a central venous catheter or an arteriovenous fistula used for hemodialysis, can sometimes result in hematogenously spread septic pulmonary emboli, which in turn can produce infection in the pulmonary parenchyma (often with a radiographically distinct pattern of multiple diffuse expanding pneumatoceles throughout the lungs). Another rare source of health care–associated pneumonia is direct inhalation of a microbe from the air. Examples of microbes that usually cause pneumonia by inhalation include *M. tuberculosis* (Chapter 332) and *Aspergillus fumigatus* (Chapter 347). Infection with the former occurs by contagion through small-particle droplet nuclei from a coughing patient. These droplet nuclei float in the air for hours and may infect patients several rooms away, although those closer to the coughing patient are at greater risk. Infection with *A. fumigatus* occurs by inhalation of its spores, which may be liberated from the surface of almost any organic material on which it can grow (e.g., an orange). These spores are virtually ubiquitous and may be present in both outdoor and indoor air. Because of the increase in airborne fungal spores that can occur in association with construction and demolition activities, implementation of effective dust control measures when such projects are performed in health care facilities is needed to minimize the risk for nosocomial transmission of these pathogens. *Legionella* infection (Chapter 322) was originally thought to result from inhalation, but it may occur more frequently after the aspiration of *Legionella*-contaminated potable water. Viruses such as respiratory syncytial virus, parainfluenza virus, and adenovirus have also been described as causes of health care–associated pneumonia, particularly in severely immunocompromised patients.

Most patients who acquire nosocomial pneumonia have been maintained on mechanical ventilators in an ICU. The most frequent microbial agents causing ventilator-associated pneumonia, according to NHSN data, are *S. aureus, P. aeruginosa, Enterobacter* species, *Acinetobacter baumannii, K. pneumoniae,* and *E. coli* (in decreasing order of relative frequency). Rates of pneumonia in mechanically ventilated patients range from 6 to 30%, with a risk of 1 to 3% per day of intubation and mechanical ventilation. A number of factors influence the risk for nosocomial pneumonia in these patients. In a critically ill, supine, ventilated patient, oropharyngeal secretions pool in the oropharynx and subglottic space above the tracheal tube cuff and form a reservoir of contaminated secretions. These secretions often get aspirated into the pulmonary parenchyma along the endotracheal tube. Using a device that provides continual subglottic suction to prevent pooling of these secretions has been associated with lower rates of clinical aspiration and early ventilator-associated pneumonia (defined as pneumonia occurring within 3 to 5 days of intubation).

The inner lumen of an endotracheal tube rapidly becomes covered with a biofilm containing high concentrations of microorganisms. Pieces of this biofilm (carrying large numbers of bacteria) can be inoculated directly into the lower respiratory tract, either by ventilatory flow or by inserting devices through the tube (such as might occur during suctioning or therapeutic bronchoscopy). These pieces of biofilm can seed the pulmonary parenchyma with microorganisms and serve as a nidus for ongoing infection.

The use of either continuous or intermittent enteral feeding also increases gastric pH and, at least in some studies, has been associated with an 80% risk for gram-negative colonization of the stomach. Conversely, maintenance of adequate nutritional status is clearly associated with a reduced risk for ventilator-associated pneumonia, and enteral nutrition is clearly the route of choice for supplementing the nutritional status of these patients.

Abnormal elevation of gastric pH related to the patient's underlying disease or to the use of histamine-2 (H_2)-blockers, proton pump inhibitors, or antacid therapy is associated with an increased risk for infection because of the resulting microbial overgrowth in stomach fluids. When these fluids are regurgitated and aspirated, they may rapidly produce pneumonia because of the large bacterial inocula involved. Use of sucralfate, which does not affect gastric pH as substantially as H_2-blockers or proton pump inhibitors, to prevent stress ulceration during mechanical ventilation has been associated with lower rates of nosocomial pneumonia in some studies; however, other studies have suggested that this agent may not be as effective in preventing gastrointestinal bleeding as H_2-blockers.

Aspiration of gastric contents occurs four times more frequently when the patient is in the supine position than when the head of the patient's bed is elevated at a 45-degree angle. Studies have demonstrated that isolation of the same organisms from the stomach, pharynx, and endobronchial samples occurs extremely uncommonly in semirecumbent patients compared with patients placed in the supine position. Nonetheless, gastric reflux occurs frequently, irrespective of body position, in mechanically ventilated patients who have nasogastric tubes. Current recommendations for the prevention of ventilator-associated pneumonia include elevating the head of the bed 30 to 45 degrees unless medically contraindicated.

Selective digestive tract decontamination with antibiotics (e.g., swabbed onto the teeth as a paste or squirted into the stomach through a nasogastric tube, or both) has also been shown to result in significantly lower health care–associated pneumonia rates and mortality,[2] but this approach has not generally been used in the United States because of potential for the rapid development of antimicrobial resistance among the gut flora in these patients. However, good oral hygiene does help prevent health care–associated pneumonia without introducing the risk for antimicrobial resistance.

Surgical Site Infections

Historically, surgical site infection was almost inevitable because of the inhospitable environment in early hospitals. Today, the reverse is true for "clean," elective procedures (e.g., coronary bypass graft or total hip replacement). Most of these operations are not complicated by infection because of the use of strict aseptic technique (i.e., antiseptic preparation of the surgeon's hands and the patient's skin),[3] the use of sterile barriers (e.g., surgical gown and gloves), timely administration of prophylactic antibiotics before (and when appropriate, additional doses during) the procedure, and sterilization of surgical instruments used for the procedure. Despite these major improvements, infections still do occur. In the 21st century, the occurrence of these infections is most highly dependent on the technical skills of the surgeon and the presence of comorbid conditions in the patient who is undergoing the procedure.

The most frequent microbial pathogens causing surgical site infections (according to NHSN data) are, in decreasing order of relative frequency, *S. aureus;* coagulase-negative staphylococci; enterococci; gram-negative bacilli such as *E. coli, P. aeruginosa, Enterobacter* species, *Klebsiella* species, and *A. baumannii*; and *Candida* species.

Both surgery-related and patient-related factors contribute to the risk for surgical site infections. Despite equivalent provision of care and preventive measures, differences in postoperative infection rates can still occur for a variety of reasons. A higher prevalence of comorbid conditions in patients being referred for care (i.e., obesity, diabetes mellitus, severe peripheral vascular disease) inevitably results in higher surgical site infection rates. A variety of factors related to the technical aspects of surgery also influence the risk for infection. For example, the presence of dead space and the presence of dead tissue in the wound (e.g., as might occur through the excessive use of electrocautery) are both associated with an increased risk for infection. Other technical factors also influence this risk; for example, shaving to remove hair the day before the operation is associated with higher infection risk than is using clippers to remove hair within the hour before the operation.

The timing of antimicrobial prophylaxis is an important variable for surgical site infections. Making certain that agents with the appropriate antimicrobial spectrum are administered in time to ensure adequate blood levels of the drug or drugs at the time of scalpel entry into the skin and that adequate levels are maintained throughout the procedures is key to the success of perioperative prophylaxis. Antibiotics should be administered within 1 hour before incision to guarantee adequate serum levels. Recent studies suggest that, within this 1-hour period, administering antibiotics 30 to 60 minutes before the surgical incision may be associated with the lowest risk for surgical site infection. Antibiotics should be redosed if the procedure lasts longer than 4 hours. Finally, antibiotics administered for prophylaxis should not be continued for longer than 24 hours after the procedure and frequently are not required at all postoperatively.

Patients who have intrinsically contaminated wounds (e.g., a ruptured appendix) have a much higher risk for intra-abdominal infection, despite modern preventive measures, primarily because high-inoculum microbial exposure occurs and infection may already be established before surgery begins. Gut decontamination before surgery remains an important, effective option to reduce the risk for postoperative infection in some settings. For

example, elective colon surgery after appropriate antimicrobial prophylaxis and mechanical cleansing is associated with much lower infection rates.

Serum glucose control has also been shown to decrease the risk for surgical site infections. Other strategies for the prevention of surgical site infections for which some evidence exists include maintenance of normothermia during surgery, screening for *S. aureus* colonization before surgery with decolonization therapy provided to identified carriers,[4] and preoperative bathing or showering with an antiseptic soap (e.g., chlorhexidine). Most of these approaches, however, have not yet been included in published guidelines or have been recommended for use only in certain procedures owing to the absence of definitive evidence of their effectiveness. Finally, surgical infection rates can also be reduced by providing information about postoperative infectious complications to the surgeons.

Blood Stream Infections

Blood stream infections may result from primary infection within the cardiovascular system (e.g., from an infected vascular catheter) or may be secondary to a local infection in another organ (e.g., *E. coli* infection of the urinary tract). Approximately 80% of health care–associated blood stream infections are primary, and the overwhelming preponderance of them are due to vascular catheter infections. Approximately 20% are secondary to infections in other organs. According to NHSN data, the most frequent microbial causes of primary blood stream infection in hospitalized patients with central venous catheters are (in decreasing order of frequency) coagulase-negative staphylococci, enterococci, *Candida* species, *S. aureus*, and gram-negative bacilli such as *K. pneumoniae* and *Enterobacter* species. Although coagulase-negative staphylococci definitely do cause such infections, a large proportion of blood cultures growing this organism actually represent contamination and not true infection. By contrast, *S. aureus* and *Candida* species are more virulent and associated with a much higher probability of true blood stream infection.

Microorganisms can reach the circulation through three separate pathways associated with the use of intravascular catheters. They can colonize the catheter insertion site and subsequently move along the catheter through the tissues; they can colonize hubs, junctions, and other connectors and gain access to the system when these sites are manipulated and through intrinsic or extrinsic contamination of the infusion fluid.

Catheter-related blood stream infection most frequently begins with colonization of the catheter. Because vascular catheters are usually placed through the patient's skin, most such colonizing microbes come from the patient's resident skin flora. Studies using electron microscopy have shown that microbial contamination of catheters is virtually universal from the first day after insertion. Organisms migrate from skin along the insertion tract by capillary action. Colonization often occurs at time of insertion but may also take place days afterward. Initially, organisms colonize along the external surface of the catheter. By contrast, after 10 days of placement, ultrastructural studies demonstrate an increasing relative frequency of intraluminal contamination, and most long-term catheters appear to become colonized and produce blood stream infection by the intraluminal route. Colonization is facilitated by the formation of a fibrin sheath around the catheter as a result of platelet deposition and is also facilitated by organism-produced biofilm.

The reason that all vascular catheters do not uniformly result in clinical infection relates to the body's innate immune response and its ability to kill microbial invaders and limit their growth and spread. Because most colonizing and infecting flora come from the patient's skin, use of antiseptics to prepare the site before catheter insertion and every few days thereafter to decrease the microbial burden has been a successful strategy for decreasing the risk for infection. In several clinical trials, chlorhexidine gluconate skin preparation has been shown to reduce the risk for catheter colonization significantly when compared with alcohol or povidone-iodine preparation of the skin. Although most such trials were designed to have statistical power only to be able to detect a reduction in catheter colonization, two of the studies demonstrated significant reductions in catheter-related blood stream infections as well. The use of maximal barriers to create a large sterile field during catheter insertion has also been shown to decrease the risk for infection.

A number of other factors, such as the type of dressing, the composition of the catheter, the number of lumens, and the type of intravenous administration system used, all influence the risk for catheter-associated primary blood stream infection. Either cotton gauze dressings covered by tape or semipermeable transparent membrane dressings can be used to protect the insertion site; however, the cutaneous microbial burden increases substantially underneath the semipermeable dressing. Conversely, the semipermeable dressing requires less frequent changes and manipulations and anchors the device in place more securely than gauze and tape dressing. These two types of dressings have been shown to be equivalent with respect to infection rate and local complications. Again, preparation of the site with chlorhexidine gluconate during dressing changes also decreases the infection rate. However, gauze dressings may be preferable if the insertion site is oozing. Use of chlorhexidine-impregnated dressings at the catheter-insertion site has been associated with reduced catheter-associated infection rates.[5] Several catheter characteristics or properties have been suggested to be associated with an increased risk for catheter-associated infection. For example, catheters made of stiff materials traumatize the vascular endothelium and move around in the insertion site—both facilitating colonization. Larger-bore catheters are also probably associated with increased risk for colonization and infection. Finally, the manner in which catheters are used may influence the risk for infection. In critically ill patients, for example, pulmonary artery catheters are frequently repositioned to obtain accurate readings (increasing local endothelial trauma, as well as the likelihood for catheter colonization).

Health care–related factors also contribute to the risk for catheter-associated primary blood stream infection. For example, antimicrobial therapy may alter the patient's skin flora, thereby facilitating colonization with an aggressive pathogen. Furthermore, health care workers who do not practice appropriate hand hygiene may inadvertently colonize a patient's catheter insertion site with health care–associated pathogens (e.g., MRSA). Manipulating the intravascular delivery system (e.g., to reposition the catheter, obtain a blood sample, administer medications) also increases the likelihood of catheter colonization. Techniques used for insertion and maintenance of catheters likewise influence the risk for infection. Inserting central venous catheters with less than maximal sterile barriers increases the risk for infection. The site chosen for insertion of a central venous catheter also influences the risk; insertion into the femoral vein is associated with a greater risk for colonization and infection than is insertion into either the subclavian or internal jugular vein. Although guidelines from the Healthcare Infection Control Practices Advisory Committee have recently recommended the subclavian route of insertion over the internal jugular approach, the data that support this recommendation are quite limited, and the risk for mechanical complications associated with insertion at each of these two sites must be considered for each patient.

One approach to attempt to reduce the risk for catheter-associated infections has been to bond antimicrobial substances (antiseptics or antibiotic agents) to the catheter. A catheter impregnated with antiseptic (chlorhexidine-silver sulfadiazine) reduced both colonization and blood stream infection by nearly 50%. Antibiotic-coated catheters (e.g., minocycline-rifampin-coated catheters) may be associated with even greater risk reduction. Minocycline-rifampin catheters are coated on both the internal and external surfaces of the catheters, whereas first-generation chlorhexidine–silver sulfadiazine catheters were coated only on their external surfaces. Compared with first-generation chlorhexidine–silver sulfadiazine, antibiotic-impregnated central venous catheters substantially reduced catheter-related blood stream infections in head-to-head comparisons. Second-generation chlorhexidine–silver sulfadiazine catheters are coated on both the internal and external surfaces but have not yet been compared with minocycline-rifampin catheters. Antimicrobial agent–coated catheters are associated with at least a theoretical risk for the development of antimicrobial resistance to the agents coating the catheters, although such resistance has not yet been documented in studies including hundreds of patients.

Recently, studies have demonstrated that the use of needleless administration systems also contributes to the risk for intravascular device–associated infections. When these devices were initially marketed, they had two primary goals—health care worker safety and device patency. They were not intended to reduce infection rates. Unfortunately, some recent studies suggest that these devices actually increase the risk for infection. The care and use practices of staff who are unfamiliar with these systems often do not follow the manufacturer's recommendations. Staff may not disinfect the device properly, or the device may be intrinsically difficult to disinfect. Nonetheless, several studies have documented increased risk for health care–related primary blood stream infections associated with the use of these devices.

Prevention of primary blood stream infections should be an important focus for all health care institutions. The Institute for Healthcare Improvement (IHI) has advocated bundling five infection prevention strategies—each of which is known to be independently effective—to prevent primary blood stream infections. The five techniques are effective hand hygiene;

maximal barrier precautions at insertion; cutaneous antisepsis with chlorhexidine; optimal insertion site selection; and daily review of the necessity for maintaining the catheter, with prompt removal when it is no longer needed. Recently, the Joint Commission, formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO), has adopted the IHI recommendation and requires implementation of these five strategies as a standard for continued accreditation.

Other Nosocomial Infections

During a national study of nosocomial infections conducted by the CDC in the 1970s, only about 6% of recognized infections did not involve the four main body sites listed earlier (see Table 290-1); currently, about 25% of all infections acquired in hospitals conducting hospital-wide surveillance are of this miscellaneous type. This category includes gastrointestinal infections caused by organisms such as *C. difficile,* rotavirus, and *Salmonella* species; viral infections caused by varicella, influenza, and respiratory syncytial virus; and candidal infections of the mouth, esophagus, and vagina. *C. difficile*–associated diarrhea and enterocolitis are of particular concern because of the emergence of a new, highly virulent strain associated with epidemic spread in the United States. This strain, which was previously quite uncommon, has variations in its toxin genes and is distinguishable, at least in part, by its increased resistance to fluoroquinolones. The highly virulent strain has emerged as an increasingly common cause of health care–associated epidemics.

INFECTION CONTROL PROGRAMS

Formal infection control programs did not exist in most hospitals until the 1970s. These programs were introduced into U.S. hospitals at that time, based on recommendations from the CDC, the American Hospital Association (AHA), and JCAHO. The primary rationale for the creation of these programs was to attempt to control antibiotic-resistant infections, which had soared out of control in most hospitals during the 1950s and 1960s.

As hospitals began to implement such programs, the CDC conducted a national study of the effectiveness of these efforts, titled the Study of the Efficacy of Nosocomial Infection Control (SENIC). The largest study of infection control ever conducted, SENIC used a probability sample of general hospitals nationwide, determined nosocomial infection rates, and assessed predictors in multivariate analysis. The size and intensity of work by the infection control program were found to predict infection rates. The most important predictors of success in decreasing health care–associated infection rates were (in decreasing order of importance) the intensity of surveillance, the intensity of control measures, the ratio of infection control practitioners to number of patient beds, the presence of a trained hospital epidemiologist on staff, and provision of surgical site infection rates to surgeons. The most effective programs (i.e., those with all these predictors) experienced a 32% relative reduction in the nosocomial infection rate compared with hospitals that did not have infection control programs.

Although programs vary from institution to institution, depending on the needs and resources available, most programs share certain essential functions, among which are surveillance for health care–associated infections; investigation of outbreaks, problematic trends, or distinctive or unusual infections; and education of staff about the epidemiology, pathogenesis, and prevention of health care–associated infections. In addition, hospital epidemiology programs work closely with other professionals in the health care setting who share similar interests. Specifically, infection control programs routinely form working partnerships with the clinical medical and nursing staffs, the infectious diseases service, the occupational medicine service, clinical microbiology, and the hospital safety program. The work of each of these services is complementary to the hospital epidemiology program. Communication among these groups is essential for success of the program.

The most likely reason that surveillance for nosocomial infections was important in SENIC is straightforward. By understanding what is happening microbiologically in an institution, specific control measures can be fashioned to intervene and thereby limit outbreaks and reduce high endemic rates of infection.

Initially, many hospitals implemented continual hospital-wide surveillance. Because some infections appeared to be more important than others in analyses from the SENIC database in terms of prolongation of stay and extra cost, and because interhospital comparison of crude hospital rates was thought to be difficult given the differences in severity of underlying illness in patients admitted to hospitals of different types in different regions, some authorities advocated targeted surveillance programs with a focus on the most significant problems for each hospital. Even though such a strategy does allow an institution to focus its efforts on its most pressing problem, the strategy may also cause institutions to overlook significant problems. For instance, outbreaks in ICUs may be missed for months in hospitals targeting only surgical site infections.

Over the past two decades, many hospitals were downsized in terms of both patient admissions and health care personnel to cut costs; because infection control programs were not viewed as revenue generating, they were often cut as well. Even when they were not reduced in size, these programs often had to assume additional duties that were not part of their original focus. For example, new Occupational Safety and Health Administration (OSHA) requirements to protect health care workers from infection with blood-borne pathogens required orientation and annual retraining of all health care workers as well as the development and annual review of exposure control plans for all hospital units and departments. Similar requirements were enacted by OSHA to protect health care workers from nosocomial tuberculosis. These activities clearly relate to infection control and were thus usually assigned to infection control programs. Because they were unfunded mandates, however, the requirements for added work were usually given to infection control programs with no added resources. Infection control programs in U.S. hospitals today are often underfunded and understaffed. A consensus report from the CDC, Joint Commission, AHA, and a variety of other agencies and national societies concluded that infection control is more difficult in the hospital now than it was during the 1970s and 1980s when SENIC was conducted. That consensus report also concluded that more than one infection control practitioner per every 250 hospital beds (the ratio found to be essential by SENIC) is needed to do an effective job of controlling infections. This report has had limited impact, however, because many hospitals continue to reduce support for infection control activities, and others are now requiring infection control personnel to work on other adverse effects associated with health care, thus again increasing the infection control program workload without increasing program resources.

OCCUPATIONAL AND NOSOCOMIAL INFECTIONS IN HEALTH CARE WORKERS

Nosocomial infection can affect health care workers as well as patients. Health care workers in facilities that pay limited attention to the rising prevalence of colonization of patients with antibiotic-resistant pathogens are more likely to become colonized at a higher rate than the general population. Casually contagious viral infections such as influenza, varicella, rubella, and measles occur more frequently in health care workers because they are exposed to sick people in the community as well as to patients who are not always recognized and placed on appropriate isolation precautions. Several infectious diseases are worthy of more detailed consideration with respect to occupational exposure and infection, among which are hepatitis B, hepatitis C, HIV, and tuberculosis.

Occupational Risk for Human Immunodeficiency Virus Infection

The risk for acquiring HIV infection from a patient in the health care setting is small (Chapter 395). Fewer than 75 documented occupational infections with HIV have occurred in more than 5 million health care workers in the United States during the nearly three decades since acquired immunodeficiency syndrome (AIDS) and HIV entered the health care workplace. The routine use of universal or standard infection control precautions, development and implementation of safer devices and other engineered controls, and education and training of staff have all contributed to additional risk reduction.

A multinational case-control study conducted by the CDC and collaborators showed that deep percutaneous injuries, visibly bloody sharp instruments, devices that had been used in blood vessels, and exposure to source patients who had end-stage HIV disease (i.e., who died within 2 months after exposure—presumably a surrogate marker for high viral burden) were independent predictors of HIV transmission. In this study, administration of postexposure antiretroviral chemoprophylaxis with zidovudine was associated with an almost 80% relative reduction in the risk for infection in multivariate analysis. This finding led to a U.S. Public Health Service recommendation for the routine administration of postexposure chemoprophylaxis after occupational exposure to HIV. The CDC updates its recommended guidelines for the use of postexposure antiretroviral prophylaxis periodically.

Because the long-term consequences of taking antiretroviral agents for a month are unknown, and because significant adverse effects such as nausea, vomiting, and diarrhea develop in more than 70% of health care workers

who take these agents for postexposure prophylaxis, they should not be administered casually or unnecessarily. Institutions should have defined protocols for determining whether an exposure has occurred, for encouraging reporting of exposures, and for facilitating access to antiretroviral agents when they are needed.

Occupational Risk for Hepatitis

Before development of the hepatitis B vaccine, hepatitis B (Chapter 150) represented the largest occupational risk to health care providers who were exposed to blood in the health care workplace. Standard precautions and OSHA requirements to offer free hepatitis B vaccine to health care workers have resulted in a dramatic decrease in hepatitis B infection in health care workers. However, approximately 10% of those vaccinated do not respond to vaccine, and some workers decline to be vaccinated because of concerns about side effects. Studies have shown the vaccine to be safe, and compliance has probably increased with dissemination of this information.

No vaccine is available as yet for hepatitis C (Chapter 150), the most common blood-borne viral infection and the most frequent indication for severe chronic liver disease requiring liver transplantation in the United States. An open trial of early interferon therapy for acute hepatitis C virus infection, as well as a National Institutes of Health consensus conference, documented higher cure rates for patients treated for acute hepatitis C than had been demonstrated for the treatment of established chronic infection. Although no formal recommendations have been issued for the management of health care workers who sustain occupational exposure to hepatitis C, one approach is to monitor the health care worker by polymerase chain reaction for hepatitis C virus RNA. Those who become PCR positive are then monitored for a brief period to make certain that the PCR findings are reproducible and to see whether individuals can clear their infections immunologically (which is thought to occur in as many as 50% of cases). Those who do not clear their infections spontaneously can be treated for acute hepatitis infection as described earlier.

Occupational Risk for Tuberculosis

Rates of tuberculosis (Chapter 332) in the United States declined for more than a century, and this decline was accelerated in the 1950s in association with the discovery and clinical use of effective antituberculous therapy. In 1985, tuberculosis rates once again began to increase and continued to do so until 1992. Epidemiologic analysis of the increase suggested that increased immigration of persons with tuberculosis and the expanding pool of immunocompromised patients produced by the HIV epidemic were the two predominant factors influencing this increase. The increase in case rates was compounded by a simultaneous, marked increase in resistance to antituberculous agents among isolates during this period.

Both these factors contributed substantially to health care–associated tuberculosis outbreaks in New York, New Jersey, and Florida. Major factors contributing to these outbreaks included (1) inadequate administrative controls (e.g., index of suspicion for the diagnosis, policies for placing patients in appropriate isolation, policies requiring that isolation patients remain in isolation), (2) inadequate engineering controls (i.e., lack of appropriate negative-pressure ventilation rooms for the isolation of patients with possible or known tuberculosis), and (3) inadequate use of personal protective equipment (e.g., respirators). These outbreaks resulted in the development of new CDC recommendations and OSHA requirements mandating administrative and engineering controls, as well as a program of respirator fit testing, annual or semiannual purified protein derivative testing, and regular retraining regarding tuberculosis. Tuberculosis case rates and health care–associated spread of tuberculosis were controlled before these guidelines were issued, thus leaving the question of the relative importance of respirators and respirator fit testing to the overall tuberculosis control effort in health care institutions unanswered. Since 1992, the rate of tuberculosis has steadily decreased in the United States, and nosocomial outbreaks have been reported much less frequently.

291 APPROACH TO THE PATIENT WITH SUSPECTED ENTERIC INFECTION

HERBERT L. DUPONT

EPIDEMIOLOGY

Enteric infections are second only to respiratory tract infections as common medical problems. In certain populations, enteric infections are hyperendemic: poorly nourished infants living in developing tropical countries showing excessive rates of mortality; infants in certain daycare centers; unhygienic residents of custodial institutions for the mentally retarded; immunosuppressed persons; and visitors from industrialized areas to developing regions with traveler's diarrhea.

ETIOLOGY

In approaching a patient with an enteric infection, epidemiologic (Table 291-1) and clinical features (Table 291-2) are used to identify the type of etiologic agent responsible for illness and to develop a plan for evaluation (Table 291-3) and management (Table 291-4).

Recent travel (Chapter 294) to mountainous regions or recreational lakes of North America should raise the suspicion of infection caused by *Giardia* species. Travel to Russia, particularly St. Petersburg, is associated with an increased risk for infection by *Cryptosporidium* and *Giardia* species because there the protozoa can be found in drinking water. When diarrhea occurs during or after travel to a developing tropical region, a bacterial enteropathogen should be suspected. The leading causes of traveler's diarrhea worldwide are the diarrheogenic *Escherichia coli*: enterotoxigenic *E. coli* (ETEC) and enteroaggregative *E. coli* (EAEC). The invasive bacteria (*Shigella*, *Salmonella,* and *Campylobacter* species) cause diarrhea among travelers to all regions but are more common in Asia. Infection with *Cyclospora* species should be suspected when persistent or recurrent diarrhea follows travel to Nepal, Haiti, or Peru (travel-related infections are discussed in detail in Chapter 294).

A specific food or water vehicle cannot be suspected unless multiple cases of illness with a common exposure occur. All too frequently, persons assume the last food consumed before an illness onset is responsible for the symptoms. The highly variable incubation period for diarrheal disease, which may be as short as 2 hours after eating a food, for preformed toxins, to a week or even longer for microbial enteropathogens, makes the determination of a specific food or beverage in a single case of illness impossible. When an outbreak of diarrhea results in multiple cases, a category of etiology often can be determined by calculating the incubation period after looking at timing of the common exposure. Short incubation periods are associated with food poisoning associated with enterotoxins (2 to 7 hours for cases caused by *Staphylococcus aureus*, 2 to 4 hours for *Bacillus cereus* enterotoxin food poisoning). Longer incubation periods (usually 12 to 48 hours) are associated with most cases of intestinal infection.

The clinical expression of diarrheal illness will give clues to the etiologic agent (see Table 291-2). In the patient with diarrhea who is receiving or

TABLE 291-1 EPIDEMIOLOGIC FEATURES IMPORTANT IN DETERMINING POTENTIAL CAUSE OF ENTERIC INFECTION IN A PERSON OR PERSONS WITH DIARRHEA

EPIDEMIOLOGIC FEATURE	ETIOLOGIC AGENT TO SUSPECT
Travel to mountainous areas of North America	*Giardia* spp
Travel to Russia (especially St. Petersburg)	*Cryptosporidium, Giardia* spp
Travel to Nepal	*Cyclospora* spp
Travel to the developing tropical/semitropical world from an industrialized region	Enterotoxigenic *Escherichia coli,* enteroaggregative *E. coli*; *Shigella, Campylobacter*, *Salmonella* spp.; other bacterial causes; *Giardia, Cyclospora, Cryptosporidium* spp and noroviruses
Presence of associated cases (an outbreak)	Use incubation period and clinical features to determine probable cause
Antibiotic, chemotherapy, or proton pump inhibitor use in the past 2 months, particularly with a history of recent or current hospitalization	*Clostridium difficile*
Contact with day care centers	Any enteropathogen, often the low-dose organisms: *Giardia, Cryptosporidium, Shigella* spp or viral pathogens
Homosexual person practicing unprotected sex	Any organism spread by fecal-oral route; in those with proctitis, suspect *Neisseria gonorrhoeae, Chlamydia trachomatis,* herpes simplex, or *Treponema palladium*
Immunosuppressed person	Any agent, especially *Cryptosporidium, Cyclospora, Isospora, Shigella,* and *Salmonella* spp, *C. jejuni, C. difficile, Mycobacterium avium-intracellulare,* microsporidia, herpes simplex virus, and cytomegalovirus
Recent or current cruise ship travel	Norovirus

TABLE 291-2 CLINICAL FEATURES OF ENTERIC INFECTION

CLINICAL SYNDROME	ETIOLOGIC AGENTS SUSPECTED	SPECIAL CONSIDERATIONS
Sustained fever, often with systemic toxicity (enteric or typhoid fever)	*Salmonella typhi,* nontyphoid *Salmonella* spp, *Campylobacter* spp, *Shigella* spp, *Yersinia enterocolitica*	Stool and blood cultures; empirical antibiotics generally indicated
Acute watery (secretory) diarrhea	Any agent. Consider *Vibrio cholerae* (if water losses are major), enterotoxigenic or enteroaggregative *Escherichia coli, Shigella* spp, *Salmonella* spp, *Campylobacter jejuni,* viral or parasitic protozoal pathogen	Fluid and electrolyte therapy crucial for recovery in dehydration
Recurrent vomiting (gastroenteritis)	Viral agents (rotavirus or noroviruses) or preformed toxin (*Staphylococcus aureus* or *Bacillus cereus*)	In case of an outbreak, incubation period suggests the etiology
Bloody diarrhea (dysentery)	*Shigella* spp, *C. jejuni, Salmonella* spp, Shiga toxin–producing *E. coli* (e.g., O157:H7 or other serotype) or invasive *E. coli, Aeromonas hydrophilia,* noncholera *Vibrio* spp, *Yersinia enterocolitica, Entamoeba histolytica,* or inflammatory bowel disease	Stool culture and occasionally parasite examination important to determining cause; hemolytic-uremic syndrome may complicate diarrheal disease caused by Shiga toxin–producing *E. coli* or rarely *Shigella dysenteriae*
Diarrhea lasting ≥2 wk (persistent diarrhea)	*Giardia* spp and other protozoal parasites, bacterial overgrowth, bacterial diarrhea, lactase deficiency, Brainerd diarrhea, postinfectious irritable bowel syndrome (PI-IBS), unmasked inflammatory bowel disease (IBD), or celiac sprue	Stool culture and parasite exam indicated; empirical anti-*Giardia* therapy may be useful; remove milk from diet; raw milk or untreated (well or surface) water consumption or international travel may predispose to Brainerd diarrhea; illness not responding to antimicrobial therapy suggests the possibility of Brainerd diarrhea, PI-IBS, or IBD

recently has completed a course of an antimicrobial drug, a proton pump inhibitor, or an anticancer drug, particularly with recent or current hospitalization, *Clostridium difficile* (Chapter 304) should be suspected. An increasing number of cases of *C. difficile* diarrhea are occurring in the community. When a person has close contact with an infant or infants attending a daycare center, a number of low-dose pathogens found in this setting (e.g., *Giardia*, *Cryptosporidium*, or *Shigella* species or viral pathogens) should be suspected. Some homosexuals may show high rates of enteric infection acquired through fecal-oral contamination, often associated with infection by multiple pathogens or through the practice of unprotected receptive anal intercourse leading to proctitis due to sexually transmitted organisms. When persons experience advanced acquired immunodeficiency syndrome (AIDS) or other forms of severe immunodeficiency associated with metastatic malignancy or chronic use of immunosuppressive drugs, depressed intestinal immunity may lead to enteric infection with a variety of parasitic, bacterial, or viral pathogens (see Table 291-1) (Chapter 397).

Enteric infection syndromes may be divided into at least five groups based on the clinical presentation: (1) febrile systemic disease (enteric fever); (2) acute watery diarrhea (secretory diarrhea); (3) recurrent vomiting as the primary manifestation of enteric disease (gastroenteritis); (4) passage of many small-volume stools containing blood and mucus (dysentery); and (5) diarrhea lasting 2 weeks or longer (persistent diarrhea). Table 291-2 lists the major syndromes along with the expected cause.

Noroviruses (Chapter 388) have become the major cause of foodborne gastroenteritis and the most commonly identified cause of waterborne enteric disease in the United States. *Campylobacter* species (Chapter 311) is the most common reportable bacterial enteropathogen in industrialized countries and is the most important definable cause of Guillain-Barré syndrome (Chapter 428), often resulting in severe disease requiring assisted ventilation, intensive care unit confinement, and permanent neurologic sequelae. *E. coli* O157:H7 and other Shiga toxin–producing *E. coli* (Chapter 312) are important causes of food-borne and waterborne colitis complicated

TABLE 291-3 LABORATORY TESTS AND PROCEDURES USEFUL IN THE DIAGNOSIS OF INFECTIOUS DIARRHEA

SPECIFIC TEST OR PROCEDURE	WHEN INDICATED	CLINICAL SIGNIFICANCE
Fecal leukocyte test	For moderate to severe cases	When present, indicates diffuse colonic inflammation, often due to *Shigella*, *Salmonella*, *Campylobacter* spp, Shiga toxin–producing *Escherichia coli*, or *Clostridium difficile*
Fecal lactoferrin	For moderate to severe cases to help identify inflammatory forms of enteric infection, to use in health care–associated diarrhea to help determine whether *C. difficile* toxin test should be performed	More sensitive test than fecal leukocytes and will pick up less striking degrees of inflammation seen in enteroaggregative *E. coli* (EAEC) and *C. difficile* diarrhea
C. difficile toxins A and B	Diarrhea associated with use of antibiotics, chemotherapy, or proton pump inhibitors, especially associated with current or recent hospitalization	Most sensitive tests are culture, tissue culture assay, and polymerase chain reaction; most specific tests are enzyme immunoassay for toxins A and B; a two-step procedure can be used: sensitive but nonspecific *C. difficile* glutamate dehydrogenase antigen test followed by toxin assay
Stool culture for *Shigella*, *Salmonella*, and *Campylobacter* spp	Moderate to severe diarrhea and when stools are positive for inflammatory markers or contain gross blood and mucus (dysentery)	The three principal invasive bacteria are the only ones routinely sought by most laboratories.
Specialized stool culture for *Vibrios* spp and *E. coli* O157:H7 and other Shiga toxin–producing *E. coli*	For cases of profuse watery diarrhea in cholera-endemic areas or in outbreaks of diarrhea especially associated with dysenteric illness	Cholera cases may need aggressive fluid therapy. Outbreaks of dysenteric diarrhea should be evaluated for Shiga toxin–producing *E. coli*.
Parasite examination: (1) trichome stain; (2) acid-fast stain for *Cyclospora* or *Cryptosporidium* spp; or (3) enzyme immunoassay (EIA) for *Giardia* spp, *Cryptosporidium* spp, and/or *Entamoeba histolytica*	In any patient with persistent diarrhea and when diarrhea follows visits to mountainous or recreational lakes in North America, Nepal, Haiti, Peru, or Russia (particularly St. Petersburg)	If microscopic evaluation is performed, experience of the laboratory personnel is important. The commercially available EIA tests are sensitive.
Esophagogastroduodenoscopy and flexible sigmoidoscopy	Persistent diarrhea in patients without evidence of cause of illness	Identified cause of diarrhea is treated; without diagnosis, subjects may be treated symptomatically.

TABLE 291-4 THERAPY AND PREVENTION OF INFECTIOUS DIARRHEA

THERAPEUTIC OPTION	INDICATION	PHARMACOLOGIC AGENT
Oral fluid and electrolyte therapy	For infants, elderly patients, and anyone with profuse watery diarrhea	Soups, soft drinks, and saltine crackers are sufficient; formal oral replacement therapy may be needed with dehydrating forms of diarrhea
Diet	In all forms of diarrhea to facilitate enterocyte renewal and recovery	Soups and broth, saltine crackers, steamed vegetables, baked or broiled meats
Nonspecific therapy	For temporary (≤48 hr) control of diarrhea in older children and adults without evidence of severe diarrhea caused by an invasive or inflammatory bacterial or parasitic pathogen	Loperamide is the most effective symptomatic treatment and will decrease number of stools passed by 60%; bismuth subsalicylate is much less effective and will reduce number of stools by 40%; new antisecretory agents are being developed
Empirical antibacterial drugs	Enteric fever with toxicity Febrile dysenteric diarrhea Traveler's diarrhea	Fluoroquinolones for 7-10 days Azithromycin for 3 days Rifaximin for 3 days, fluoroquinolone or azithromycin for 1-3 days
Specific antibacterial therapy	Shigellosis, campylobacteriosis, cholera	See Chapters 310, 311, and 317
Antiparasitic drugs	Giardiasis, amebiasis, cryptosporidiosis, cyclosporiasis,	See Chapters 358, 359, and 361
Prophylaxis in traveler's diarrhea	Persons traveling to developing areas on tight schedules, those with history of prior traveler's diarrhea, persons with unstable underlying medical disorders, and those interested in prophylaxis	Rifaximin, 200 mg twice daily with meals, while in a high-risk region

by hemolytic-uremic syndrome in children and occasionally in elderly people.

DIAGNOSIS

Laboratory Findings

Laboratory tests (Fig. 291-1; see Table 291-3) can be useful and are of particular value in the more severely ill patients when subjects are forced by their illness to alter activities or are totally disabled and confined to bed, or when many patients are afflicted during an outbreak. In each of these situations, the laboratory may help establish cause and allow development of a proper plan of treatment (see Table 291-3). Useful laboratory tests include procedures looking for fecal inflammatory markers such as microscopic detection of fecal leukocytes or the more sensitive, commercially available test, fecal lactoferrin. These tests are particularly helpful to suggest the presence of the invasive bacterial pathogens, *Shigella*, *Salmonella,* and *Campylobacter* species or the noninvasive but inflammatory *C. difficile*. Stool culture is performed in more severe cases of sporadic diarrhea and in disease outbreaks and is carried out with blood culture in a patient with fever and systemic toxicity. Other indications for stool culture are presence of dysentery (passage of grossly bloody stools) and when fecal inflammatory markers are found. In dysenteric diarrhea, particularly in the presence of an outbreak, the laboratory should also be instructed to look for *E. coli* O157:H7 and other Shiga toxin–producing *E. coli*. Parasite examination is indicated by diarrhea and persistent (≥14 days) illness; a recent trip to Nepal, Haiti, Peru, or Russia; evidence the subject practices oral-anal sex or unprotected receptive anal intercourse; or associated immunosuppression. Other tests are indicated in special situations, including stool culture for *Vibrio cholerae* in a patient with severe watery diarrhea with excessive fluid losses in a cholera-endemic area and culture for *Mycobacterium avium-intracellulare*, herpes simplex virus, and cytomegalovirus in those with immunosuppression. For patients with persistent diarrhea without etiologic diagnosis when routine tests are employed, endoscopy (esophagogastroduodenoscopy and flexible sigmoidoscopy, or colonoscopy) may be indicated in attempting to determine the nature and cause of illness.

TABLE 291-5 NONINFECTIOUS CAUSES OF DIARRHEA

Running	Small bowel bacterial overgrowth
Fecal impaction	Systemic mastocytosis and eosinophilic gastroenteritis
Drugs and laxatives	Tropical sprue
Enteral feeding	Celiac sprue
Irradiation	Dermatitis herpetiformis
Pancreatic insufficiency	Whipple's disease
Intestinal lymphangiectasia	Thyrotoxicosis
Foods (especially dietetic)	Adrenal insufficiency
Cirrhosis and biliary obstruction	Factitious
Diabetic diarrhea	Inflammatory bowel disease
Alcoholism	Food allergy
Collagenous colitis	Carcinoid
VIPoma	Villous adenoma
Ischemic bowel disease	Stress with autonomic stimulation
Irritable bowel syndrome	

TREATMENT Rx

Treatment of diarrhea should be tailored to the clinical syndrome. Oral rehydration with fluids and electrolytes is used to treat acute watery diarrhea and gastroenteritis and all forms of enteric infection complicated with any degree of dehydration. ORT is particularly important in infants; it can be life-saving in developing countries for infants with severe diarrhea. Patients with diarrhea should be fed easily digestible foods to facilitate enterocyte renewal and to speed up disease recovery. In afebrile, nondysenteric diarrhea, symptomatic drugs may allow older children and adults with illness to return earlier to school or work. Loperamide is the most active drug for improvement of

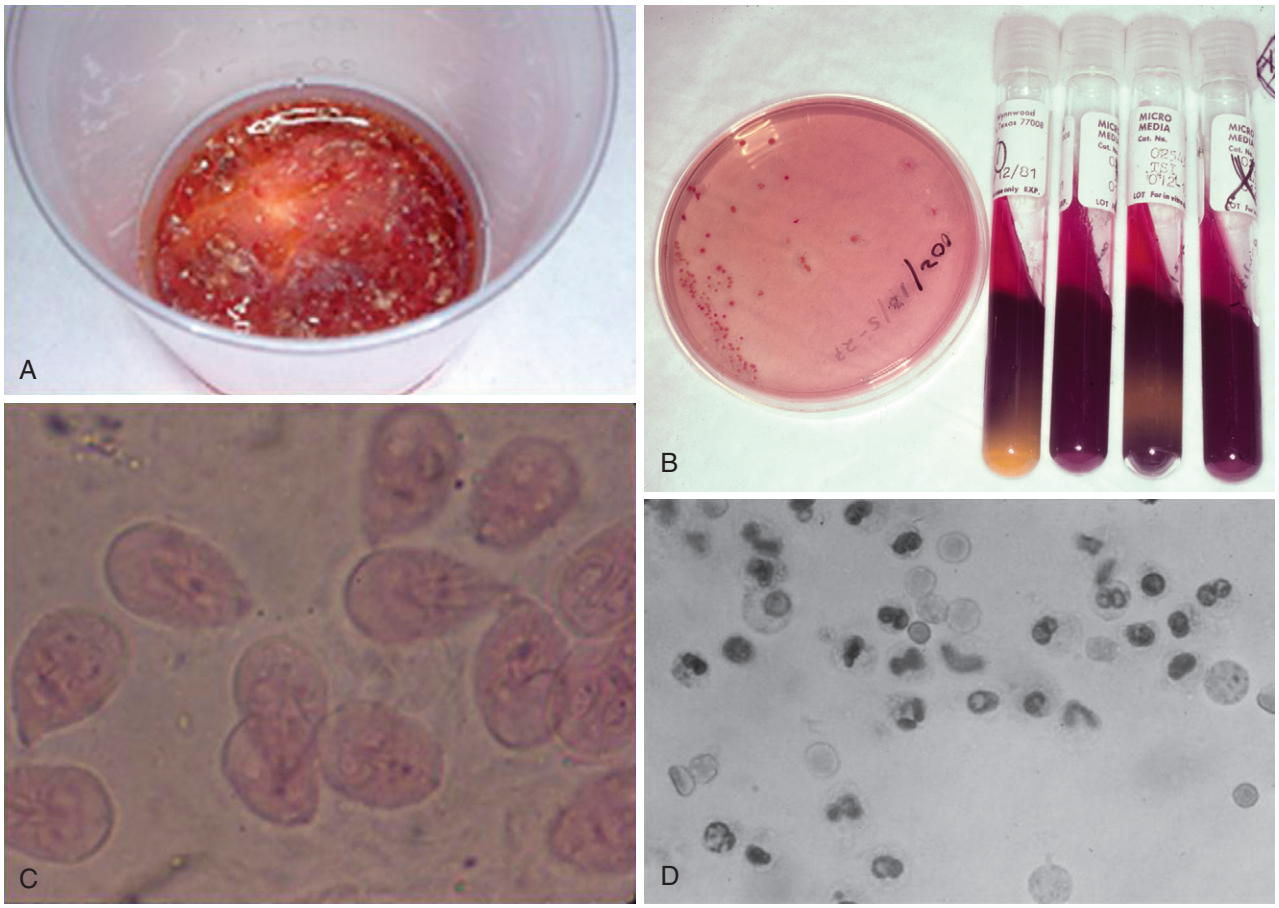

FIGURE 291-1. Laboratory tests to diagnose cause of diarrhea. A, Dysenteric stool. **B,** Stool culture and biochemical tests confirm *Salmonella*. **C,** *Giardia* trophozoites. **D,** Many leukocytes in diffuse colonic inflammation.

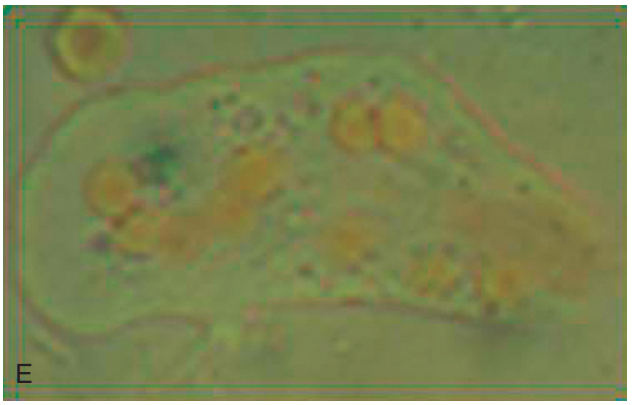

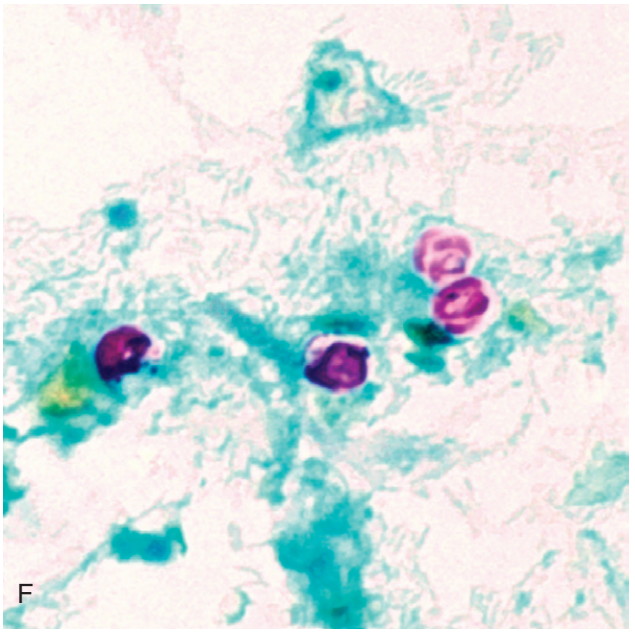

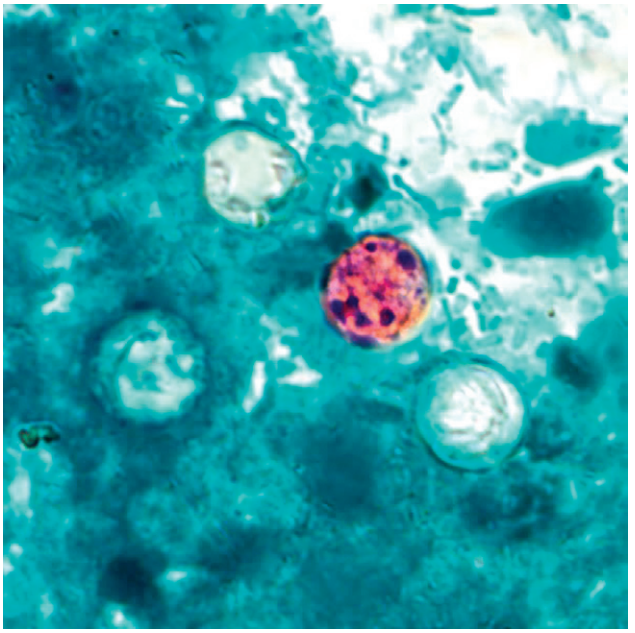

FIGURE 291-1, cont'd. **E,** *Entamoeba histolytica* trophozoite with ingested red blood cells. **F,** Oocysts of *Cryptosporidium* (*left*) and *Cyclospora* (*right*). (From the CDC Public Health Information Library. http://phil.cdc.gov/phil/home.asp: images 7829 and 7827.)

symptoms. Bismuth subsalicylate can reduce diarrhea and is mildly effective in reducing nausea and vomiting associated with viral gastroenteritis.

For enteric fever, febrile dysenteric disease, and moderate to severe cases of traveler's diarrhea, empirical antimicrobial therapy is indicated (see Table 291-4). For outbreaks of dysenteric diarrhea, particularly in children in whom fever is not significant, antibacterial and antimotility drugs should be initially withheld while the etiology of the outbreak is being established in order to prevent patients infected by Shiga toxin–producing *E. coli* from being predisposed to hemolytic-uremic syndrome. For bacterial and parasitic pathogen-specific diarrhea, antimicrobial therapy is often advised (see other chapters in the text for specific treatments). Because of the importance of diarrhea when persons travel from industrialized regions to developing countries, prophylaxis with the orally administered, poorly absorbed rifaximin can be employed for some groups (see Table 291-4), with expected protection rates exceeding 70%.

In sporadic cases of acute or persistent diarrhea, infectious agents are not always responsible. Table 291-5 offers a partial list of the noninfectious causes of diarrhea that should be considered.

292

APPROACH TO THE PATIENT WITH URINARY TRACT INFECTION

S. RAGNAR NORRBY

DEFINITION

This chapter addresses bacterial and fungal infections of the normally sterile urine, including asymptomatic bacteriuria, cystitis, pyelonephritis, and urosepsis (dissemination of microorganisms from the urine to blood). Urethritis caused by *Chlamydia trachomatis, Ureaplasma urealyticum* (Chapter 293), or *Neisseria gonorrhoeae* (Chapter 307); prostatitis (Chapter 131); and renal tuberculosis (Chapter 332) are addressed elsewhere in this text.

In the 1950s, Kass studied patients with or without bacterial colonization of the bladder urine. He defined *significant bacteriuria* as 10^5 or more colony-forming units (CFUs; where 1 CFU is one or more bacterial cells forming a colony when growing on an agar plate) per milliliter in two consecutive samples of midstream urine (i.e., urine obtained during voiding, discarding the first and last urine portions). Since then, *significant bacteriuria* has been redefined to optimize the sensitivity and specificity of diagnostic tests. In women with symptoms of uncomplicated cystitis, significant bacteriuria is now defined as 10^2 or more CFU/mL midstream urine plus pyuria (≥5

leukocytes/mm^3 of urine). In women with uncomplicated pyelonephritis and men with urinary tract infections (UTIs), significant bacteriuria is defined as 10^4 CFU/mL plus pyuria. In patients with complicated UTIs, the definition is 10^5 or more CFU/mL with or without pyuria.

CLASSIFICATION

It is clinically important to classify UTIs by type of infection, presence or absence of symptoms, tendency to recur, and presence or absence of complicating factors (Table 292-1). Recurrent infections can be subdivided into reinfections caused by new bacterial strains and relapses caused by the same strains that caused preceding infections. Complicating factors are host factors facilitating the establishment and maintenance of bacteriuria or worsening the prognosis of UTIs engaging the kidneys. The most common ones are listed in Table 292-2.

TABLE 292-1 CLASSIFICATION OF URINARY TRACT INFECTIONS

Type of UTI	Cystitis Pyelonephritis Asymptomatic bacteriuria
Symptoms	Symptomatic Asymptomatic
Recurrences	Sporadic (≤1 UTI/6 mo and ≤2 UTIs/yr) Recurrent (≥2 UTIs/6 mo or ≥3 UTIs/yr) Relapse Reinfection
Complicating factors	Uncomplicated Complicated (see text)

UTI = urinary tract infection.

EPIDEMIOLOGY

Worldwide, at least 150 million cases of symptomatic UTIs occur each year. Because many UTI patients have recurrent infections, the number of individuals who have UTIs each year is lower than the number of cases.

In general, 90% of patients have cystitis and 10% have pyelonephritis. The infections are sporadic in about 75% of patients and recurrent in 25%. About 2% have complicated infections related to factors that increase the risk of the establishment and maintenance of bacteriuria. These patients typically have frequently recurring UTIs. If factors that can increase the severity of a renal infection are included, the frequency of complicated infections is about 8%.

UTIs are somewhat more common in very young boys than in very young girls because of the higher frequency of urethral malformations in boys. Later in childhood, symptomatic UTIs are more common in girls, who are also more likely to have asymptomatic bacteriuria. In most cases, this is due to the short urethra, but it may also be the result of sexual abuse. Symptomatic UTIs are most common in sexually active women. In young men, bacterial UTIs are rare and are often the result of underlying infections of the prostate. In elderly people, both symptomatic UTIs and asymptomatic bacteriuria are common. In women, this is often the result of an atrophic vaginal mucosa, whereas in men, it is often a consequence of prostate hyperplasia or prostate cancer.

UTI is also the most common type of hospital-acquired infection because of the frequent use of bladder catheters.

TABLE 292-2 HOST FACTORS COMPLICATING BACTERIURIA

OUTCOME	FACTORS
Facilitated establishment and maintenance of bacteriuria	Residual bladder urine after voiding Physiologic Neurogenic bladder Prostate hyperplasia/tumor Turbulent urethral urine flow Strictures Foreign bodies Catheters Calculi Tumors Atrophic vaginal mucosa after menopause Vesicoureteral reflux Anatomic defects Pregnancy
Worse prognosis of urinary tract infections involving the kidneys	Childhood pyelonephritis Diabetic nephropathy Malignant hypertension Chronic pyelonephritis

PATHOBIOLOGY

In a majority of patients, UTIs are the result of colonization of the urine with fecal bacteria, which grow aerobically. Growth of anaerobic bacteria, such as *Bacteroides fragilis*, in the urine indicates a communication between the intestines and the urinary tract. This is seen in rare cases of fistulas between the intestines and the renal tract and following reconstructive surgery in the urinary tract, which involves the intestines. Growth of fungi in the urine may be seen in patients with bladder catheters and in immunocompromised patients with hematologic dissemination of *Candida* species from infections at other sites.

In women, bacteria colonize the periurethral area; from there, they reach the distal part of the urethra. Atrophic vaginal mucosa with altered vaginal flora after menopause and the use of diaphragms and spermicides in sexually active women are factors that increase the risk of colonization with large numbers of uropathogenic bacteria. Sexual intercourse results in increased numbers of bacteria in the periurethral area of the vagina and the distal part of the urethra, increasing the risk of bacteriuria.

In the normal male urethra, the distance between the end of the urethra and the bladder is too long to allow ascending transport of bacteria to the bladder. Therefore, bacteriuria in men should always be considered an abnormal finding, and men cannot have uncomplicated infections. However, transport of bacteria to the bladder urine through the male urethra is possible when there is turbulent urine flow, such as with a stricture or obstruction of the urethra, as a result of prostatic hyperplasia, and when the patient has a bladder catheter.

The female urethra is short and allows transport of bacteria to the bladder in healthy individuals. With many uropathogens, such transport is facilitated by adherence of the bacteria to urethral epithelial cells. Bacterial cells, such as *Escherichia coli* strains causing uncomplicated pyelonephritis, have fimbriae that adhere to α-D-Gal-4-β-D-Gal receptors (the P blood group) on the mucosal cells in the urethra and the ureters, thus facilitating the establishment of bacteriuria and further transport to the kidneys. Such adhesion stimulates mucosal cells to release cytokines such as interleukin-6, which causes fever and increases C-reactive protein, and interleukin-8, which mobilizes leukocytes. Individuals who lack the receptors for bacterial adhesion (those who do not have the P blood group) are less likely to have acute pyelonephritis. In patients with complicated UTIs, bacterial adhesion seems to be of less importance. The role of other bacterial virulence factors, such as the O and K antigens of *E. coli,* in the pathogenesis of UTIs is less well known.

When bacteria have reached the bladder, the establishment of bacteriuria is facilitated by incomplete bladder emptying. Even with residual urine volumes as low as 10 mL, which are not uncommon in healthy individuals, bacterial growth in the urine may be established. Pyelonephritis results from ascending bacteriuria from the bladder through the ureter to the renal pelvis and the renal parenchyma. This transport may be facilitated by host factors such as anatomic defects of the ureters or the kidneys, vesicoureteral reflux, or, in patients without anatomic defects, adhesion to the ureter mucosa. About one third of patients with pyelonephritis are also bacteremic.

In rare cases, bacteriuria and funguria may result from the hematogenous dissemination of bacteria to the kidneys, causing a renal abscess. The primary focus of the infection is usually an infection at a site outside the renal tract, such as endocarditis.

Patients with asymptomatic bacteriuria frequently harbor organisms that are less virulent than those causing symptomatic infections. Such organisms are often killed by normal human plasma or serum ("serum bactericidal effect"). Patients with persistent asymptomatic bacteriuria may be protected from symptomatic UTIs by large numbers (≥10^6 CFU/mL) of less virulent bacteria in the urine. However, in pregnant women and in patients with type

2 diabetes, asymptomatic bacteriuria is a strong predictor of subsequent symptomatic infection. Pyelonephritis is common during pregnancy because vesicoureteral reflux often occurs during the second and third trimesters. In children and adults, asymptomatic bacteriuria may be a sign of underlying urinary tract malformations.

Bladder catheterization leads to bacteriuria or funguria in all patients who have had their catheters for more than 1 week. Formation of a biofilm on the catheter surfaces facilitates the growth of microorganisms. Urosepsis, resulting from dissemination of bacteria from the urine to the blood in a patient with bacteriuria, is often the consequence of removing or changing a bladder catheter during the preceding 24 to 48 hours. This risk is further increased if the catheter has been in place for more than 1 week and the softener in the plastic material of the catheter is eluted, rendering the catheter stiff. The urethral mucosa may also be damaged by crystals that form on the catheter surface.

ETIOLOGY

The microbiologic etiology of a UTI depends on several factors. Table 292-3 summarizes the most common findings. In all types of UTI, *E. coli* is the dominating bacterial species, causing up to 85% of all symptomatic UTIs in women with community-acquired, sporadic, uncomplicated infections. In most countries, the second most common species causing such infections is *Staphylococcus saprophyticus,* which, at least in northern Europe, has a pronounced seasonal pattern, accounting for up to 40% of all uncomplicated cases of cystitis and pyelonephritis in July and August and virtually no infections in January and February. In patients with recurrent infections, species such as *Enterococcus faecalis, Enterococcus faecium, Klebsiella* species, *Proteus* species, *Providencia stuartii,* and *Morganella morganii* become more common. In patients with very frequent recurrences or with bladder catheters, especially in hospital and nursing home settings, where antimicrobials are frequently used, *Pseudomonas aeruginosa, Acinetobacter baumannii, Serratia marcescens,* and *Stenotrophomonas maltophilia* are important organisms. In such patients, *E. coli* accounts for less than 50% of infections. Findings of *Proteus mirabilis* or other *Proteus* species may indicate that the patient has renal calculi or a tumor because these organisms grow in an alkaline environment. Calculi in the renal pelvis, ureter, or bladder may also form as a result of the growth of ammonia-producing organisms such as *Proteus* species. Because *Proteus* species are common in the male preputial flora, the finding of such organisms in a voided urine sample from uncircumcised men or young boys could represent contamination and not bacteriuria.

TABLE 292-3 MICROBIAL ETIOLOGY OF URINARY TRACT INFECTIONS

ORGANISMS	CLINICAL CHARACTERISTICS
GRAM-NEGATIVE BACTERIA	
Escherichia coli	Typical
Klebsiella pneumoniae	Often reinfection
Enterobacter spp	Often reinfection and/or health care–associated infection*
Proteus spp	May indicate tumor or calculi
Providencia stuartii	Often reinfection and/or health care–associated infection*
Morganella morganii	Often reinfection and/or health care–associated infection*
Serratia marcescens	Often health care–associated infection*
Acinetobacter baumannii	Often health care–associated infection*
Burkholderia spp	Often health care–associated infection*
Pseudomonas aeruginosa	Often health care–associated infection*
Stenotrophomonas maltophilia	Often health care–associated infection*
GRAM-POSITIVE BACTERIA	
Staphylococcus saprophyticus	Most common during summer
Staphylococcus aureus	May indicate focus outside the genitourinary tract
Enterococcus spp	Often reinfection
Other gram-positive bacteria	In most cases contaminants
FUNGI	
Candida spp	May indicate focus outside the genitourinary tract

*Includes hospital and nursing home care.

CLINICAL MANIFESTATIONS

Typical symptoms of cystitis, pyelonephritis, and urosepsis are listed in Table 292-4. The onset of cystitis is rapid, and symptoms develop over less than 24 hours. Clinically, it is often impossible to differentiate between cystitis and urethritis caused by chlamydia, ureaplasma, or gonococci, especially when there is no urethral discharge. Fever is unusual among patients with cystitis. In sexually active women, cystitis commonly occurs 24 to 48 hours after intercourse, especially if the practice of postcoital bladder emptying has not been followed. Cystitis patients normally have symptoms for 3 to 5 days. Antimicrobial therapy does not markedly reduce the duration.

Pyelonephritis also has a rapid onset, with or without preceding cystitis symptoms. About one third of patients develop bacteremia. The typical flank pain, resulting from inflammation and edema of the renal parenchyma, may be masked by the intake of analgesic drugs such as acetaminophen, which may also reduce the fever. An important differential diagnosis is renal calculi, which may result in a similar location of the pain but characteristically do not cause fever. Also, patients with appendicitis and cholecystitis can present with flank pain similar to that in a patient with right-sided pyelonephritis.

Urosepsis is a life-threatening condition caused by dissemination of bacteria from the urine in a patient with bacteriuria. The most common reason for urosepsis is withdrawal (and sometimes insertion) of a bladder catheter. Thus, uroseptic patients do not always have a renal infection.

DIAGNOSIS

Laboratory Findings

The hallmark of the types of UTIs dealt with here is demonstration of bacteriuria in a urine sample that has been incubated in the bladder for at least 2 hours to allow the growth of bacteria. The most reliable result is obtained if the sample is taken by suprapubic aspiration, a technique frequently used in infants but rarely in older children and adults. It is superior to sampling by bladder catheterization, which carries about a 2% risk of introducing bacteria into the bladder and subsequently causing bacteriuria. The normal procedure for quantitative cultures is to collect a midstream urine sample. This requires the patient to be well informed about the sampling procedure. Men should withdraw the foreskin, and women should keep the labia apart. Washing of the genital tract before sampling is not recommended. During voiding, the first and last parts of the urine should not be sampled. After sampling, the urine should be chilled (but not frozen) to prevent growth during transportation to the laboratory. At the laboratory, the sample is streaked onto agar plates using a loop, which delivers a known amount of urine. The result is obtained after incubation overnight, providing a determination of the bacterial species present in the sample and the number of organisms per milliliter of urine. The presence of more than one species in a sample usually indicates defective sampling procedures and contamination.

A simplified quantitative urine culture can be obtained outside the microbiologic laboratory by using a dip slide. With that technique, a plastic slide

TABLE 292-4 CLINICAL SYMPTOMS OF URINARY TRACT INFECTIONS

TYPE OF URINARY TRACT INFECTION	TYPICAL SYMPTOMS
Cystitis	Frequent voiding Burning during and after voiding Suprapubic pain Hematuria and/or cloudy urine
Pyelonephritis	Fever Chills Flank pains Cystitis symptoms (may be absent)
Urosepsis	Fever Chills Septic shock

with agar media on both surfaces is dipped in the urine sample, or the urine sample is poured over the slide's surfaces. After overnight incubation at room temperature or in a simple incubator, the culture allows highly reliable quantification of bacteriuria. Because gram-negative, but not gram-positive, bacteria grow on both sides of the slide, the method also allows quick classification. However, if a determination of the species or the antimicrobial sensitivity pattern is required, the dip slide must be transported to a regular laboratory. The dip slide is most suitable for use in outpatient settings, especially when laboratories are unavailable locally.

All culture techniques require overnight incubation. For screening of bacteriuria, a nitrite test can be used. It is a stick test that demonstrates the presence of nitrite in the urine. Gram-negative bacteria, with the exception of *P. aeruginosa,* metabolize nitrate to nitrite, which can be demonstrated by a color reaction on a paper stick. Gram-positive bacteria and fungi do not metabolize nitrate. The technique is rapid (<1 minute) and inexpensive. It has a high degree of specificity but is rather insensitive because it does not detect infections caused by gram-positive organisms. Thus, it is not suitable for use in patients with recurrent infections (in whom an enterococcal cause is common) or when the frequency of *S. saprophyticus* infection is high.

Pyuria should be demonstrated in patients with UTIs. This is best done by staining uncentrifuged urine and counting leukocytes in a Bürker chamber. The second best technique is to use a leukocyte esterase stick test, which is highly sensitive and allows a crude quantification of pyuria. The technique of counting leukocytes in the sediment obtained after centrifugation of a urine sample was once used routinely, but it is imprecise and is not recommended. Persistent pyuria with negative routine bacteriologic cultures should lead to the suspicion of renal tuberculosis, and a sample should be obtained for direct microscopy and culture for *Mycobacterium tuberculosis* (Chapter 332).

Blood cultures should be obtained in all patients with suspected pyelonephritis or urosepsis. It is recommended that at least two cultures be obtained.

Imaging

Radiography and ultrasound examination are normally not helpful in the acute phase of suspected pyelonephritis unless there is suspicion of a blockage of the urine flow, which may indicate formation of a renal abscess. When the patient has recovered, such investigations are recommended in those with recurrent infections to exclude complicating factors. Normally, a simple pyelography or ultrasound examination is performed. For the diagnosis of vesicoureteral reflux, special radiographic techniques are used.

Differential Diagnosis

Although clinical manifestations should lead to a relatively clear differentiation of acute cystitis and acute pyelonephritis, it is often difficult to diagnose the latter. Laboratory tests may offer some help and should be used. Patients with acute pyelonephritis, but not those with acute cystitis, have increased levels of C-reactive protein in blood. That acute phase parameter increases rapidly in patients with acute pyelonephritis. It is also a useful test for determining response to therapy and diagnosing recurrences. The erythrocyte sedimentation rate is a less useful test because it takes several days to increase in a patient with acute pyelonephritis. In patients with acute pyelonephritis, leukocyte casts can often be demonstrated in urine sediment. When a patient has become afebrile, the diagnosis of acute pyelonephritis can be supported by testing urine osmolality, which is markedly reduced for at least 1 month after the onset of symptoms. Although not routinely indicated, the osmolality of urine is checked in a sample obtained after 12 hours of fasting and no fluid intake or 1 to 8 hours after intramuscular or subcutaneous injection of a small dose of desmopressin, a vasopressin analogue. Urine osmolality in individuals with normal renal concentrating ability is 850 to 1000 mOsm/L and varies with age. Demonstration of antibody-coated bacteria in the urine is neither sensitive nor specific for diagnosing pyelonephritis and is no longer recommended.

TREATMENT

Rx

All symptomatic UTIs should be treated. The purpose of early treatment of cystitis is to reduce the risk of progression to pyelonephritis. Treatment does not affect the duration of symptoms, which is 3 to 4 days. In patients with pyelonephritis, early treatment is important to reduce the duration of symptoms, eliminate microorganisms from the renal parenchyma, and reduce the risk of dissemination to the blood.

Because verifying the microbial etiology and determining the susceptibility to antimicrobial drugs take at least 1 day and often more than 2 days, initial treatment is empirical. The best guide is the antimicrobial susceptibility pattern of organisms obtained from comparable patients. For example, if the patient is a woman with sporadic, uncomplicated cystitis or pyelonephritis, antimicrobial susceptibility patterns generated from outpatients with sporadic UTIs are the appropriate reference. If the patient is hospitalized and has hospital-associated pyelonephritis, susceptibility patterns generated from samples collected in the hospital, preferably in the department or ward where the patient acquired the infection, are the appropriate reference. Large national or international surveillance studies have limited value when choosing antimicrobial treatments for individual patients. Susceptibility patterns developed from large reference laboratories may overestimate antimicrobial resistance because patients with uncomplicated infections are less likely to have cultures. However, there has recently been a marked increase of multidrug-resistant bacteria causing UTIs. Examples of such organisms are *E. coli* and *Klebsiella* species producing extended-spectrum β-lactamases and vancomycin-resistant enterococci. Due to this trend, the use of urine cultures and antibiotic resistance tests in patients with UTIs is recommended. Should multidrug resistance be demonstrated, the choice of antibiotics depends on resistance patterns.

Cystitis

Table 292-5 lists possible choices for the antimicrobial treatment of cystitis. Ideally, the antimicrobial should be excreted renally to achieve high concentrations in the renal parenchyma and in the urine. The safety profile is also important because cystitis is common and is associated with low mortality. The treatment time varies with the type of antimicrobial. Trimethoprim, trimethoprim-sulfamethoxazole, and fluoroquinolones are effective treatments,[1] even in pregnant women,[2] because they reduce uropathogenic bacteria in the periurethral flora and the fecal flora; a 3-day course is recommended. β-Lactam antimicrobials and nitrofurantoin generally have shorter elimination times and do not affect the periurethral and fecal flora; treatment for 5 to 7 days is required to eliminate bacteriuria in most patients. Single-dose treatment is recommended only for a high dose of trimethoprim-sulfamethoxazole and for fosfomycin (which is licensed only for single-dose treatment). Although these single-dose regimens may seem preferable to treatment for several days, 3-day regimens seem to have the best acceptance among patients. When patients have recurrent or complicated cystitis, the treatment duration should be at least 7 days.

Fluoroquinolones are not recommended for routine use in sporadic cystitis, although many of them have well-documented efficacy when used at relatively low doses for 3 days or even as a high single dose. The reason is that widespread use in cystitis patients is likely to lead to overuse and the emergence of resistance.

Patients with frequently recurring cystitis can benefit from early self-treatment if they are well informed and compliant. If treatment is started very shortly after the onset of symptoms, a 3-day course or even a single dose of antimicrobial provides rapid relief of symptoms.

Pyelonephritis

For antimicrobial treatment of pyelonephritis, the primary decision is whether the patient needs initial treatment with a parenteral antimicrobial or whether oral treatment alone will suffice. Table 292-6 lists antimicrobials suitable for the treatment of pyelonephritis. Oral formulations of penicillins or cephalosporins should be used only after initial parenteral therapy. After initial treatment with a parenteral drug, a transition to oral treatment is normally possible after 24 to 48 hours unless the patient does not improve. The recommended treatment time is still 14 days, although recent information indicates that in patients with uncomplicated pyelonephritis, treatment for 7 days may suffice.

Only fluoroquinolones and trimethoprim-sulfamethoxazole can be used for initial oral treatment of pyelonephritis, if the patient's general condition allows it. Because both these alternatives are unsuitable for use in pregnant women, pyelonephritis during pregnancy should be treated with a parenteral antimicrobial, preferably a cephalosporin, followed by oral step-down therapy.

Bacteriuria

Bacteriuria in patients with catheters should not be treated unless the patient is febrile or has other evidence of systemic infection. Administration of antimicrobials to catheterized patients with asymptomatic bacteriuria inevitably results in multiresistant and difficult-to-treat organisms.

Urosepsis

In patients with suspected urosepsis, antimicrobial treatment must start as early as possible. Antimicrobials should be given intravenously, and those recommended for injectable treatment of pyelonephritis should be used. Previous antimicrobial treatment should always be ascertained in patients with urosepsis because such treatment may have resulted in resistant organisms. A relatively new cause of urosepsis is vancomycin-resistant enterococci *(E. faecium* or *E. faecalis),* which usually occurs in immunocompromised patients.

TABLE 292-5 ANTIMICROBIALS USED TO TREAT CYSTITIS

ANTIMICROBIAL	DOSE* AND DURATION
Trimethoprim	100-150 mg q12h for 3 days
Trimethoprim/sulfamethoxazole	80/400 mg q12h for 3 days or 320/1600 mg single dose
Nitrofurantoin	50 mg q8h for 5-7 days
Amoxicillin/clavulanic acid	250 mg (amoxicillin dose) q8h for 5-7 days
Cefuroxime axetil	250 mg q8h for 5-7 days
Cefpodoxime proxetil	200 mg q8h for 5-7 days
Cefixime	400 mg/day for 5-7 days
Ceftibuten	400 mg/day for 5-7 days
Cefprozil	250 mg/day for 5-7 days
Norfloxacin†	200 mg q12h for 7 days
Ciprofloxacin†	100 mg q12h for 7 days
Levofloxacin†	250 mg/day for 7 days
Fosfomycin	400 mg single dose

*Doses given are for adults with normal renal function. The need to reduce dosages because of renal impairment related to infection in the kidneys, other renal diseases, or advanced age should always be considered.
†Should be reserved for recurrent and/or complicated cystitis.

TABLE 292-6 ANTIMICROBIALS USED TO TREAT PYELONEPHRITIS

ROUTE OF ADMINISTRATION AND ANTIMICROBIAL	DOSE*	COMMENTS
INJECTABLE		
Cefepime	2 g q12h	Health care–associated infections†
Cefotaxime	1 g q12h	Community-acquired infections
Ceftazidime	1 g q12h	Health care–associated infections†
Ceftriaxone	2 g/day	Community-acquired infections
Cefuroxime	750 mg q8h	Community-acquired infections
Amikacin	15 mg/kg/day	Monitor renal function
Gentamicin	4.5 mg/kg/day	Monitor renal function
Netilmicin	4.5 mg/kg/day	Monitor renal function
Tobramycin	4.5 mg/kg/day	Monitor renal function
Ciprofloxacin	200 mg q12h	
Levofloxacin	250 mg/day	
Trimethoprim/sulfamethoxazole	160/800 mg q12h	Community-acquired infections
ORAL		
Amoxicillin/clavulanic acid	500 mg (amoxicillin dose) q8h	Only step-down therapy
Cefuroxime axetil	250 mg q12h	Only step-down therapy
Cefpodoxime proxetil	200 mg q8h	Only step-down therapy
Cefixime	400 mg/day	Only step-down therapy
Ceftibuten	400 mg/day	Only step-down therapy
Cefprozil	250 mg/day	Only step-down therapy
Norfloxacin	400 mg q12h	
Ciprofloxacin	100 mg q12h	
Levofloxacin	250 mg/day	

*Doses given are for adults with normal renal function. The need to reduce dosages because of renal impairment related to infection in the kidneys, other renal diseases, or advanced age should always be considered.
†Includes hospital and nursing home care.

Funguria

Funguria can be treated with fluconazole 400 mg once daily for 1 day, followed by 200 mg once daily for 7 to 14 days. Funguria in catheterized patients should be treated only when there is a symptomatic UTI.

Follow-up

Patients with sporadic, uncomplicated cystitis do not require follow-up. Patients with symptomatic recurrences, pyelonephritis, or complicated UTI should be observed. Table 292-7 lists some examinations that may be considered. Follow-up cultures are important because bacteriuria may persist and cause renal damage in afebrile pyelonephritis patients. The decision process for upper (pyelonephritis) and lower (cystitis) UTIs appears in Table 292-8.

PREVENTION

There are well-known measures that markedly reduce the risk of UTI recurrence. The most important is for sexually active women to urinate shortly after sexual intercourse. In doing so, they wash out the increased number of bacteria in the distal urethra. Another useful suggestion is for patients with recurrent UTIs to practice double or triple voiding. This means that the patient should make an extra effort to empty the bladder at each urination, thus decreasing the volume of residual urine. Increased fluid intake was

TABLE 292-7 FOLLOW-UP PROCEDURES IN PATIENTS WITH URINARY TRACT INFECTIONS OTHER THAN SPORADIC CYSTITIS

PROCEDURE	RECOMMENDATION
Urine culture	All patients with pyelonephritis, complicated infections, or frequent recurrences; 4-5 days and 3-4 wk after treatment
Pyuria test	Always perform together with urine culture
C-reactive protein	4-5 days and 3-4 wk after treatment of pyelonephritis
Radiography or ultrasonography	After pyelonephritis to exclude scars from childhood infections in patients with recurrent infections and to exclude complications
Serum creatinine	Before treatment in elderly; 3-4 wk after treatment in patients with pyelonephritis
Urine osmolality	Verification of suspected pyelonephritis

TABLE 292-8 DECISION PROCESS FOR UPPER (PYELONEPHRITIS) AND LOWER (CYSTITIS) URINARY TRACT INFECTIONS

	CYSTITIS	PYELONEPHRITIS
SIGNS AND SYMPTOMS		
Fever	No	Yes
Dysuria	Yes	May be present
Frequency	Yes	May be present
Flank pain	No	Yes
DIAGNOSIS		
Pyuria	Yes	Yes
Nitrite test	Normally positive	Normally positive
Bacteriuria	Yes	Yes
C-reactive protein	Normal	Increased
Blood cultures	Negative	Positive in ≈30%
TREATMENT		
First line	Trimethoprim or trimethoprim-sulfamethoxazole for 3 days	Fluoroquinolone or trimethoprim-sulfamethoxazole for 2 wk orally
Second line	Fluoroquinolone for 3 days or cephalosporin for 5-7 days	Injectable cephalosporin until afebrile, followed by oral step-down for total of 2 wk
Pregnant women	Nitrofurantoin or cephalosporin for 5-7 days	Injectable cephalosporin until afebrile, followed by oral cephalosporin for 2 wk

previously advocated, probably because of the risk of crystalluria with older sulfonamides; however, there are no obvious benefits of excessive diuresis.

Today, antimicrobial prophylaxis of UTIs is restricted to just a few groups of patients. One group in which it is still recommended is pregnant women with asymptomatic bacteriuria. Thus, screening for bacteriuria at regular intervals during pregnancy is recommended. Another group in which screening of bacteriuria and prophylaxis have been proposed is patients with diabetes mellitus, especially those with type 2.

Cranberry products have been proposed for the prevention of recurrent UTIs. Analyses of studies suggest that these products might have a low preventive effect in young and middle-aged women, but the use of cranberries as prophylaxis of UTI is not recommended.

Prophylaxis is sometimes used in patients with frequently recurring UTIs, especially when there are no defined, treatable complications. In such patients, one daily dose of nitrofurantoin 50 to 100 mg or trimethoprim 150 to 200 mg, taken at bedtime, is recommended.

Antimicrobial prophylaxis should not be used in catheterized patients because it results in the selection of microbes resistant to the antimicrobial used.

In postmenopausal women with atrophic vaginal mucosa and recurrent symptomatic UTIs, replacement therapy with oral or vaginal estriol should be considered. Such treatment restores the normal premenopausal vaginal and periurethral microbial flora and reduces the incidence of symptomatic UTIs.

PROGNOSIS

The prognosis of uncomplicated cystitis and pyelonephritis is generally good unless urosepsis occurs. Secondary morbidity is rare.

In patients with complications such as renal scars from childhood pyelonephritis, chronic pyelonephritis or glomerulonephritis, or other chronic renal diseases, acute pyelonephritis may lead to a further reduction of renal function. As mentioned earlier, infections with *Proteus* species or other ammonia-producing organisms may lead to the formation of calculi or the worsening of existing ones.

Patients with urosepsis have a poor prognosis, with fatality rates of about 30% or higher. Factors increasing the risk of death are advanced age and underlying diseases, as well as inadequate antimicrobial treatment. It has been demonstrated that in patients with sepsis caused by gram-negative bacteria, the death rate increases drastically if the organisms are resistant to the empirical treatment given.

APPROACH TO THE PATIENT WITH A SEXUALLY TRANSMITTED DISEASE

MYRON S. COHEN

SEXUALLY TRANSMITTED DISEASES

DEFINITION

Sexually transmitted diseases (STDs) include a wide variety of organisms that are transmitted through intimate contact involving skin and/or mucosal surfaces of the oropharynx, vagina, penis, and rectum. STDs can generally be divided into five broad categories (Table 293-1).

ETIOLOGY

The interaction between the host and the STD pathogen plays a critical role, and characteristic tissue changes offer exceptionally strong clues about etiology. Several STD pathogens cause local inflammation only (*Neisseria gonorrhoeae, Chlamydia trachomatis, Trichomonas vaginalis*), with the potential for local tissue invasion (*N. gonorrhoeae, C. trachomatis*) or systemic dissemination (*N. gonorrhoeae*). Some STD pathogens cause tissue ulceration (*Treponema pallidum, Haemophilus ducreyi,* herpes simplex viruses 1 and 2). Human papillomaviruses (HPVs) cause epithelial cell changes and predispose to neoplasm. And several STDs (human immunodeficiency virus [HIV], hepatitis B and C, cytomegalovirus) routinely use the genital tract for access without causing any local changes.

EPIDEMIOLOGY

STDs are among the most common infections worldwide, and most are never reported. Each year there are more than 9 million new STD infections among persons aged 15 to 24 years in the United States, and many infections are asymptomatic during the time they are transmissible. The incidence of syphilis declined in the 1990s, but since 2000, rates have been increasing among women (from 0.8 cases per 100,000 in 2004 to 1.5 cases per 100,000 in 2008) and men who have sex with men (from 3.0 cases per 100,000 in 2001 to 7.6 cases per 100,000 in 2008). Following years of decline, gonorrhea rates have been stable over the past 12 years (111.6 cases per 100,000 in 2008). Approximately 20% of the U.S. population is already infected with herpes simplex virus type 2 (HSV-2), and many newly acquired genital ulcers are now due to HSV-1. It is estimated that 26.8% of U.S. women aged 14 to 59 have had HPV infection (including high- and low-risk serotypes), and 5.6% of sexually active 14- to 59-year-old women have reported genital warts.

The spread of STDs depends on the organism and the host, the length of time an infected person remains contagious, and the number of people exposed. These parameters have been reduced to the following formula:

$$R_o = B \times D \times C$$

where R_o is the basic reproductive rate of an infection, or the mean number of secondary cases a typical single infected person will cause in a population; B is the efficiency of transmission; D is the duration of infectiousness; and C is the number of sexual partners.

PATHOGENESIS

The STD pathogens depend entirely on human-human transmission, although *T. vaginalis* may have some inanimate sources. The efficiency of transmission reflects the infectiousness of the host (which depends on the concentration and phenotype of the organism in the genital tract) and the susceptibility of the sexual partner (which reflects the resistance of the host and can be hereditary, acquired, or innate). Because immunity to STDs is rare, reinfections are common, and vaccine development has been difficult; the only STD vaccines available target hepatitis B and HPV.

STDs produce syndromes precisely because each pathogen has a proclivity for one or more tissues and (when symptomatic) can evoke a predictable inflammatory response. For example, gonococci that infect the male urethra generally produce an intense neutrophil response that leads to a purulent discharge and pain with urination, whereas *C. trachomatis* is less likely to

TABLE 293-1 SYNDROMES OF SEXUALLY TRANSMITTED DISEASES

Recommended
Azithromycin 1 g orally (single dose), or Doxycycline 100 mg orally twice daily for 7 days
Alternative
Erythromycin base 500 mg orally four times daily for 7 days, or Erythromycin ethylsuccinate 800 mg orally four times daily for 7 days, or Ofloxacin 300 mg orally twice daily for 7 days, or Levofloxacin 500 mg orally once a day for 7 days

*Uncomplicated anorectal and genital disease.

produce such a response in the same tissue and is more likely to produce a mild, watery discharge or no symptoms at all.

STDs serve as markers for sexual risk-taking behavior, and coinfections are common. The detection of an STD should lead to a variety of other (seemingly unrelated) tests. STD pathogens move together: gonorrhea and chlamydia cause urethritis; genital ulcers greatly increase the probability of HIV acquisition.

DIAGNOSIS AND TREATMENT

Syndromic Strategies

For a variety of common STD syndromes, treatment of the index case based on signs and symptoms is empirical, as is treatment of sexual partners. This approach reflects the facts that the diagnostic accuracy of some tests is imperfect, coinfection demands concomitant therapy that overrides the search for individual pathogens, and patients who are not treated immediately may not return for therapy. Empirical therapy is so successful that follow-up care ("proof of cure") is usually unnecessary.

The syndromic approach is particularly critical in resource-constrained countries or in areas of the United States where laboratory tests are not available or their cost is prohibitive. In the United States, concomitant microbiologic diagnosis is preferred because it (1) confirms the choice of empirical therapy or redirects subsequent care; (2) permits the detection and monitoring of resistance to treatment; and (3) enables specific diagnoses to be reported to public health authorities, which is required by state law for many STDs. However, even when laboratory tests are ordered, the most appropriate agents should be provided empirically at the point of care to resolve infection and to reduce the spread of STDs.

Relationship of STDs to HIV

Diagnosis of an STD demonstrates increased sexual risk-taking behavior and inconsistent condom use and serves as a marker for potential HIV infection. Genital ulcers disrupt the epithelium and allow the entry of HIV, and inflammation recruits macrophages and lymphocytes, increasing the number of targets for HIV. Any patient undergoing evaluation or treatment for an STD should be tested for HIV. Early diagnosis of HIV has very great personal and public health benefits.

SYNDROMES

Urethritis

Urethritis is characterized by some combination of urethral discharge and dysuria, but prostatitis can cause similar complaints. Urethritis is caused by a limited group of pathogens (see Table 293-1) that may be difficult to visualize microscopically or grow in culture. Accordingly, empirical therapy is provided to treat a spectrum of potentially causative organisms.

Urethritis is diagnosed when one or more of the following are demonstrated: (1) mucopurulent or purulent urethral discharge, (2) Gram stain of urethral secretions demonstrating 5 or more leukocytes per oil immersion microscopic field, (3) positive leukocyte esterase test on first-void urine, or (4) microscopic examination of first-void urine demonstrating 10 or more leukocytes per high-power field. If no discharge can be expressed from the urethral meatus, a calcium alginate swab can be inserted 5 mm into the urethra; the material collected is transferred to a slide by rolling the swab along the glass.

A Gram stain of urethral discharge is a simple and rapid diagnostic test to document both urethritis and gonococcal infection (Chapter 307), characterized by the detection of leukocytes containing intracellular gram-negative diplococci. Confirmation of gonococcal urethritis does not rule out concomitant infection with *Chlamydia* or *Mycoplasma.* As culture and Gram stain have become less popular or less available, nucleic acid amplification tests (NAATs) that are highly sensitive and specific for the detection of organisms have been used routinely. NAATs for gonorrhea, *Chlamydia*, and *Trichomonas* can be applied to first-voided urine samples (the meatus is intentionally not cleaned so that the urine is contaminated with these organisms) and/or urethral swab material. Specific diagnosis may enhance the management of sexual partners, and the results from such tests should be reported to the health department. However, in practice, patients and (in most cases) sexual partners must be treated before the results of these tests are available.

Treatment for urethritis should be initiated as soon as possible after the clinical diagnosis and should be directly observed if feasible (Table 293-2). *N. gonorrhoeae* (Chapter 307) has become resistant to many antimicrobials, including quinolones, so the choice of optimal therapies is limited. Dual therapy with azithromycin and ceftriaxone increases the cure rate of uncomplicated urogenital, anorectal, and pharyngeal gonorrhea. Azithromycin can also be expected to cure most causes of nongonococcal urethritis (NGU), including those caused by *Mycoplasma genitalium*, an increasingly recognized cause of NGU. *T. vaginalis*, which is susceptible to metronidazole or tinidazole, also causes urethritis and should be considered in the face of NGU treatment failure.

Women with urethritis present with some combination of dysuria and pyuria, which must be differentiated from bacterial cystitis. Because treatment for urinary tract pathogens may also resolve urethritis, the clinician treating a presumed bladder infection should consider an STD as well.

Genital Ulcers

In the United States, HSV-1 and HSV-2 (Chapter 382) and *T. pallidum* are responsible for virtually all the ulcers encountered, and HSV-1 and -2 are by far the most common cause.

GENITAL HERPES

Genital herpes usually develops after an incubation period of less than 21 days and arises as clustered vesicles on an erythematous base. The vesicles become pustular and then rupture to form shallow, painful ulcers, which may coalesce. The ulcers heal by crusting over, and the process is usually completed 2 to 3 weeks after the initial lesions. Recurrences proceed through the same stages but generally last only about 5 to 7 days. The first (incident) episode of HSV-2 may be accompanied by systemic signs and symptoms including fever and headache, the latter reflecting the spread of HSV to the central nervous system. About 20% of infected individuals manifest the classic presentation, 60% have mild and atypical signs and symptoms, and at least 20% are completely asymptomatic. Individuals who have acquired HSV-2 shed the virus approximately 3 to 4% of the time (even while asymptomatic), posing an ongoing risk to sexual partners.

SYPHILIS

The ulcerative lesion of syphilis (Chapter 327)—the chancre—is indurated and painless, and in many cases it escapes detection. Secondary syphilis results when the spirochetes spread systemically, leading to a characteristic rash, alopecia, oral mucous patches, or condyloma latum. These skin manifestations should prompt testing for syphilis. The serologic screening test of choice for syphilis is based on the formation of antibodies to cardiolipin, a constituent of the spirochetal cell wall (e.g., rapid plasma regain [RPR], Venereal Disease Research Laboratory [VDRL], TRUST tests). Confirmatory testing requires the search for an antitreponemal antibody (e.g., microhemagglutination assay–*T. pallidum* [MHA-TP], FTA-Ab). The anticardiolipin test provides a titer that must be used to monitor the response to treatment. Some larger commercial laboratories have reversed the order of testing, using an antitreponemal test followed by an anticardiolipin test, which allows automation and may be cost-effective in areas of low endemicity. Dark-field microscopy of ulcer scrapings suspended in normal saline or touch preparations of moist lesions reveals motile spirochetes. A patient who had a negative syphilis test in the past year and now has a positive test is said to have early latent syphilis. This patient may not recall any of the signs or symptoms of primary or secondary syphilis.

Later stages of syphilis may be identified only serologically or on pathologic specimens. Late latent syphilis and syphilis of unknown duration are managed similarly. Neurosyphilis can occur at any stage of infection and should be suspected in any patient with a positive serologic test who also has findings suggestive of nervous system involvement, including ocular and vestibular symptoms.

Worldwide, syphilis infection has been detected in a substantial number of people with recognized or unrecognized HIV infection, especially men who have sex with men. Accordingly, the diagnosis of syphilis requires HIV testing.

CHANCROID

Chancroid (Chapter 309), infection with *H. ducreyi*, produces ragged, dirty ulcers and tender inguinal lymphadenopathy, which may be fluctuant. Unlike the lesions of HSV, these genital ulcers are likely to vary in size.

Epithelial Cell Infections

HUMAN PAPILLOMAVIRUS

HPV infection (Chapter 381) is generally transient and asymptomatic, but some patients develop visible genital warts. These warts are painless, soft, moist, pink, or flesh-colored swellings that vary in shape and can be raised or flat, single or multiple, small or large, and sometimes cauliflower shaped. Warts occur in the vulva, vagina, and anus; on the cervix; and on the penis, scrotum, groin, or thigh. Genital warts are diagnosed by visual inspection. Treatment is primarily with topical agents but is generally not curative.

Two oncogenic HPV genotypes (16 and 18) are responsible for at least 85% of all cervical neoplasia, and HPV types 6 and 11 are responsible for most cases of genital warts. HPV vaccines are available that target these genotypes. Pap smears are recommended for sexually active women beginning at age 21 or 3 years after they become sexually active; the frequency of rescreening is influenced by normal examinations and risk factors.

Female Genital Discharge

Infections of the female genitourinary tract produce several syndromes with overlapping symptoms (dysuria, vaginal discharge, vulvar irritation), the cause of which can usually be established with a careful history, examination, and laboratory tests. The initial approach depends on the primary anatomic site of infection—urinary tract, endocervix, or vagina. The columnar epithelium of the endocervix is susceptible to infection with *N. gonorrhoeae, C. trachomatis,* and *T. vaginalis*, and the vagina is susceptible to infection with *Candida albicans, T. vaginalis,* and the syndrome of bacterial vaginosis. The cervix may appear completely normal in women with cervical infection, whereas mucopurulence at the cervical os or mucosal friability suggests infection. Vaginitis is associated with a visible discharge, and the characteristics of the vaginal fluid offer diagnostic clues.

Female genital discharge is a condition in which syndromic management strategies often lack sensitivity and specificity. In women with vaginal discharge, microscopic examination of a wet mount preparation substantially enhances the effectiveness of syndromic treatment.

BACTERIAL VAGINOSIS

Bacterial vaginosis (BV) is the most common cause of vaginal discharge in the United States. Affected women are often minimally symptomatic but may note mild vaginal discharge and vaginal odor (which is often increased after coitus). The normal vaginal flora contains hydrogen peroxide–producing lactobacilli such as *Lactobacillus crispatus* and *Lactobacillus jensenii,* which probably help "defend" the vagina against a number of pathogens (an example of innate immunity). *Lactobacillus acidophilus* is rarely found in the normal vagina, which explains the failure of yogurt to serve as a remedy or a preventive. BV begins with the unexplained disappearance of the normal vaginal flora and its replacement with *Gardnerella vaginalis* and many species of anaerobic bacteria. The precise mechanism causing this shift in vaginal flora is poorly understood. Most recently, previously unrecognized anaerobic bacterial species (BV-associated bacteria) have been described as causative and potentially transmissible. The discharge of BV is homogeneous and may contain bubbles. Vaginal pH is elevated above the normal 4.0 to 4.5. Adding 10% potassium hydroxide to the vaginal discharge on the microscope slide or to the discharge present in the extracted speculum elicits an amine-like, fishy odor, yielding a positive "whiff" test because of the elaboration of amines from the anaerobic flora. Examination of vaginal material as a wet mount reveals the absence of bacilli and their replacement with clumps of coccobacilli. Some vaginal epithelial cells are coated with coccobacilli, which may obscure their edges (clue cells) or the normally clear appearance of the cytoplasm. Relatively few polymorphonuclear leukocytes are observed; large numbers of leukocytes in the wet mount of a woman with BV suggest a coincident infection, possibly trichomoniasis or bacterial cervicitis.

BV is not necessarily a benign change in flora. It is associated with an increased rate of upper tract infection (endometritis, salpingitis) and, on occasion, with complications of pregnancy, including premature rupture of the membranes and preterm delivery. However, treating asymptomatic women with BV who are not at high risk for preterm delivery appears to confer no benefit. Women with BV appear to have increased risk for the acquisition of HIV. Treatment is generally directed against the anaerobic flora and consists of metronidazole or clindamycin for 7 days. A single oral dose of metronidazole is not recommended for BV because of the high failure rate. The BV relapse rate is about 30%, and treating male sexual partners offers no benefit.

CANDIDIASIS

Vulvovaginal candidiasis (Chapter 346) is common and is seen most frequently in women taking antibiotics or using oral contraceptives when endogenous *Candida* species outgrow normal bacterial flora. Women usually complain of vulvar itching and discomfort and may or may not notice an accompanying discharge. The vagina generally maintains normal numbers of lactobacilli, so the vaginal pH is usually normal; this is very helpful in discriminating between candidiasis and other vaginal infections. The labia and

vaginal walls may be erythematous. Although classically described as "curdy," the discharge of candidiasis is frequently loose and is difficult to distinguish from other discharges. Vaginal material may be treated with 10% potassium hydroxide to destroy other cellular elements and make the fungi easier to observe. Wet mount, however, has a sensitivity of only about 50%, and a woman with a classic presentation should be treated even if fungal elements are not observed.

A wide range of topical antifungal medications are available (many without a prescription), and all these drugs are approximately equally effective, although the cure rate with some single-dose therapies appears to be lower than that with longer regimens. Fluconazole administered as a single oral dose of 150 mg is highly effective. Infection with yeasts other than *C. albicans* may require longer therapy. Recurrent vulvovaginal candidiasis is a problem for many women, and optimal management has not been defined. Recurrent infection should lead the clinician to consider underlying diabetes mellitus or HIV. Treatment of sexual partners of women with candidiasis confers no benefit.

Women with *T. vaginalis* infection complain of a purulent discharge and vulvar irritation. The vaginal walls are red, and the vagina may contain excessive yellow or green discharge displaying large bubbles. The ectocervix may also be inflamed or have punctate microhemorrhages, causing the pathognomonic "strawberry cervix" (colpitis macularis). Vaginal pH is elevated, but the whiff test is generally negative. Wet mount reveals large numbers of polymorphonuclear leukocytes as well as motile protozoa about the same size as the leukocytes, with visible flagellae; motile organisms may be recognized in about two thirds of cases. Therapy for trichomoniasis requires metronidazole or tinidazole, but resistant organisms are encountered with increasing frequency.

CERVICITIS

The diagnosis of cervicitis is suggested by tenderness on bimanual examination, visible inspection revealing inflammation, and/or discharge. The specific diagnosis can be made only by detecting microorganisms from the cervix. *N. gonorrhoeae* and *C. trachomatis* have tropism for cervical tissue, whereas other pathogens (including HIV) can apparently infect the vaginal tissues as well.

PELVIC INFLAMMATORY DISEASE

Each year, 250,000 to 500,000 women develop salpingitis in the United States. *N. gonorrhoeae, C. trachomatis,* and *Mycoplasma* species ascend from the cervix into the uterine cavity, producing endometritis, and then extend to the fallopian tubes, causing salpingitis. The STD pathogens cause inflammatory changes that allow the tissues to become coinfected with bowel and vaginal anaerobic bacteria. Chlamydial salpingitis may be mild, and patients may not seek medical attention. Some intrauterine devices have been associated with an increased risk of salpingitis, and some data suggest that vaginal douching is a predisposing factor.

Adnexal tenderness on bimanual examination leads to the clinical diagnosis of salpingitis. Cervical tenderness, fever, leukocytosis, and an elevated sedimentation rate are sometimes observed. The clinical diagnosis is confirmed laparoscopically in only about 70% of cases. Vaginal ultrasonography or computed tomography is often helpful in defining the cause of pelvic pain syndromes. Pregnant women with evidence of salpingitis should be hospitalized. Infertility complicates approximately 15% of initial attacks of salpingitis and affects about 75% of women who suffer three or more attacks. Ectopic pregnancy and tubo-ovarian abscess are long-term complications of salpingitis.

PREVENTION

STDs are preventable. The Centers for Disease Control and Prevention recommends five strategies as the foundation for an effective prevention program: (1) education and counseling of persons at risk to motivate the adoption of safer sexual behavior; (2) identification of asymptomatic infected persons and symptomatic persons unlikely to seek diagnostic and treatment services; (3) rapid and effective diagnosis and treatment of infected persons; (4) evaluation, treatment, and counseling of exposed sexual partners; and (5) pre-exposure vaccination of persons at risk for vaccine-preventable STDs.

Abstinence or Monogamy

Abstaining from sexual intercourse or being in a long-term, mutually monogamous relationship with an uninfected partner is the most reliable way to prevent STDs. Abstinence should be recommended during treatment for an STD and for anyone who wants to avoid STDs and unintended pregnancy. Both partners should be tested for STDs, including HIV, before initiating sexual intercourse.

Barrier Methods

When used consistently and correctly, male latex condoms are effective in preventing the sexual transmission of HIV infection and can reduce the risk of other STDs (gonorrhea, chlamydia, trichomoniasis). However, because condoms do not cover all exposed areas, they are likely to be more effective in preventing infections transmitted by fluids from mucosal surfaces (e.g., gonorrhea, chlamydia, trichomoniasis, HIV) than in preventing those transmitted by skin-to-skin contact (e.g., HSV, HPV, syphilis, chancroid). Male condom failure usually results from inconsistent or incorrect use rather than condom breakage. Non-latex condoms (those made of polyurethane or other synthetic material) can be used by persons with latex allergy. There is less information available on the effect of female condoms on the incidence of STDs. Although cervical caps and diaphragms cover the cervix, there is little evidence that they can prevent STDs or HIV.

Male Circumcision

Male circumcision reduces mucosal tissue susceptible to HIV and STD pathogens. Circumcision reduces the acquisition of HIV by more than 50% and appears to reduce the acquisition of viral STDs, including HSV-2 and HPV.

Counseling

Counseling is essential for people with STDs. Interactive counseling, video presentations, peer groups, and other formats that emphasize correct condom use have reduced the incidence of subsequent infections among STD clinic patients and adolescents. Randomized controlled trials demonstrate that structured risk-reduction counseling can reduce the incidence of infections by 25 to 40% among some STD clinic populations. HIV testing is preceded by a counseling session, but there is little evidence of a preventive benefit from this communication.

Partner Services

The detection of an STD demands consideration of the infected person's sexual partners, who may have undetected and serious disease. In addition, in the absence of partner treatment, reinfection of the index case can be expected. The probability that a sexual partner is also infected reflects the efficiency of transmission of the STD pathogen, as described earlier. For example, most men with gonococcal urethritis infect their partners, whereas only about half of patients with HIV infection have infected their partners at the time of outreach; partners who differ in terms of STD or HIV infection status are referred to as "discordant."

Sexual partners can be notified directly by the infected person or by health care workers, sometimes through proactive contact tracing. In general, dependence on the infected person is a less reliable way to get partners treated. However, in many states it is legal to pursue expedited care by providing the infected patient with the appropriate treatment for his or her partners. Expedited partner care appears to work well for the treatment of gonorrhea and chlamydia infections.

Pre-exposure Interventions

Pre-exposure vaccination is the most effective method for preventing the transmission of certain STDs. For example, because hepatitis B virus is frequently transmitted sexually, hepatitis B vaccination is recommended for all unvaccinated persons being evaluated for an STD. In addition, hepatitis A vaccine is recommended for men who have sex with men and for drug users (both injection and noninjection). Vaccines for HPV are now available for both females and males.

Antiretroviral agents are in development to prevent HIV acquisition. Topical antivirals are considered "microbicides" and can be used in gel form or as slow-release cervical rings. Oral antiretroviral agents are considered pre-exposure prophylaxis. Clinical trials to evaluate the antiretroviral agent tenofovir or tenofovir plus emtricitabine are in progress.

Post-Exposure Prophylaxis

After consensual or nonconsensual sexual exposure, a variety of STDs can be prevented with empirical antibiotics. Prevention of HIV appears to require several antiretroviral agents that must be used in combination for 28 days.

Contraception

All methods of birth control can influence the acquisition and outcome of an STD. In addition, pregnancy itself (in the absence of effective birth control) affects STD acquisition and the health of the pregnancy and the neonate. Accordingly, STD management demands consideration of the reproductive health of both partners, as well as family planning issues.

TOWARD A COMPREHENSIVE MANAGEMENT STRATEGY

Although most STDs are self-limited and readily treated, the comprehensive and proper management of the patient with an STD requires considerable skill. First, the correct syndrome must be recognized, and a decision about specific diagnostic tests must be made. Second, empirical therapy must be provided and must be sufficiently broad to promise cure or reduced duration of illness. Third, the clinician is obligated to search for other STDs of public health or personal significance. Fourth, the clinician must deal with the patient's sexual partners, through either referral or expedited partner therapy. Fifth, the patient needs counseling and adjunctive preventive measures, where appropriate. Such measures might include vaccination for hepatitis B or HPV or antibiotics to prevent another STD such as incubating syphilis or HIV.

APPROACH TO THE PATIENT BEFORE AND AFTER TRAVEL

PAUL ARGUIN

According to the World Tourism Organization, approximately 700 million international trips are taken each year. This estimate includes travel to and from developed and developing countries and exotic vacation destinations as well as travel for business, government, or humanitarian activities in remote areas of the world. International travelers encompass a wide variety of unique subsets, including children, the elderly, the immunocompromised, missionaries, military personnel, immigrants, and refugees. Some of these subsets of travelers may be particularly vulnerable to certain problems while traveling and may require more specialized counseling. In fact, first- and second-generation immigrants to developed countries who return to their countries of origin to visit friends and relatives have some of the highest risk for acquiring infectious diseases during travel.

PRETRAVEL HEALTH CARE AND RISK ASSESSMENT

Destination country–based recommendations are not applicable to everyone. To determine the best health advice for prospective travelers, the approach should be tailored both to the individual and to the itinerary. Thus, the practice of travel medicine has become a new specialty; its practitioners include primarily physicians in internal medicine, primary care, family medicine, pediatrics, emergency medicine, and occupational health, as well as nurses, physicians' assistants, and pharmacists. These health care providers review the entire itinerary with the traveler to characterize potential risks and exposures along the route. These risks are dependent on the destination city, the style of travel, specific activities, the length of stay, the altitude of the destination, and the season of travel. The underlying health of the traveler is also important. Previous and current medical problems must be considered, as must potential immunodeficiency, current prescription and over-the-counter medications, previous vaccinations, and pregnancy. It is essential to determine whether the traveler has medical conditions that would affect the ability to complete the planned itinerary or would alter any prophylactic measures.

PREVENTION AND RISK REDUCTION

Based on assessment of the risk, travelers should be advised about and provided with appropriate vaccinations, medications for prevention or self-treatment of certain diseases such as malaria and traveler's diarrhea, and prevention counseling about behavioral modifications that can help reduce the risk for injuries, infections, and other adverse health events. Specific advice should include information on hand washing. Hand washing is one of the most important practices in preventing illness from infections at home and while traveling. Travelers should wash their hands often with soap and water or use an alcohol-based hand rub to remove potentially infectious material from the skin and help prevent transmission of diseases. Finally, all travelers should be given some guidance about common over-the-counter items (in addition to their prescription medications) that they should remember to carry with them in their travel health kit: pain relievers and antipyretics, cold and motion sickness medicines, antacids, laxatives, sunscreen, and insect repellent. Unless security regulations demand it, travelers should be told to keep these kits with them at all times and not to place them in checked baggage.

Some primary care providers are comfortable in giving some pretravel health advice and are encouraged to learn the basics. However, patients who have more complicated travel itineraries or multiple medical problems should be referred to a travel health specialist. International travelers should contact health care providers who provide pretravel health advice at least 4 to 6 weeks before departure to obtain vaccinations and prophylactic medications. Travel to developed countries (e.g., United States, Canada, Australia, New Zealand, Japan, and Western Europe) involves lower risk than travel to developing countries. Travelers visiting urban tourist areas and staying in first-class accommodations may also have a lower risk for exposure to infectious diseases. Thus, additional vaccines and protective measures may be recommended for the more adventuresome travelers.

After their pretravel visit but before departure, travelers should continue to assess both their health status and the conditions at their destination. It is advisable for persons to postpone travel if they are not feeling well, particularly if they have febrile illnesses. By delaying travel, persons who are ill avoid potential emergencies and are courteous toward other travelers who may not wish to be exposed to someone with a transmissible illness. Travelers should be aware of the occurrence of any disease outbreaks, natural disasters, political unrest, or other major events at their international destinations. Current travel notices on diseases of international concern are posted on the Travelers' Health home page on the Centers for Disease Control and Prevention (CDC) website at *www.cdc.gov/travel*.

Injury Prevention

Most international travel health guidelines concentrate on the prevention of exotic infectious diseases. However, injuries, especially those caused by motor vehicle crashes, are the leading cause of preventable mortality among travelers. Trauma from motor vehicle crashes accounts for 21 to 26% of travel-associated deaths. Accidents tend to occur more frequently at dusk, in poor weather conditions, at crossroads, while speeding, while passing other drivers, and when the participants are impaired by alcohol consumption. Other factors such as failure to use safety measures, including seat belts and

helmets, contribute not only to increased accidents but also to increased injuries. Travelers should always try to choose safe vehicles equipped with seat belts and use them. If their vehicle has only two wheels, they should always wear a helmet.

Protection against Mosquitoes and Other Arthropods

In addition to being nuisances, the bites of mosquitoes and other arthropods such as ticks can transmit a variety of infectious diseases, many of which are associated with specific travel itineraries (e.g., malaria, dengue fever, Japanese encephalitis, and African tick bite fever). Thus, no matter where they travel, patients should be counseled on avoidance of arthropod bites. Health care providers should remind travelers of some commonsense prevention tips, such as wearing long sleeves and pants, sleeping under an insecticide-treated mosquito net if not in air-conditioned quarters, and using appropriate insect repellents.

For the prevention of malaria, the CDC recommends the use of one of the four insect repellents approved by the U.S. Environmental Protection Agency; these are DEET (*N,N*-diethyl-*m*-toluamide), picaridin, oil of lemon eucalyptus, and IR3535. The efficacy and duration of protection are affected by factors such as temperature, perspiration, exposure to water, and abrasive removal. In general, higher concentrations of the active ingredients in these repellents provide longer duration of protection. Products with 10% or less of the active ingredient may offer only limited protection, often from 1 to 2 hours. However, products that offer sustained release or controlled release (i.e., microencapsulated) formulations may provide longer protection times. Note that DEET efficacy tends to plateau at about 50%, so higher concentrations are not recommended. Regardless of what product is used, if travelers start to get mosquito bites, they should reapply the repellent according to the label instructions or leave the area with biting insects if possible.

To avoid overexposure to the repellents, these products should be applied only to exposed skin, not under the clothing. They should not be applied to mucous membranes or sprayed in enclosed spaces. Parents should also apply the repellent to young children rather than allowing them to do it themselves. In addition, certain insect repellents, such as those containing permethrin, are recommended for use on clothing, shoes, bed nets, and camping gear. Permethrin-treated clothing repels and kills ticks, mosquitoes, and other arthropods and retains this effect after repeated laundering, but it should be reapplied after every five washings.

Immunizations

Immunizations for international travel can be categorized as routine, recommended, and required (Table 294-1). Routine vaccinations are childhood and adult vaccinations recommended for all persons regardless of travel. Recommended vaccinations are those that are prescribed according to the traveler's risk for infection. Required vaccinations are those needed to cross international borders, as required by international health regulations or specific countries. The specifics of vaccine administration are provided in package inserts and should be consulted before giving any vaccine. It is the responsibility of the health care provider to ensure that travelers are not allergic to any of the vaccine components. Multiple vaccines may be given at the same time at different sites, depending on patient tolerance. Live-virus vaccines should be administered simultaneously or at a 4-week interval to avoid immune interference.

TABLE 294-1 VACCINATIONS THAT MAY BE INDICATED FOR TRAVELERS*

ROUTINE VACCINES: RECOMMENDED REGARDLESS OF TRAVEL	
Tetanus, diphtheria, and pertussis (Td or Tdap)	Every 10 years; substituting a tetanus and diphtheria toxoid and acellular pertussis (Tdap) booster once for the next Td booster is now recommended as well
Measles, mumps, and rubella (MMR)	Persons without two documented doses if born after 1956
Varicella	Persons without evidence of previous infection or vaccination
Human papillomavirus	Females between the ages of 11 and 26 years
Pneumococcal	Older and chronically ill persons if not already appropriately vaccinated
Varicella-zoster virus	Persons 60 years of age and older
RECOMMENDED VACCINES: PRESCRIBED IF TRAVEL POSES AN EXPOSURE RISK	
Hepatitis A	First dose before travel to developing countries; second dose 6 to 12 months later
Hepatitis B	Three dose series for those with indications or at risk for exposure
Influenza	Travel at any time during the year, especially to tropical latitudes
Japanese encephalitis	Travel to rural southern and eastern Asia with extensive outdoor exposure
Meningococcal disease	Travel to the sub-Saharan meningitis belt during the dry season or to areas experiencing outbreaks
Poliomyelitis	Single adult booster for travel to countries where disease is present or where outbreaks have recently occurred
Rabies	Travel to countries where rabies is common and exposure to animals is anticipated
Typhoid fever	Travel to developing countries
Yellow fever	Travel to yellow fever–endemic zones in sub-Saharan Africa and South America, unless contraindicated (older age, thymus disease)
REQUIRED VACCINES: REQUIRED BY INTERNATIONAL HEALTH REGULATIONS OR SPECIFIC COUNTRIES TO CROSS INTERNATIONAL BORDERS	
Meningococcal vaccine	Travel to Saudi Arabia during Hajj and Umrah pilgrimages
Yellow fever	Travel to countries where vaccination is required by international health regulations unless waived for medical contraindications by an official vaccine provider; primary dose at least 10 days before departure, administered by a World Health Organization Yellow Fever Vaccinating Center and documented on the international certificate of vaccination to be carried by the traveler

*Vaccine recommendations continue to evolve, so always check http://wwwnc.cdc.gov/travel for the most current advice for travelers and other information about indications, contraindications, dosing, and side effects.

Routine Immunizations

A consultation before travel is an excellent opportunity to update routine immunizations, especially because adults are often not up to date on these. The CDC recommends that most adults have a tetanus and diphtheria toxoid (Td) booster vaccine every 10 years; have two recorded doses of measles, mumps, and rubella (MMR) vaccine (if born after 1956); and have evidence of previous varicella infection or vaccination. Finally, the pretravel visit is also a great opportunity to provide additional routine vaccines such as pertussis (Tdap), human papillomavirus (HPV), varicella-zoster virus, and pneumococcal vaccines to patients for whom these vaccines would be recommended but have not yet received them from their primary care providers.

Recommended Immunizations

Hepatitis A

Hepatitis A (Chapter 150), transmitted through contaminated food or water or intimate contact with another infected person, is one of the most frequently reported vaccine-preventable, travel-related illnesses. In 2006 in the United States, among cases for which information regarding exposures during the incubation period was collected, the most frequently identified risk factor for hepatitis A was international travel (reported by 15% of case-patients overall). Although not usually fatal, acute hepatitis A infection can result in weeks of lost work time and early repatriation of travelers. The hepatitis A vaccine is indicated for most travelers to the developing world unless they are known to be immune. One dose should be administered before travel; a second dose 6 to 12 months later increases protection to long term. Before the introduction of hepatitis A vaccine, immune globulin injections were used to provide short-term protection against hepatitis A. They are still recommended for children younger than 1 year.

Hepatitis B

Hepatitis B (Chapter 150) is transmitted through infected blood and body fluids, has a case-fatality rate of 1%, and can result in chronic infection in up to 5% of adults. Almost one fourth of international travelers have pretravel indications for hepatitis B vaccine, including occupational risk for exposure

to blood and body fluids or a history of a recent sexually transmitted disease, and 10% of travelers experience exposures that would be categorized as high risk for hepatitis B infection during travel. However, less than one third of persons who should be immunized against hepatitis B receive the full three-dose series before travel. Travelers should be advised to avoid behavior that is high risk for the acquisition of hepatitis B, although it is clear that it is difficult to identify travelers at risk during the pretravel encounter. Travelers going to areas with intermediate to high levels of endemic hepatitis B transmission should receive the three-dose series. The usual schedule for this vaccine is a dose at 0, 1, and 6 months, which is often difficult to complete for last-minute travelers. There are also accelerated schedules with doses at 0, 7, and 14 days; however, these have not been approved by the U.S. Food and Drug Administration. The CDC recommends that persons who receive vaccinations on an accelerated schedule also receive a booster dose 6 months after the start of the series to promote long-term immunity. A combination vaccine that provides protection against hepatitis A and B infections is also available.

Influenza

Recently, the influenza situation has become more complicated. It is no longer appropriate to consider this a single entity with a single set of prevention recommendations for travelers. Consideration should be given to the prevention of seasonal influenza, the long-standing clusters of H5N1 avian influenza, and pandemic influenza such as the H1N1 novel influenza A that emerged in 2009. Seasonal influenza tends to circulate predominantly in the respective winter months in the Northern and Southern hemispheres and year round in the tropical latitudes. Thus, all travelers, especially those at high risk for complications, should be considered candidates for seasonal influenza vaccination. Travelers visiting areas with active outbreaks of H5N1 avian influenza are advised to avoid direct contact with live birds, particularly in venues such as farms or live bird markets. In the event of a circulating pandemic influenza virus, specific and rapidly evolving guidance on appropriate prevention measures will be promulgated by national and international health authorities, including recommendations on vaccination.

Japanese Encephalitis

Japanese encephalitis (Chapter 391) is transmitted by infected mosquitoes in rural parts of southern and eastern Asia. Travelers to endemic areas who will have extensive rural outdoor exposure, such as campers and hikers, should consider receiving this vaccination series and be very vigilant in their mosquito avoidance measures. For persons 18 years and older, a new two-dose cell culture–derived vaccine has become the standard. For persons younger than 18 years, the three-dose inactivated mouse brain–derived vaccine is still available.

Meningococcal Disease

The sub-Saharan African "meningitis belt," which extends from Mali to Ethiopia, experiences increased rates of transmission of *Neisseria meningitidis* (Chapter 306) regularly during the dry season, which is usually December through June. Travelers to an area where there is an ongoing outbreak of meningococcal disease and those traveling to the meningitis belt of sub-Saharan Africa during the dry season should receive one of the two quadrivalent (A, C, Y, and W-135) meningococcal vaccines that are currently available: the polysaccharide and the conjugate vaccine.

Poliomyelitis

The global polio eradication effort has reduced the number of countries with ongoing transmission to just a few, specifically, Afghanistan, Pakistan, India, and Nigeria. However, occasional outbreaks of polio (Chapter 423) still occur in countries that had previously eradicated it. A single adult booster for polio is recommended for travel to all of these countries.

Rabies

Rabies is a fatal disease transmitted by the bite of infected mammals; however, effective prevention strategies are available. The three-dose preexposure vaccination series is indicated for persons with a higher likelihood of encountering animals such as stray dogs in countries where both rabies transmission is known to occur and access to antirabies biologics, including human rabies immune globulin and cell culture–produced vaccines, may not be available. Travelers who will be spending extended periods outdoors, such as hikers, spelunkers, and small children, are examples of persons who may be at higher risk for rabies. Health care providers should counsel travelers on appropriate behavior around stray, wild, or domesticated animals not known to be vaccinated against rabies to try to prevent rabies exposure. Travelers should always avoid contact with these animals and not feed or pet them. In the event of an animal bite, all travelers should be instructed to seek appropriate rabies postexposure prophylaxis. Previously unimmunized persons will need to receive the full postexposure regimen, including vaccine and rabies immune globulin. It is important to realize that persons who received the preexposure series still need two booster doses of rabies vaccine if they are bitten by a rabid animal. Health care providers should be strongly discouraged from deviating from these established preexposure and postexposure regimens in an attempt to reduce costs or for the convenience of the traveling patient.

Since 2007, the United States has been experiencing a limitation in the supply of rabies vaccines. To ensure sufficient availability of vaccine for postexposure use, preexposure vaccine has not been available to international travelers. Thus, there should be increased emphasis on educating travelers on the importance of animal bite avoidance and the correct steps to take if they are exposed to rabies while traveling.

Typhoid Fever

Annually in the world, 22 million cases of typhoid fever result in 200,000 deaths (Chapter 316). In the United States, approximately 400 travel-associated cases are reported each year, mostly among travelers visiting friends and relatives and returning from their home countries. Although typhoid fever is a treatable bacterial infection, prevention is preferable because of increasing rates of antibiotic resistance. Travelers to certain developing countries should be vaccinated against typhoid fever with either of the two types of typhoid vaccine: the live oral vaccine (Ty21a) or the inactivated injectable vaccine (Vi capsular polysaccharide).

Yellow Fever

Yellow fever (Chapter 389) is transmitted by the bite of infected mosquitoes in sub-Saharan Africa and tropical South America, where it is endemic and intermittently epidemic. All persons traveling to the yellow fever–endemic zones without contraindications should be vaccinated with the live viral vaccine. In rare but severe instances, yellow fever–like syndromes develop from the attenuated live vaccine virus; these adverse events are characterized as either viscerotropic disease or neurotropic disease. Being older than 60 years and having a history of thymus disease have been identified as independent risk factors for development of one of these severe but rare adverse events. Persons with contraindications should reconsider their travel itinerary. If they choose to travel to yellow fever–endemic areas despite contraindications, they should be very vigilant in their mosquito avoidance measures.

Required Immunizations

Meningococcal Meningitis

Vaccination against meningococcal disease is not a requirement for entry into any country except Saudi Arabia for travelers to Mecca during the annual Hajj and Umrah pilgrimage.

Yellow Fever

In addition to vaccination for protection of the traveler, yellow fever vaccine may be required by some countries as a condition of entry, as outlined in the International Health Regulations. Vaccination becomes valid for the purpose of entry 10 days after primary inoculation, and it must be administered at an approved World Health Organization Yellow Fever Vaccinating Center. Receipt of the vaccine must be documented on an international certificate of vaccination that should be carried with the passport. A national registry of such providers in the United States is available on the CDC website at *wwwnc.cdc.gov/travel/yellow-fever-vaccination-clinics-search.aspx*. Persons for whom the vaccine is contraindicated should be issued a vaccination waiver letter bearing the official yellow fever vaccine provider stamp.

Malaria Protection

As many as 30,000 travelers from industrialized countries acquire malaria annually (Chapter 353). On average, 1400 cases of malaria (including about four fatalities) are diagnosed in the United States and reported to the CDC each year. The CDC also maintains a country-by-country listing, often with regional- or subcountry-level recommendations for malaria prevention. All travelers to malaria-endemic countries should be counseled to avoid mosquito bites by the appropriate use of repellents and insecticide-treated

mosquito nets. An individual risk assessment should be conducted for every traveler, taking into account not only the destination country but also the detailed itinerary, including specific cities, types of accommodation, season, and style of travel. In addition, conditions such as pregnancy or the presence of antimalarial drug resistance at the destination may modify the risk assessment. Depending on level of risk, it may be appropriate to recommend mosquito avoidance measures only, or mosquito avoidance measures plus chemoprophylaxis. Depending on the destination, there are usually several medication options so that travelers who may not have tolerated one type of medication in the past because of unpleasant side effects can still be prescribed one of the others. For travel to areas with predominantly *Plasmodium vivax*, primaquine can be used for primary prophylaxis (provided that the person does not have glucose-6-phoshate dehydrogenase deficiency). For travel to areas of risk where chloroquine-resistant malaria has *not* been reported, chloroquine can still be used. For areas with chloroquine resistance, the CDC currently recommends mefloquine, doxycycline, or the combination of atovaquone and proguanil as equal alternatives. The choice of one or the other is usually based on the side effects, cost, and duration of the trip.

Travelers should also be warned about trying to acquire malaria medications while overseas, either for reasons of cost or for convenience. Medicines with similar-sounding names, such as Malarone, Malasone, or Maloprim, do not contain the same active ingredients. In addition, counterfeit medicines that contain either smaller amounts or none of the active ingredient stated on the box are increasingly prevalent in many developing countries. Travelers should also be counseled to be alert for symptoms consistent with malaria after returning and to seek prompt evaluation and treatment if indicated.

Traveler's Diarrhea

A diarrheal illness develops in about 50% of travelers to developing countries, with an average duration, if untreated, of approximately 4 days. All travelers should be instructed on ways to avoid illnesses transmitted through food and water. Although diarrheal illness is sometimes very difficult to avoid, travelers should be taught when possible to make safer choices to reduce the chance of acquiring a food-borne or waterborne illness. They should avoid tap water or ice made with tap water in favor of beverages that have been boiled or placed in sealed containers, such as bottled water or carbonated items. Selecting foods freshly prepared rather than eating from communal vessels or buffets is also a safer choice.

Frequently, despite the best efforts, diarrhea occurs, and travelers should be taught how manage the situation by drinking abundant fluids to avoid dehydration and by trying to manage symptoms with over-the-counter medications such as bismuth subsalicylate or loperamide. The current standard of care also includes prescribing an antibiotic for the traveler to carry—not to take to prevent diarrhea, but rather to have readily available for use when needed to treat a moderate to severe case of diarrhea acquired while traveling. Fluoroquinolone antibiotics are generally used for self-treatment of diarrhea, although azithromycin is now also being used for travel to areas with high rates of antibiotic resistance (e.g., parts of Southeast Asia) and for treatment of children and pregnant women.

POST-TRAVEL CARE

Travelers may be exposed to a variety of pathogens and risks, both exotic and mundane. Approximately half of all travelers will experience some health problems while traveling. Overall, during international travel, 5 to 8% of travelers seek medical attention, some requiring emergency medical evacuation. Health care providers who see returned travelers should be aware that most ailments diagnosed during the post-travel period are not necessarily travel related. However, providers should also be able to recognize important syndromes in returned travelers that may be travel related and require prompt treatment or referral for definitive management. A thorough history, including a review of the travel itinerary and specific exposures (e.g., insect bites, unprotected sexual contact, and consumption of untreated water), is an essential first step. The most frequent health problems in ill returned travelers are chronic diarrhea, rashes, and respiratory infections. Although gastrointestinal ailments are the most frequent problem, fever is the most serious. Fever in a traveler who has recently returned from a malaria-endemic region should be immediately evaluated so that antimalarial treatment can be initiated rapidly if indicated. Finally, certain long-term travelers should be evaluated by a travel or tropical medicine specialist when they return to screen for conditions that may be asymptomatic, such as schistosomiasis or strongyloidiasis.

ANTIBACTERIAL CHEMOTHERAPY

GEORGE L. DRUSANO AND WILLIAM A. CRAIG

Antibiotics have been classified as "miracle drugs" since their introduction and have transformed our expectations regarding the outcome of infection. More recently, they have been the backbone of modern interventional medicine. Barriers not meant to be breached have been. Catheters have been inserted into veins and arteries, the bladder, and the tracheal tree. These interventions support the seriously ill patient, but they also give bacteria access to normally sterile areas. Therapies for cancer and immune-mediated disease often leave patients severely immunosuppressed. Bacterial infections in such patients are serious and, when untreated or treated late, frequently result in death. Antibacterial agents allow critical life-saving support for such patients.

What is clear is that the overuse and poor use of antibiotics have allowed many pathogens to develop resistance to drugs. Multiresistant *Staphylococcus aureus* has become a plague both in the hospital and, of late, in the community. Extended-spectrum β-lactamases and *Klebsiella pneumoniae* carbapenemase enzymes have mediated resistance to many of our most potent and broad-spectrum β-lactam agents, including the carbapenems. Consequently, it is important to understand the principles of antibacterial chemotherapy to obtain the best clinical outcomes for our patients but also, in a broader sense, to lower the probability of the emergence of resistance and maintain the potency of the drugs we currently have in our therapeutic armamentarium.

CHOICE OF ANTIBIOTIC, ANTIBIOTIC DOSE, AND SCHEDULE TO OPTIMIZE CLINICAL OUTCOME

As in all of clinical medicine, a well-done history and physical examination are central to proper decision making and to the achievement of optimal therapeutic outcomes in patients with infections. Key to choosing the correct drug, dose, and schedule is recognition that an infection exists. The next step is to document where the infection exists, and then to identify the dominant organisms present at each site of infection. The next step is to determine whether there are any risk factors that might predict the presence of drug-resistant pathogens.

As an example, we know that community-acquired pneumonia is caused by certain traditional pathogens. *Streptococcus pneumoniae, Haemophilus influenza,* and perhaps *Moraxella catarrhalis* are the "classic" bacterial pathogens associated with this entity. "Atypical" pathogens such as *Legionella* species, *Mycoplasma pneumoniae,* and *Chlamydophila pneumoniae* may also be seen. In contrast, intra-abdominal infections are dominated by *Escherichia coli* and other Enterobacteriaceae and anaerobic organisms such as *Bacteroides* species. Consequently, it is important to understand the dominant pathogens present at different infection sites so that the best drug or combination of drugs can be chosen to treat the infection.

Knowing the source of infection is also critical because drugs penetrate differently into different spaces. Classically, penetration is poorer into spaces

TABLE 295-1 PRIMARY INFECTION SITES AND THE DOMINANT BACTERIAL SPECIES PRESENT

SITE	BACTERIA
Complicated skin/skin structure infection	*Staphylococcus aureus* and *Streptococcus* spp
Diabetic foot ulcer	Organisms above plus Enterobacteriaceae
Intra-abdominal infections	*Escherichia coli* and other Enterobacteriaceae plus anaerobes
Community-acquired bacterial pneumonia	*Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis,* "atypical" pathogens
Hospital-acquired pneumonia	*S. aureus, Klebsiella pneumoniae, Enterobacter* spp, *Pseudomonas aeruginosa, Acinetobacter* spp
Meningitis	*S. pneumoniae, H. influenzae* (nontypable), meningococci; in hospital settings, *S. aureus* and gram-negatives may be seen
Urinary tract infections	Enterobacteriaceae, particularly in sexually active women; multiresistant gram-negatives in patients with complicated urinary tract infections or those instrumented; enterococci, particularly in elderly men
Prostatitis	Enterobacteriaceae, enterococci, atypical pathogens

where there are tight junctions, such as the central nervous system, the eye, and the prostate. Generally, the penetration of many classes of antibacterial agents is quite good into complicated skin and skin structure infection sites. What is often not appreciated is the divergent penetrations of different agents and even agents within the same class into the lung to treat bacterial pneumonia. For instance, the penetration by macrolide antibiotics into skin infection sites is modest, but their penetration into the lung is quite good, with penetration ratios (area under the concentration-time curve [AUC] in epithelial lining fluid/AUC in plasma) ranging from 4 to 20. The penetration of β-lactam drugs can range from 15 to 100%, but there is no set of variables (at least to date) that explains such a range of penetrations. Table 295-1 presents a partial list of infection sites and their dominant pathogens. The point is not to have an encyclopedic knowledge of infection sites or of pathogens but to appreciate that different infection sites require different drugs to provide adequate coverage for the most likely pathogens present.

It is also important to understand other factors that increase the probability that a resistant organism is present at the primary infection site. An example is a patient who has recently taken antibiotics before acquiring the present infection. Other examples are the acquisition of an infection in the hospital or in an extended care facility or in a patient who is immunosuppressed. In such patients, the choice of antimicrobial agents must be carefully considered to cover more resistant pathogens.

CULTURE AND GRAM STAIN

Once the site of infection has been definitively identified or the most likely source of infection has been determined, it is critical to obtain cultures from that site as well as to obtain blood cultures. Coordination with the microbiology laboratory is key to make sure that culture specimens are handled appropriately. Also of great importance is the performance and interpretation of a Gram stain on the specimen. This can be straightforward if the specimen is from a normally sterile space, or it may require considerable skill in interpretation if the specimen is from an area where mixed flora is normally present, such as sputum.

Although it is not possible to make a definitive diagnosis based on the cellular morphology of the organism, it is quite possible to combine information on the morphology, the organism's gram positivity or negativity, the infection site, and the most likely pathogens to make an initial antimicrobial choice with the highest probability of producing effective chemotherapy. It should be noted that the initial antibiotic chosen to cover organisms present at the primary infection site has a significant influence on the outcome of therapy. Initial choices should err on the side of caution. When definitive cultures are available, the chemotherapy can be "streamlined" to provide the most effective and least toxic antimicrobial for the patient. As the seriousness of the infection increases, providing the correct initial coverage becomes more important with regard to the ultimate outcome.

SUSCEPTIBILITY

Because infections occur at a specific place, it is important to have an understanding of the antimicrobial susceptibility patterns in one's particular hospital. Most frequently, the microbiology susceptibility patterns are different in the cultures taken from patients on the general wards as opposed to those in intensive care units (ICUs), because the former are generally (but not always) infected with pathogens derived from the community setting. In severely infected patients, particularly those whose infections were acquired in the ICU, it is critical to know the susceptibility patterns for these pathogens, which are likely to be multiply resistant to different classes of agents.

After the definitive culture, the identified pathogen must be examined in an antimicrobial susceptibility test. This can be automated, in which case the information returned is the minimal inhibitory concentration (MIC), or it can be reported from a disc diffusion test, where the results are typically reported as "S" (susceptible), "I" (intermediate), or "R" (resistant). The MIC is often misunderstood as the concentration of drug that prevents the pathogen from growing, but it is actually the concentration of drug that allows a tube (or well) containing the pathogen to remain clear by visual examination after 18 to 24 hours. If one starts with an organism concentration of 1 to 5×10^5 colony-forming units (CFUs)/mL, this criterion can actually allow almost a 1 $\log_{10}$ (CFU/mL) increase in bacterial count over this time frame and still be read as the MIC. With all its limitations, the MIC provides critical information regarding drug choice. For several infections, such as meningitis, endocarditis, and perhaps bacteremia, knowing the minimal bactericidal concentration (defined as the concentration required to kill 99.9% of organisms over 18 to 24 hours) is valuable. In these cases, it is important to obtain multilog killing of the organism to ensure a high probability of a good clinical outcome. For meningitis and endocarditis, there is also the confounding problem of penetration of the drug to the primary infection site. In other circumstances (e.g., ventilator-associated pneumonia) in which bacterial burdens are very high, optimizing the probability of cure requires highly bactericidal therapy.

DETERMINING THE "CORRECT" DRUG DOSE

The correct drug dose is the one that produces a high likelihood of achieving a good clinical response with a low probability of causing a concentration-driven adverse event. Another consideration is that the optimal dose should have a high probability of suppressing the emergence of resistant mutants. To be confident that a drug dose has a high likelihood of producing a good clinical outcome requires an understanding of the relationship between the measure of drug exposure and infection outcome—that is, pharmacodynamics (Chapter 28).

When we administer a drug either intravenously or orally, the drug concentration starts low, increases to a maximal value, then declines over time until another dose of the drug is given (in a multidose regimen). This drug concentration–time profile should be seen relative to a measure of drug potency against the pathogen in question: the MIC (or minimal bactericidal concentration). It is also critical to note that protein binding is important because in almost all cases, it is the free or non-protein-bound drug that kills the causative pathogen. So understanding the pharmacodynamics of a drug or class of agents first requires knowledge of the concentration-time profile, protein binding, and MIC (Fig. 295-1). For drugs that kill organisms much faster as their concentrations rise (e.g., fluoroquinolones, aminoglycosides), the free drug AUC/MIC ratio is most closely linked to drug effect. For other drugs (e.g., penicillins, carbapenems, cephalosporins, monobactams), the rate of organism kill rises slowly with concentration and plateaus quickly, in which case the free drug time greater than MIC is most closely linked to drug effect. Occasionally, the free drug peak concentration/MIC ratio is linked to drug effect. This is seen when there is a rapid and frequent emergence of resistance and the peak concentration helps suppress the amplification of resistant mutant subpopulations.

These measures of drug exposure need to be linked to drug effect. There are a number of ways to do this, but two are most common. In the first and most valuable way, patients are studied during the course of a clinical trial. Multiple plasma samples are taken for documentation of the drug's pharmacokinetics and corrected for protein binding. The MIC of the infecting pathogen is determined for the drug being administered, and the three measures of drug exposure cited earlier are calculated. The outcome of the patient is then determined (usually success or failure, but in some instances, time to success or failure serves as the outcome measure). If the outcome is success or failure, the appropriate measure of drug exposure is linked to the outcome

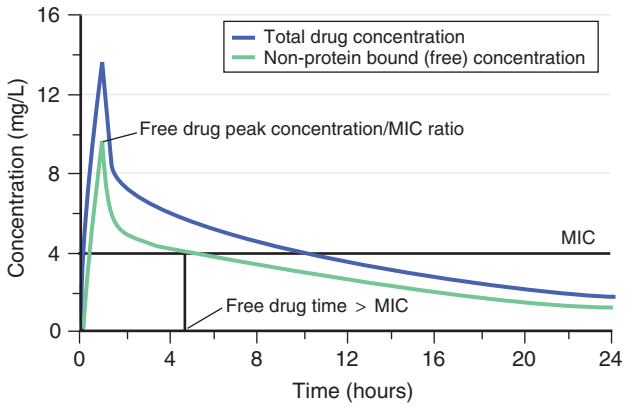

FIGURE 295-1. Three measures of drug exposure are important to the measure of potency, or the minimal inhibitory concentration (MIC). Free drug peak concentration/MIC ratio, free drug time greater than MIC, and free drug area under the curve (AUC)/MIC ratio.

through logistic regression analysis. By creating such a relationship, we can directly estimate the probability of a patient having a successful outcome if a certain measure of drug exposure is achieved. For example, if a patient receiving a drug that is a concentration-dependent killing agent achieves a free drug AUC/MIC ratio of 88, the logistic regression relationship allows the calculation that the probability of a good outcome is a specific number (perhaps 91%). Over the past 10 years, we have been able to generate such relationships for a great number of drugs and across drug classes. The most common relationships are for the fluoroquinolone antimicrobials, but examples can be found for the aminoglycosides, oxazolidinones, β-lactams, and glycylcyclines, among others.

The second way to link exposure to antibacterial effect is through preclinical animal models of infection. Here, the end point is microbiologic. We observe the drug concentration–time profile in the animals and at the end of the experiment determine the number of organisms left after therapy at the infection site (the baseline number of organisms having been previously determined). We can then link the measure of drug exposure (as earlier) to the number of bacterial cells killed by a specific regimen. In this way, we can determine whether free drug peak concentration/MIC ratio, free drug AUC/MIC ratio, or free drug time greater than MIC is the best measure of drug exposure for the class of drug being studied.

How does knowing the relationship between drug exposure and microbiologic effect in an animal infection model help in treating patients? Based on experience with different drugs and drug classes, it has become possible to link a drug's microbiologic effect in an animal model to clinical outcome. For instance, in the therapy of complicated skin and skin structure infections, a drug exposure in the animal model that stops organisms from growing for 24 hours or reduces their number by approximately 1 $\log_{10}$ (CFU/g) is adequate to generate a high probability of a good clinical outcome. This has been documented for oxazolidinones and glycylcyclines. For severe community-acquired pneumonia or for hospital-acquired pneumonia, a greater cell kill—generally 2 $\log_{10}$ (CFU/g)—is required for a high likelihood of a good clinical outcome.

Thus, when we have clinical data with a logistic regression function, it is possible to identify an exposure target that is associated with a specific probability of a good outcome (e.g., a free drug AUC/MIC ratio of 88 generates a 91% probability of a good outcome). In the case of the animal model, it is possible to identify a target drug exposure that will achieve a certain microbiologic effect associated with a good clinical outcome (the logic is one step removed). In both cases, we have a target drug exposure, and this is used to identify the "correct" dose.

It is important to remember that when the same dose of a drug is administered to a number of patients, no two concentration-time curves will be identical. Indeed, it is not unusual to have a 10-fold range in measures of drug exposure (e.g., peak concentration, trough concentration, AUC). When these are transformed by incorporating MIC values, ranges of 100- to 1000-fold are commonly encountered. As part of the drug development process, the pharmacokinetics of new agents are now identified in a large number of patients with the infection of interest. As part of this process, the interpatient variability in important pharmacokinetic parameters (e.g., drug clearance = 10 ± 4 L/hour) is determined. This information is then used with a tool called the Monte Carlo simulation to ask and answer a key question: If I give this specific drug dose to a large number of patients and I recognize that the MIC values I am likely to encounter will range (for example) between 0.06 and 8 mg/L, how many patients will achieve the desired measure of drug exposure to give them a high likelihood of a good clinical outcome? This can be calculated directly from the data indicated earlier plus the MIC distribution for the drug and the type of infection one wishes to treat. Indeed, many of the dosage recommendations for new drugs are calculated in this manner and validated in large phase III clinical trials. It provides the clinician with a degree of confidence that the recommended doses are likely to work if the infecting pathogen is still susceptible to the drug.

EMERGENCE OF RESISTANCE

If the drug is properly chosen, the organism should have a high probability of being susceptible to it. However, during the course of therapy, the organism has many mechanisms available to make it less susceptible (the MIC increases) to the drug being used. This leads to less effect than was originally envisioned, which results in a lower probability of cure.

When are organisms likely to become resistant? There are many determinants, but five factors account for the majority of cases of resistance emerging during therapy. The first is the mutational frequency of the organism being treated. Because mistakes are made by the organism during replication, mutations occur in the genome at a specific rate, which is organism dependent. For antibiotic resistance, the mutational frequency rate is generally around $1/10^8$ to $1/10^6$. There are organisms, however—referred to as hypermutators—that have mutations in other places in the genome (often mutS) that alter their DNA replication error-checking mechanisms. These organisms' mutational frequencies are generally 10- to 100-fold higher than those of organisms without these other mutations.

The second factor is related to the bacterial burden. The higher the bacterial burden, the more likely it is that a preexistent mutant is already extant in the bacterial population. Antibiotic pressure then provides this mutant with a selective advantage, and it amplifies in the population while its more susceptible cousins are killed by the antibiotic. As the bacterial burden increases and ultimately surpasses the inverse of the mutational frequency to resistance, it becomes more and more likely that a resistant mutant exists in the population. For instance, if the mutational frequency to resistance is $1/10^7$ (1 resistant organism per a population of 10^7), and the patient has a bacterial infection in which the total bacterial burden is 10^9 organisms, it is highly likely that a resistant organism is present in the population a priori. A calculation of the actual probability can be performed using a Poisson distribution, the bacterial burden, and the mutational frequency to resistance. Consequently, infections in which the bacterial burden is high are more likely to generate resistance during therapy. For example, in clinical trials of ventilator-associated pneumonia, single-agent β-lactam drugs or fluoroquinolones allowed the emergence of resistance during therapy 33 to 50% of the time.

The third issue is drug penetration. There are circumstances (e.g., empyema) in which the bacterial burden is high but the drug's penetration to the infection site is reduced. In this case, the emergence of resistance is more likely. In contrast, poor penetration with relatively low bacterial burdens (e.g., meningitis) generally does not result in a high probability of the emergence of resistance.

The fourth issue has to do with error-prone replication in bacterial pathogens. When resistance occurs relatively late in therapy and the bacterial burden is modest, error-prone replication is often to blame. Antibiotics differ greatly with respect to their ability to induce the bacterial isolate to perform error-prone replication. Perhaps the best example is the fluoroquinolone antimicrobials, because these drugs strike at the heart of DNA replication. The organism senses the attack of the antibiotic, and a whole cascade of events takes place, the most important of which is the induction of error-prone polymerases (e.g., pol V). These polymerases markedly increase the error rate in DNA replication. Most of these errors are lethal to the organism and therefore unhelpful to it. But because this is a totally random process, by chance, a mutation can occur in a spot that provides protection from the onslaught of the antibiotic (e.g., a mutation in the DNA gyrase when the patient is receiving a fluoroquinolone). We perceive this as the organism having a selective replication advantage (emergence of resistance), and we see an increase in the MIC of the mutant organism relative to the baseline organism.

The fifth factor has to do with mechanisms other than antibacterial target site mutations that allow the organisms to survive in the face of appropriate

antibiotic chemotherapy. One extremely common mechanism seen in the vast majority of both gram-positive and gram-negative organisms is the upregulation of efflux pumps. These pumps are quite indiscriminate in their ability to pump molecules; they can eject multiple classes of antibacterials from the organism, as well as natural substances that can harm it. These pumps keep drug concentrations at their target sites much lower than they would be in the absence of the pumps. The pumps can be induced and then downregulated once the threat has passed, or occasionally, the organism can pick up a mutation in the part of the genome where the pump is expressed, so the pump is always expressed (constitutive expression).

A similar process is seen with the production of β-lactamases. Often, these enzymes are situated on plasmids and are produced all the time. Sometimes, as with the efflux pumps, they sense the attack by the β-lactam, and their production is markedly increased (the phenomenon of induction, seen with ampC-type enzymes, which reside on the chromosome). Sometimes, also like the pumps, the organisms pick up a mutation in the part of the genome that regulates production of the β-lactamase. This is referred to as stable derepression, and the enzyme is made all the time. The enzyme hydrolyzes its substrate (the β-lactam drug), thus preventing its binding to the target sites, the β-lactam binding proteins.

Finally, in gram-negative organisms, the drug must cross the diffusional barrier of the outer membrane before binding to β-lactam binding proteins (if the drug is a β-lactam) in the periplasm of the organism, or it must cross the inner membrane if its target site is actually inside the organism. For many agents, particularly those that are water soluble, a large percentage of their influx is due to passage through porin proteins. These proteins are water-filled channels that pass through the entirety of the outer membrane of gram-negative bacteria. Part of their function is to provide access to nutrients for the organism and allow the easy diffusion of waste products. These channels are also used to obtain passage by water-soluble antibacterial agents. The organism has the ability to downregulate these channels, either temporarily or permanently (by mutation). An example is *Pseudomonas aeruginosa*, in which downregulation of the porin channel oprD markedly diminishes the penetration of carbapenem antibiotics (β-lactam agents), with a resultant two- to eight-fold rise in MIC. With all these mechanisms that can be brought to bear, it is no surprise that poor dosing and prolonged courses of therapy often lead to the emergence of resistance.

These mechanisms also interact. In the case of fluoroquinolone antimicrobials, where error-prone replication almost always occurs under pressure, the upregulation of efflux pumps relieves some of the antibiotic pressure, allowing the organisms to undergo more rounds of replication per unit of time, giving the error-prone replication mechanism more time to find a mutation that is not lethal and provides protection against the drug at the primary target site.

SUPPRESSING THE EMERGENCE OF RESISTANCE

Suppressing the emergence of resistance is an end point that is different from achieving a good clinical or microbiologic outcome. It should be recognized that the antimicrobial exposure (free drug peak concentration/MIC ratio, free drug AUC/MIC ratio, or free drug time greater than MIC) necessary to suppress resistance is always at least as high as that required to attain maximal killing of bacterial cells, and in the vast majority of instances, it is substantially higher.

Recently, it has been shown experimentally that it is possible to identify doses and schedules of drugs that suppress the emergence of resistance as well as provide optimal killing of bacterial cells. Unfortunately, many of the exposures necessary to achieve such an outcome are high enough to result in increased drug toxicity. Nevertheless, as new agents are developed, it will become important to identify resistance-suppressive exposures and ascertain whether they are too toxic to be used clinically, as a way of retaining the potency of the antibacterial therapeutic armamentarium.

The other way to help suppress the emergence of resistance is to employ combination chemotherapy. Combination therapy has major advantages, but there are significant disadvantages as well. Among the advantages are that combination therapy can improve the spectrum of coverage in the setting of empirical treatment, as well as help suppress the emergence of resistance. This is best seen in the treatment of *Mycobacterium tuberculosis*, although there is growing evidence that this may also be true for difficult-to-treat pathogens such as *P. aeruginosa* and *Acinetobacter* species. Combination therapy can be effective against some pathogens in serious infections for which a single agent would not be adequate. Enterococcal endocarditis is the classic example: Ampicillin or vancomycin is generally static and not up to the task of curing this disease, and the second agent (an aminoglycoside, streptomycin, or gentamicin) is somewhat resistant when used alone (MIC values <500 mg/L). Yet the combination produces excellent bacterial kill in the endocarditic vegetation, with a high probability of cure if the patient can tolerate the combination for the requisite period of time. Some authors have discussed reducing drug doses in combination as a way of ameliorating toxicity, but this theoretical advantage is difficult to demonstrate convincingly in the clinical setting.

The disadvantages of combination therapy are also well known. At full doses of each, there may be added toxicity, and there are certainly greater costs associated with combinations. Finally, combinations of agents may interact antagonistically instead of either additively of synergistically. For example, the combination of tetracycline and penicillin is somewhat antagonistic and caused a number of failures in the treatment of pneumococcal meningitis in the 1950s. However, there are circumstances in which weak antagonism is tolerable. It has been shown that isoniazid plus rifampin, part of the standard therapy for *M. tuberculosis*, is somewhat antagonistic with respect to cell killing, but the combination provides superb protection against the emergence of resistance. Consequently, when discussing drug interactions (synergy, additivity, antagonism), it is important to be specific about the end point to which one is referring.

MECHANISM OF ACTION

The search for new antimicrobials begins with the principle that the target that affects pathogens must not be in the human genome or must be sufficiently different that the agent in question does not cause appreciable human toxicity. β-lactam antibiotics are a good example: the inhibition of peptidoglycan synthesis has no effect on humans, because this target is simply not present. An example of differing susceptibility to inhibition because of poor sequence homology between bacteria and humans can be seen in the inhibitors of the bacterial ribosome. The bacterial ribosome is much smaller than that in humans and has differing affinities for such drugs as aminoglycosides, tetracyclines, macrolides, and clindamycin. Consequently, such agents are an important part of the therapeutic armamentarium and cause only minor adverse effects related to their primary mode of action. It should be recognized that in some cases so-called off-target toxicity may take place. Again, an example is the β-lactams: a major toxicity is accelerated allergic reaction, even though the target for the agents is not present in humans. Table 295-2 lists the sites of action and the effects of many antimicrobial agents.

Often, antimicrobials are thought of as either *bacteriostatic* or *bactericidal*, for which there are standard definitions. An agent that causes a 1000-fold decline (3 $\log_{10}$ [CFU/mL] decrease) in an in vitro test system over 18 to 24 hours is defined as being bactericidal. Any agent that causes a smaller decline is defined as bacteriostatic. It is clear that these definitions are arbitrary; however, there is a clinical connection. In some circumstances, such as meningitis and endocarditis, it is critical to kill every last organism with the combination of drugs employed and the immune system. Obviously, the more organisms the antimicrobial kills, the easier this is to accomplish. In other circumstances, such as multilobar pneumonia, it is critical to kill as many of the organisms as possible so as not to overwhelm the body's immunologic defenses. For these reasons, clinicians generally prefer bactericidal to bacteriostatic agents.

MECHANISMS OF RESISTANCE

Earlier, we examined how to suppress the emergence of resistance. Here we examine the mechanisms by which organisms can become less susceptible to antimicrobial agents. As stated earlier, in the vast majority of cases, resistance is caused by an alteration in the target site; by an enzyme that alters the drug, resulting in a lack of activity; by the drug's being pumped out of the organism; or, in the case of gram-negative pathogens, by the loss or downregulation of a transmembrane porin protein. These mechanisms, along with error-prone replication, can interact to cause large increases in the MIC. For example, a gram-negative pathogen that acquired a mutation in its gyrase enzyme would generally have only a 4-fold increase in its MIC value for a fluoroquinolone antimicrobial; however, if this isolate also had an efflux pump upregulated, the MIC could change 8- to 16-fold. Table 295-3 shows the mechanisms of resistance for multiple drug classes, as well as the most common organisms in which these mechanisms are seen.

EFFECTS OF PHARMACOKINETIC CHANGES

Whereas antimicrobial pharmacodynamics is the study of the effect of a drug on an infecting organism, pharmacokinetics is the study of the effect of the

TABLE 295-2 MECHANISMS OF ACTION OF ANTIMICROBIAL AGENTS

AGENT	SITE OF ACTION	EFFECT	BACTERICIDAL	BACTERIOSTATIC
β-Lactams (penicillins, cephalosporins, carbapenems, aztreonam)	Cell wall: penicillin binding proteins	Inhibit cross-linking of peptidoglycan (transpeptidation), impair cell wall synthesis	+	Occasionally (enterococci)
Vancomycin, teicoplanin, dalbavancin, telavancin	Cell wall: terminal D-alanyl-D-alanine of pentapeptide peptidoglycan precursor	Inhibit polymerization of disaccharide precursors to peptidoglycan (transglycosylation), impair cell wall synthesis	+	Occasionally (enterococci)
Daptomycin	Cell membrane	Rapid depolarization of membrane potential	+	Occasionally (enterococci)
Aminoglycosides	Protein synthesis: 30S ribosome subunit	Inhibit peptide elongation, cause misreading of genetic code, inhibit protein synthesis	+	
Tetracyclines, glycylcyclines	Protein synthesis: 30S ribosome subunit	Inhibit binding of transfer RNA, inhibit protein synthesis	Occasionally	+
Chloramphenicol	Protein synthesis: 30S ribosome subunit	Block attachment of aminoacyl transfer RNA, inhibit protein synthesis	Occasionally	+
Macrolides, azalides, ketolides	Protein synthesis: 50S ribosome subunit	Block transfer of amino acids to peptide chain, inhibit protein synthesis	Occasionally	+
Clindamycin	Protein synthesis: 50S ribosome subunit	Block transfer of amino acids to peptide chain, inhibit protein synthesis	Occasionally	+
Quinupristin/dalfopristin	Protein synthesis: 50S ribosome subunit	Block extrusion of peptide chains, inhibit protein synthesis	+	+ (with quinupristin resistance)
Linezolid	Protein synthesis: 50S ribosome subunit	Block formation of 70S initiation complex, inhibit protein synthesis	Occasionally	+
Rifampin	Nucleic acid synthesis: β-subunit of DNA-dependent RNA polymerase	Inhibit RNA synthesis	+	
Metronidazole	Nucleic acid synthesis	Damage nucleic acids, inhibit DNA synthesis	+	
Quinolones	Nucleic acid synthesis: DNA gyrase, topoisomerase IV	Impair supercoiling of DNA, prevent decatenation of DNA molecules after replication, inhibit DNA synthesis	+	
Sulfonamides	Folic acid synthesis: dihydropteroate synthetase	Competitive inhibition of synthesis of dihydrofolate from *p*-aminobenzoic acid, pteroate, and glutamic acid	Occasionally (when used with trimethoprim)	+
Trimethoprim	Folic acid synthesis: dihydrofolate reductase	Inhibit reduction of dihydrofolate to tetrahydrofolic acid	Occasionally (when used with sulfonamide)	+

body's processes on the drug concentration–time profile and the drug's ability to penetrate to the infection site (or the toxicity site). As such, it is a prime determinant of whether a drug will be able to kill or inhibit the offending pathogen and, because many toxicities are concentration related, whether a serious drug-related toxicity will occur.

Earlier, the algorithm for identifying appropriate drug doses and schedules was outlined. Table 295-4 shows recommended doses and schedules of important antimicrobial agents, as well as their protein binding ability and whether alterations in renal or hepatic function generate major changes in the concentration-time profile. As in all chemotherapy, the aim is to generate a concentration-time profile in the plasma to generate a concentration-time profile at the infection site that allows the drug to inhibit or kill the pathogen without causing toxicity.

Although there is almost always a guide to the concentration-time profile that results in an appropriate antimicrobial effect, it is more difficult to identify a linkage between drug exposure and the occurrence of toxicity. Data in this regard are available for the aminoglycosides, including a considerable amount of information on the association between drug concentrations and the likelihood of nephrotoxicity, and for daptomycin, for which a link between exposure and the likelihood of creatine phosphokinase (CPK) elevation has been elucidated.

For aminoglycosides, the relationships between drug exposure and the likelihood of a good clinical outcome and between drug exposure and the likelihood of nephrotoxicity have been determined. These are in the form of logistic regression functions, so the actual probability of both outcomes can be calculated. The one difference is that for the relationship with good outcome, the MIC value is part of the evaluation, whereas it does not figure in the toxicity relationship. Nevertheless, it is possible to derive appropriate information by making the outcome relationship MIC specific. Figure 295-2 illustrates the effect and toxicity relationships for aminoglycosides at three different MIC values. As shown, it is relatively easy to achieve a high probability of good clinical outcomes with aminoglycosides when the MIC is 0.25 mg/L, but it is virtually impossible to do so when the MIC rises to a value of 1.0 mg/L. The evaluation in the figure is based on twice daily dosing; daily aminoglycoside dosing markedly improves this circumstance. Also, it should be noted that these relationships permit one to calculate the probabilities of effect and toxicity when, for example, aminoglycoside AUC is increased owing to renal dysfunction, because these agents are largely eliminated renally.

When no toxicity relationship is available, there is still a target for good clinical effect. Achievement of this target should be paramount, and alterations for renal or hepatic impairment should strive to maintain the high likelihood of effect seen in patients with a relatively normal clearance function. One can change the dose or schedule of a drug to decrease its accumulation in the presence of renal or hepatic impairment (depending on the drug) and then recalculate the impact on the likelihood of attaining a good clinical outcome. One can also calculate the amount of accumulation with the proposed dose reduction or extension of the dosing interval. For the increase in exposure (relative to that in normally clearing patients), there is no clear guidance, but one can accept a certain maximal amount of accumulation as long as the proposed dose adjustment maintains a high likelihood of a good outcome. The acceptability of the increased drug exposure after dosage adjustment is usually based on a combination of preclinical toxicology and the largest exposures seen in phase I and phase II clinical trials. However, the overarching issue is that the proposed dose or schedule alteration maintains a high probability of a good clinical outcome.

TABLE 295-3 MECHANISMS OF ANTIMICROBIAL RESISTANCE

ANTIBACTERIAL AGENT	MECHANISM	REPRESENTATIVE ORGANISM
β-Lactams (penicillins, cephalosporins, carbapenems, aztreonam)	Altered target (penicillin binding proteins)	Methicillin-resistant *Staphylococcus aureus* (MRSA), penicillin-resistant *Streptococcus pneumoniae, Enterococcus faecium*
	Reduced permeability	*Enterobacter* spp, *Pseudomonas aeruginosa*
	Enhanced efflux	*P. aeruginosa*
	β-Lactamases	*S. aureus*, Enterobacteriaceae (includes ESBLs), *Haemophilus influenzae, Moraxella catarrhalis, Neisseria gonorrhoeae, Enterococcus faecalis*
Aminoglycosides	Inactivating enzymes (acetylation, adenylation, phosphorylation)	*S. aureus,* enterococci, *P. aeruginosa,* Enterobacteriaceae
	Reduced permeability	Enterobacteriaceae, *P. aeruginosa*, enterococci
	Enhanced efflux	*P. aeruginosae*
	Decreased ribosomal binding	*S. aureus, E. faecalis*, mycobacteria (streptomycin)
Chloramphenicol	Enhanced efflux	*H. influenzae*
	Reduced permeability	Enterobacteriaceae
	Inactivating enzyme (acetylation)	*S. aureus, S. pneumoniae*, enterococci
Daptomycin	Altered target	*S. aureus*
Glycylcyclines	Enhanced efflux	Enterobacteriaceae, especially *Proteus*
Macrolides, clindamycin, ketolide, quinupristin	Altered target (methylation of ribosomal RNA)	*S. aureus, S. pneumoniae* (not ketolide), streptococci, *Bacteroides fragilis*
	Enhanced efflux (not clindamycin or ketolide)	*S. pneumoniae*, streptococci
	Reduced permeability	Enterobacteriaceae
	Inactivating enzymes	*Escherichia coli, Klebsiella pneumoniae, S. aureus*
Linezolid	Altered target	Enterococci, *S. aureus*
Quinolones	Altered target (DNA gyrase, topoisomerase IV)	Enterobacteriaceae, *P. aeruginosa*
	Reduced permeability	Enterobacteriaceae, *P. aeruginosa*
	Enhanced efflux	*E. coli, P. aeruginosa*
Tetracyclines	Altered target (ribosome)	*N. gonorrhoeae*, streptococci
	Enhanced efflux	*E. coli, S. pneumoniae*
	Reduced permeability	Enterobacteriaceae
	Drug inactivation	*B. fragilis*
Rifampin	Altered target (β-subunit of polymerase)	*E. coli, S. aureus*
Sulfonamides, trimethoprim	Altered target (dihydropteroate synthetase or dihydrofolate reductase)	Enterobacteriaceae, *M. catarrhalis*
	Enhanced *p*-aminobenzoic acid production	*S. aureus, N. gonorrhoeae*
	Reduced permeability	*P. aeruginosa*, Enterobacteriaceae
Vancomycin	Altered target (peptidoglycan precursor binding site)	*E. faecium, E. faecalis, S. aureus*

ESBL = extended-spectrum β-lactamases.

DRUG CLASSES AND THEIR PROPERTIES

Over the past 70 years, a large number of different classes of antimicrobial agents have been developed. These classes differ in their mechanisms of action, mechanisms of emergence of resistance, and whether they kill substantial numbers of organisms or only shut off bacterial growth. The following sections examine some of the properties of the major classes of antimicrobial agents in use today.

β-Lactam Agents

This class of drugs is arguably the most important group of antimicrobials. With chemical modification, they have an exceptionally broad spectrum of activity and, in general, an excellent safety profile. The major toxicity is related to allergic reactions to a degradation product of the drug. There are a number of different types of β-lactams, including the penicillins, the cephalosporins, the monobactams, and the carbapenems.

These agents bind to their target, the β-lactam binding proteins (sometimes referred to as penicillin binding proteins). These binding proteins have an active site serine, and the drug forms a covalent bond with this site through the carbonyl of the β-lactam ring. Sometimes, the binding has direct effects on the organism's shape. For example, in gram-negative organisms, binding to penicillin binding protein (PBP)-2 causes the organism to assume a spherical shape, whereas binding to PBP-3 causes the formation of long chains of organisms. Generally, high-affinity binding to PBP-1 leads to the rapid death of the organism, sometimes accompanied by lysis. The classic response of *S. pneumoniae* to penicillin G is rapid lysis of the organism. Binding to PBP-1 (1a or 1b) leads to activation of *N*-acetylmuramic acid amidase, which destroys the bacterial cell wall, resulting in lysis.

The most common way for pathogens to protect themselves from β-lactams is by elaborating β-lactamases. The genes for these enzymes may be on plasmids or other bits of transmissible DNA, or they may reside on the bacterial chromosome. Some drugs, such as the carbapenems, are resistant to hydrolysis by many enzymes (but certainly not all of them—especially the metallo-β-lactamases and *K. pneumoniae* carbapenemase–type β-lactamases). One of the ways developed to protect these drugs is to add a second agent, the β-lactamase inhibitor. Examples include K-clavulanate, sulbactam, tazobactam, and, most recently, NXL-104 (an experimental drug). These agents inhibit different types of β-lactamases, with NXL-104 being the only one able to inhibit the ampC-type enzymes carried by *P. aeruginosa*, *Enterobacter* species, *Citrobacter* species, *Serratia marcescens,* and indole-positive *Protea* (SPICE organisms).

All β-lactams are relatively non–concentration dependent in their kill rate, and free drug time greater than MIC is the important factor for increased organism killing. The classes differ somewhat, with carbapenems requiring approximately 40% free drug time greater than MIC for near-maximal cell killing. For penicillins, this percentage is approximately 50%, and for cephalosporins and monobactams, it is 60 to 70%.

Aminoglycosides

These important agents were discovered in the late 1940s for the treatment of *M. tuberculosis* (streptomycin). Screening of natural products identified a

*Dose in milligrams per kilogram body weight at hour intervals and/or oral dose in milligrams in patients with normal renal function; all doses are parenteral unless specified PO.
†Significant decrease or delay in absorption when administered with food.
‡Refers to information for clavulanic acid.
§Includes parent compound and active metabolites.
¶Oral vancomycin is not absorbed; it is used for intraluminal therapy only.
H = hemodialysis; P = peritoneal dialysis; STD = sexually transmitted disease.

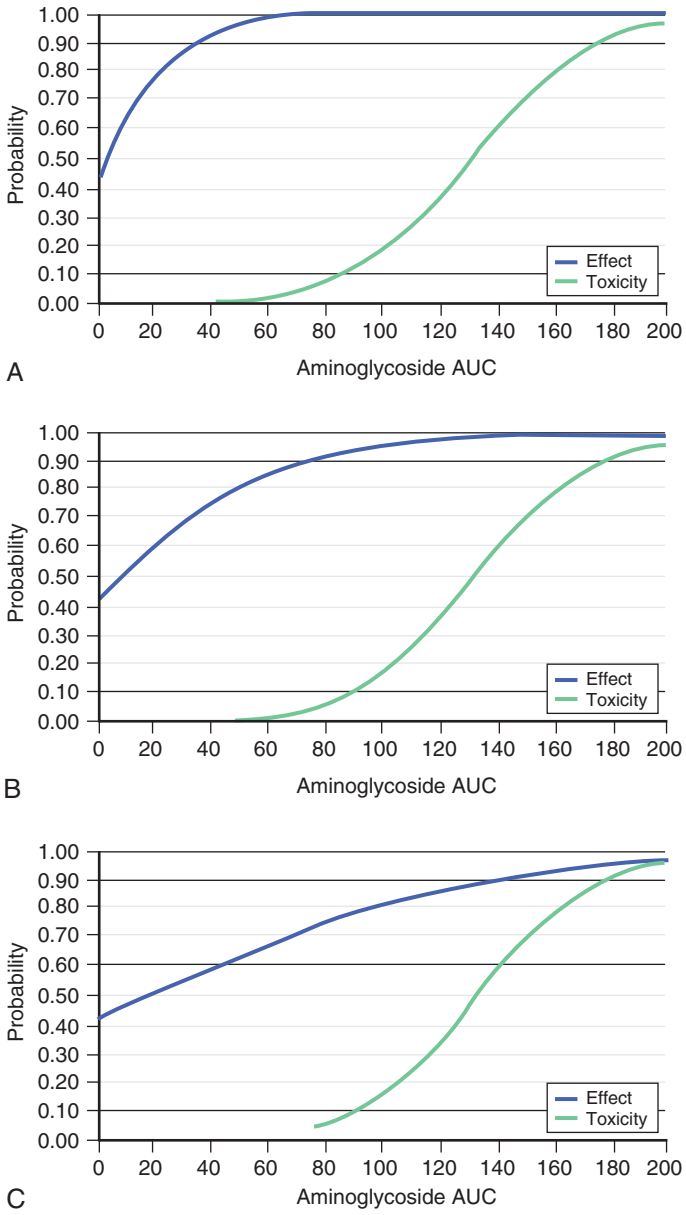

FIGURE 295-2. Probability of clinical effect versus nephrotoxicity as a function of aminoglycoside area under the curve (AUC). A, Minimal inhibitory concentration (MIC) = 0.25 mg/L. **B,** MIC = 0.5 mg/L. **C,** MIC = 1.0 mg/L.

number of different aminoglycosides such as kanamycin, neomycin, gentamicin (actually a combination of three congeners), and tobramycin. Other semisynthetic agents such as amikacin, netilmicin, and arbekacin (among others) have been discovered and used for therapy in the United States and elsewhere.

Nephrotoxicity and middle ear toxicity (hearing loss or loss of balance) are these drugs' defining dose-limiting toxicities and resulted in aminoglycosides going out of favor in the 1990s and early in the first decade of the 21st century. It has now been recognized that most (but not all) of the nephrotoxic potential can be ameliorated by intermittent dosing of these drugs (usually once daily). Even with daily therapy, however, prolonged use can still result in nephro- or ototoxicity.

The recent rise in resistance, particularly among gram-negative isolates, and new resistance mechanisms, such as the advent of *K. pneumoniae* carbapenemase enzymes mediating resistance to even our best β-lactam agents, has resulted in renewed interest in existing aminoglycosides and a search for new ones that are more resistant to inactivation by the aminoglycoside-modifying enzymes.

These drugs are concentration dependent in terms of their kill rate and are quite rapid killers. Hence, the AUC/MIC ratio (or, as sometimes reported, peak concentration/MIC ratio) is the factor most closely associated with bacterial cell killing. Therefore, large doses administered daily to patients with normal renal function would be expected to optimize bacterial cell killing while minimizing the probability of inducing an aminoglycoside-related toxic event.

The older aminoglycosides (streptomycin and gentamicin) have the best profile for synergizing with drugs active against gram-positive streptococci (particularly enterococci). Tobramycin generally has the most potent activity against *P. aeruginosa* (depending on the aminoglycoside-modifying enzymes present in a specific locale), and less resistance is generally seen with amikacin (again, depending on the locale). Streptomycin and amikacin, because of the number of amino groups carried, are usually about four-fold less potent than gentamicin or tobramycin. Consequently, their dosages are approximately three- to four-fold higher.

These agents should be thought of as components of combination regimens for seriously ill patients, particularly those thought to be infected by gram-negative organisms, in the empirical therapy setting.

Quinolones

These agents are completely synthetic and do not exist in nature. They are inhibitors (depending on the drug and the organism) of topoisomerases II and IV. This means that they strike at the heart of DNA replication, making them rapidly bactericidal. The use of fluorination markedly enhanced the microbiologic activity of these drugs, so they became useful for both community-acquired infections (especially urinary tract infections and pneumonia) and hospital-acquired gram-negative infections.

These drugs penetrate well into most spaces, with substantial concentrations inside cells. This makes them active against obligate intracellular pathogens such as *Chlamydophila, Legionella,* and *Mycoplasma.* They also penetrate well into spaces with tight junctions (prostate, eye, central nervous system) and into epithelial lining fluid.

Typically, the toxicities associated with these drugs are "off target." A number of these drugs were either withdrawn from the marketplace or given black box warnings by health authorities because of the infrequent occurrence of torsades de pointes (Chapter 65) or other serious and life-threatening toxicities, such as eosinophilic hepatitis.

These agents are concentration-dependent bacterial killers, indicating that the free drug AUC/MIC ratio is best associated with a regimen's ability to kill bacterial cells. Of interest, particularly for a drug that is completely synthetic, there are a number of resistance mechanisms that allow bacterial escape from drug pressure. The combination of efflux pump overexpression and error-prone replication, resulting in target site mutants as well as serious underdosing for some of the earlier drugs in the class, has resulted in the emergence of considerable resistance, particularly among gram-negative isolates and in the ICU setting.

Macrolides, Tetracyclines, Ketolides, Clindamycin, and Linezolid

These agents all bind to different places in the bacterial ribosome, making them inhibitors of protein synthesis and, for the most part, drugs with limited bactericidal activity. An exception may be their activity against *S. pneumoniae*.

Macrolides (particularly clarithromycin and azithromycin) are most useful for community-acquired respiratory tract infections, for two reasons. First, their spectrum is well suited to the classic and atypical pathogens encountered in these patients. Second, they concentrate quite well in the epithelial lining fluid, with accumulations that range from 6-fold to almost 20-fold that in plasma. This accumulation also partially explains why these agents have fared much better in the respiratory tract setting than in the skin and skin structure setting. Telithromycin, a ketolide, retains activity against many (but not all) macrolide-resistant isolates.

The macrolides and telithromycin are free drug AUC/MIC ratio–driven drugs with respect to bacterial activity, but for different reasons. Telithromycin is somewhat concentration dependent with regard to its microbiologic activity, whereas classic macrolides are not. Telithromycin is more like aminoglycosides or quinolones in terms of the association between exposure indices and bacterial effect. Classic macrolides, especially azithromycin, induce a long persistent or post-antibiotic effect and are *not* concentration dependent in their bacterial effect. This post-antibiotic effect suppresses bacterial regrowth after the drug concentration declines below the MIC until the next dose of drug is administered. In this way, we perceive the linkage to be driven by the free drug AUC/MIC ratio, but with a different mechanism from agents whose bacterial kill rate is concentration dependent.

Most of the toxicities seen here are off target and gastrointestinal. However, there is also some elongation of the QT interval (Chapter 54).

Tetracyclines have an exceptionally broad spectrum of activity, including both gram-positive and gram-negative pathogens, and are quite active against atypical pathogens. The latest incarnation of a tetracycline-type agent (tigecycline, a glycylcycline) has good activity against methicillin-resistant *S. aureus* (MRSA) as well. Tigecycline differs from previous tetracyclines (e.g., doxycycline, minocycline) in that its structure prevents many efflux pumps from removing the drug from the bacteria and also provides a degree of ribosomal protection.

The lincosamide antibiotic clindamycin has a spectrum that covers most clinically significant anaerobes, including many in the *Bacteroides* group (although some resistance is being seen). It is thus a useful agent for infections in which anaerobes play a prominent role, such as lung abscesses and intra-abdominal infections. In many areas of the country, it retains activity against MRSA, but this should be verified with a D-test (inducible macrolide-lincosamide-streptogramin resistance) in the microbiology laboratory. It also has good activity against many streptococci. Because it is a protein synthesis inhibitor, it may provide improved results when the staphylococcal or streptococcal isolate elaborates a great deal of toxin.

Again, most toxicity is off target, with gastrointestinal symptoms being most frequent. Antibiotic-associated diarrhea and the more serious *Clostridium difficile* colitis can occur.

Linezolid is a member of the oxazolidinone class of antibiotics and is a protein synthesis inhibitor. It is distinguished by having excellent gram-positive activity and robust activity against MRSA. It has been used in skin and skin structure infections and is being evaluated in MRSA nosocomial pneumonia. Linezolid penetrates well into skin as well as the epithelial lining fluid, which is the reason for its evaluation in hospital-acquired MRSA against vancomycin. It is also distinguished by having an oral formulation that is highly bioavailable.

The free drug AUC/MIC ratio is the pharmacodynamic index most associated with cell killing for linezolid. Its toxicity is reflected by dropping counts of bone marrow–derived cells, particularly platelets, seen most frequently with prolonged use. Resistance occurs rarely and is seen with enterococci more frequently than with *S. aureus*. There are five or six gene copies of the target site. As more and more copies become mutated, the MIC increases almost linearly. Because these mutated targets have some biofitness cost, there is a slow reversion to wild-type targets when therapy is discontinued. If all copies become mutated, however, they cannot revert to wild type. The early detection of MIC changes should lead to the consideration of changing or stopping therapy.

Vancomycin, Quinupristin/Dalfopristin, and Daptomycin

Though structured differently, these agents (along with linezolid) are distinguished by having reliable activity against MRSA.

Vancomycin acts at the cell wall and is bactericidal. The free drug AUC/MIC ratio is the driver of antimicrobial effect. Vancomycin has activity against many gram-positive pathogens and has lately become distinguished for its activity against *C. difficile* when administered orally. As with most drugs, wide use has caused the emergence of vancomycin resistance in both enterococci and *S. aureus* (although the latter is rare).

Although vancomycin has a reputation for being a somewhat slow killer, no new agent has significantly outperformed it, at least in trials of skin and skin structure infections. MIC creep has been documented. Although many *S. aureus* isolates were once susceptible with MIC values of 0.25 and 0.5 mg/L, these are now in the distinct minority; 1.0 mg/L represents the modal value, with a few isolates having values of 2.0 mg/L. The higher MICs make these isolates more difficult to treat reliably with standard dosing (1 g IV every 12 hours). Also, it has recently become clear that higher vancomycin doses are associated with a significantly higher risk of nephrotoxicity, even when the agent is administered alone. In addition to nephrotoxicity, vancomycin causes histamine release ("red man syndrome") when administered too quickly intravenously. Infusion times of approximately 1 hour are recommended for standard doses.

Quinupristin/dalfopristin is a combination of streptogramin A and streptogramin B antibiotics. Although each is bacteriostatic, the combination can produce some cell killing because the two drugs are synergistic. The synergy is lost, however, with the emergence of resistance to either drug. Further, the amount of bacterial cell killing is modest because of the drugs' rapid half-lives and the imposition of a 12-hour dosing interval. This combination product has activity against resistant enterococci as well as MRSA. Its toxicity includes relatively severe muscle pain in some patients. It is also quite phlebitogenic and has to be administered with a central venous catheter, limiting its utility.

Daptomycin is a lipopeptide antibiotic discovered in the 1980s and resurrected in the 1990s with a greater understanding of the relationship between exposure and effect versus exposure and toxicity. It was discovered that the antibacterial effect against MRSA was driven by the free drug AUC/MIC ratio. Muscle effects were seen early in its development that limited therapy. Trough concentrations of daptomycin drive this toxicity and can be ameliorated by once-daily dosing (thus minimizing trough concentrations).

This agent has been licensed for skin and skin structure infections and, of note, for complicated *S. aureus* bacteremia and right-sided endocarditis. It also has activity against enterococci. The drug is bound up in epithelial lining fluid by surfactant, excluding its use in the therapy of pneumonia.

Daptomycin may cause muscle toxicity, which is quite rare, but this may be preceded by the harbinger of an elevated CPK level. The muscle damage is driven by daptomycin trough concentrations, generally above a concentration of about 25 mg/L. Monitoring of CPK is useful in the management of patients on daptomycin therapy.

TOXICITIES

All antimicrobials have toxicities. The most common observed toxicities for many antimicrobial agents are presented in Table 295-5.

DURATION OF THERAPY

Relatively little is known about the optimal duration of therapy. Some work has been done to define certain circumstances in which short courses of chemotherapy are effective. For instance, gonorrhea is highly likely to be cured by a single dose of drug (ceftriaxone, cefixime, fluoroquinolones), as long as the organism is susceptible to the drug given.

For trimethoprim-sulfamethoxazole and fluoroquinolones, controlled trials have shown that 3 days of therapy is adequate for uncomplicated urinary tract infections. For β-lactam antimicrobials, a somewhat longer duration is required.

In community-acquired pneumonia, controlled trials with fluoroquinolones have demonstrated optimal results with 5 days of therapy, most likely because of concentration-dependent killing. For bacterial sinusitis, direct sampling from the infected sinus has demonstrated that bacterial pathogens were eradicated by day 3 of therapy or earlier, particularly for *S. pneumoniae* infections.

In ventilator-associated pneumonia, a double-blind comparison of 8 versus 15 days of therapy demonstrated that, with a single exception, clinical outcomes were just as good, there was less emergence of resistance, fewer antibiotics were administered, and there was less toxicity in the group receiving 8 days of therapy. The single exception was when a nonfermenting gram-negative rod was recovered (*P. aeruginosa* or *Acinetobacter* species). In this circumstance, there were significantly more relapses with 8-day versus 15-day treatment, but clinical outcomes were no different.

In some infections, the organisms are slow growing and require more time for control. Both endocarditis and osteomyelitis are examples. Therapy durations of 4 to 6 weeks and occasionally longer may be required for cure in this circumstance.

Finally, one of the longest durations of therapy is seen in the treatment of tuberculosis. In this case, some organisms are in the "non-replicative persister" (NRP) state, indicating that they are not growing or metabolically active. When recovered, they are still fully susceptible to the antimicrobials being used, but while in the NRP state, they cannot be readily killed with current chemotherapy (phenotypic, not genotypic resistance). Therapy durations of 6 months for wild-type organisms and 18 to 24 months for multidrug-resistant tuberculosis are required because of the need to use suboptimal regimens. Indeed, it is a major research goal to find drugs that will readily kill organisms in the NRP state and thus substantially shorten the therapeutic course for *M. tuberculosis*.

FAILURE OF ANTIMICROBIAL THERAPY

Occasionally, antimicrobial therapy fails, with failure defined as the persistence of signs and symptoms of infection or the persistence of fever. When one is confronted with failure after what was thought to be adequate antimicrobial therapy, it should set off a sequence of investigations: (1) Did resistance emerge, or did superinfection occur? (2) Is there an obstructed hollow viscus (e.g., urinary or gastrointestinal tract)? (3) Is there an undrained abscess or infected collection (e.g., empyema)? (4) Is there an infected foreign body (e.g., intravenous catheter or prosthesis), or is there devitalized

TABLE 295-5 ADVERSE EFFECTS OF ANTIMICROBIAL AGENTS

AGENT	GENERAL	SKIN	GI TRACT	BLOOD CELLS	KIDNEY	NERVOUS SYSTEM	OTHER
Penicillins	Hypersensitivity, anaphylaxis, serum sickness	Rash, urticaria, erythema multiforme	Diarrhea (ampicillin, amoxicillin-clavulanate), hepatitis (oxacillin)	Coombs-positive hemolytic anemia, impaired platelet function (ticarcillin), leukopenia, thrombocytopenia	Nephritis (methicillin), hypokalemia (carboxy- and ureido-penicillins)	Seizures, twitching (high doses, renal failure)	Inactivates aminoglycosides when admixed; possible with concurrent therapy in renal failure
Cephalosporins	Serum sickness (cefaclor), hypersensitivity, anaphylaxis (rare)	Rash, urticaria	Diarrhea, hepatic dysfunction, precipitates in bile (ceftriaxone), mild increase in LFTs	Neutropenia, increased prothrombin time, bleeding (due to MTT side chain), positive Coombs test	Enhances aminoglycoside toxicity, acute renal failure (rare), interstitial nephritis		Disulfiram-like reaction with alcohol use (MTT side chain)
Carbapenems	Hypersensitivity	Rash, urticaria, erythema multiforme	Vomiting with rapid infusion (imipenem), abnormal LFTs	Bone marrow suppression, positive Coombs test	Renal dysfunction	Seizures, myoclonus	
Aminoglycosides	Fever	Rash			Reversible renal failure	Irreversible vestibular toxicity and/or auditory damage, muscular blockade (with anesthetics and myasthenia gravis)	
Vancomycin	Allergy, fever	Rash		Leukopenia, thrombocytopenia	Nephrotoxic with aminoglycoside	Decreased hearing, neuropathy	Histamine release with flushing and hypotension (infusion <1 hr, antihistamines can prevent)
Quinolones	Headache, allergy, anaphylaxis (rare)	Rash (gemifloxacin), urticaria, photosensitivity (lomefloxacin)	GI distress, abnormal LFTs			Dizziness, insomnia, nervousness, tremors, visual changes, seizures	Tendon rupture arthropathy in young animals
Sulfonamides	Hypersensitivity, anaphylaxis, serum sickness, fever	Rash, Stevens-Johnson syndrome, photosensitivity	Hepatitis	Hemolysis (G6PD deficiency), agranulocytosis, marrow suppression	Crystalluria	Neuropathy	Vasculitis
Trimethoprim ± sulfamethoxazole	Fever	Rash, erythema multiforme, Stevens-Johnson syndrome, TEN	Hepatitis, pancreatitis	Marrow suppression	Hyperkalemia, acute renal failure		
Chloramphenicol	Fever			Marrow suppression (dose related), aplastic anemia		Optic neuritis, neuropathy	Circulatory collapse (gray baby syndrome in neonates)
Tetracyclines	Hypersensitivity	Photosensitization (doxycycline)	GI discomfort, hepatotoxicity in azotemia or pregnancy		Antianabolic aggravation of azotemia (except doxycycline)	Vertigo (minocycline)	Deposition in bone (dysplasia) and teeth (staining)
Macrolides	Fever	Rash	GI discomfort			Reversible decreased hearing	Phlebitis (IV erythromycin), metallic taste (clarithromycin)
Clindamycin	Fever	Rash	Diarrhea, pseudomembranous colitis				
Metronidazole	Headache, hypersensitivity		Nausea, metallic taste, pancreatitis	Leukopenia		Peripheral neuropathy, ataxia	Mutagenic, carcinogenic in rodents, disulfiram-like reaction with alcohol

GI = gastrointestinal; G6PD = glucose-6-phosphate dehydrogenase; LFT = liver function test; MTT = methylthiotetrazole; TEN = toxic epidermal necrolysis.

tissue (e.g., sequestrum in osteomyelitis)? (5) Is the fever (if present) attributable to a drug being administered? Thoughtful re-examination should sort out the cause in many instances.

296 STAPHYLOCOCCAL INFECTIONS

HENRY CHAMBERS

Staphylococci are well adapted as both commensals and pathogens. Coagulase-negative species constitute a significant proportion of the normal human cutaneous microbiome. *Staphylococcus aureus*, a coagulase-positive species, is present in nasopharyngeal flora in a third of individuals, most of whom will not become infected. As a pathogen, *S. aureus* is one of the most common causes of bacterial infections, which range in severity from relatively trivial skin infections to lethal invasive disease. Coagulase-negative species are intrinsically less virulent and less invasive than *S. aureus* but are responsible for one in four health care–associated infections, almost always involving an indwelling medical device. Antibiotic-resistant strains of staphylococci are quite prevalent, which has a profound impact on therapy.

THE PATHOGEN

The genus *Staphylococcus* consists of more than 30 distinct species. These organisms have co-evolved as normal flora of mammals and birds. They are gram-positive spherical cells (i.e., cocci) 0.5 to 1.5 µm in diameter that divide in multiple planes to form clusters resembling grapes (*staphylo* is derived from the Greek word for "bunch of grapes") when viewed under the microscope. Staphylococci are nonmotile, nonsporulating, hardy organisms that are resistant to desiccation, extremes of pH, and high salt concentrations and are capable of growth under aerobic or anaerobic conditions. Staphylococci produce catalase, an enzyme that degrades hydrogen peroxide into water and oxygen, which definitively distinguishes them biochemically from streptococci and enterococci. The coagulase test is the basis for differentiating *S. aureus* from the numerous other nonpathogenic, coagulase-negative species. Coagulase is a secreted cell surface protein that, in the presence of a prothrombin-like plasma protein, converts fibrinogen to fibrin, forming a clot. *S. aureus* produces a variety of other species-specific surface proteins that differentiate it from other species.

The staphylococcal chromosome is circular; approximately 75% of the genes constitute a core genome common to all staphylococcal species. The remaining 25% contains species-defining elements and mobile genetic elements acquired by horizontal gene transfer. The *S. aureus* genome is abundant in genes encoding toxins, superantigens, and adhesins, whereas coagulase-negative species contain few adhesin and no toxin or superantigen genes. Genetically, *S. aureus* is sufficiently uniform to classify it as a single species; greater diversity among coagulase-negative species merits their classification as distinct species.

STAPHYLOCOCCUS AUREUS

EPIDEMIOLOGY

S. aureus is maintained in the human population primarily through asymptomatic colonization of the anterior nares, mucous membranes, and other moist areas of the body, as well as the groin, perineum, and perianal area in healthy children and adults. Infants become colonized by strains from their mothers within weeks of birth. Carriage rates are higher in children than in adults. Higher-than-average *S. aureus* carriage rates are associated with atopic dermatitis, eczema, chronic skin ulcers, and other acute and chronic skin conditions; insulin-dependent diabetes; dialysis; human immunodeficiency virus (HIV) infection; and recreational injection drug use. Carriers have a several-fold higher risk of developing a subsequent *S. aureus* infection compared with noncarriers. The principal mode of transmission of *S. aureus* is direct contact with an infected individual or an asymptomatic carrier, probably via transient hand carriage. *S. aureus* may also contaminate environmental surfaces, where it can persist for days. The role of environmental contamination in transmission is not well defined, but it may be important if heavily contaminated surfaces or materials are contacted. Droplet and aerosol transmission of *S. aureus* plays little if any role.

S. aureus is responsible for millions of infections in the United States each year, most of which are community-acquired skin infections. Approximately 5 to 10% of *S. aureus* infections are invasive and are often associated with bacteremia. *S. aureus* also causes hundreds of thousands of health care–associated infections each year, 50 to 60% of which are caused by methicillin-resistant *S. aureus* (MRSA). Prior to the mid-1990s, MRSA strains were almost exclusively hospital or health care associated, but they have now become prevalent in the community. Community-associated MRSA strains are distinct from classic health care–associated MRSA strains in several ways (Table 296-1).

TABLE 296-1 COMPARISON OF COMMUNITY AND HOSPITAL CLONES OF METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* (MRSA)

PROPERTY	COMMUNITY MRSA	HOSPITAL MRSA

PATHOBIOLOGY

Virulence Factors

S. aureus is highly adapted to humans through millions of years of co-evolution with hominids. Well over 50 virulence factors, including adhesins, toxins, enzymes, surface-bound proteins, and capsule polysaccharides, may be produced (E-Table 296-1). Genes encoding these factors may be located on the chromosome either as part of the core genome or within mobile genetic elements (or their remnants), including bacteriophages, pathogenicity islands, and cassettes, or on plasmids. Biofilm formation occurs in the presence of foreign material such as vascular catheters or implanted devices. Biofilm is a complex network of extracellular polysaccharides, DNA, and protein in which bacterial cells become embedded, rendering them inaccessible to clearance by host defense mechanisms. Organisms within biofilms tend to be metabolically inactive and tolerant to killing by antimicrobial agents.

Virulence factors serve to promote binding to host tissues; to evade, circumvent, or disrupt host immune responses; and to facilitate cell injury and tissue invasion. Variability in both the presence of virulence determinants and their expression among strains allows extreme diversity among clinical isolates and the remarkable adaptability of *S. aureus* as a pathogen. An extensive network of two component response systems, DNA binding proteins and regulatory RNAs, controls the expression of virulence (and other) factors in response to environmental conditions. Principal among these is the accessory gene regulator *agr*, a two-component quorum sensing and global gene regulator that controls the expression of numerous surface and secreted proteins. Mutations in *agr* are associated with reduced susceptibility to vancomycin and with loss of virulence.

Mechanisms of Disease

Pathogenesis of *S. aureus* disease occurs by two mechanisms: tissue invasion, which may be local or systemic; and toxin mediated. The characteristic lesion of tissue invasion is the abscess, a focal collection of pus (liquefied and necrotic host tissue, blood, inflammatory cells, DNA, and cellular debris) and bacterial cells surrounded by an ill-defined, surrounding layer of edematous and inflamed tissue infiltrated by acute and chronic inflammatory cells.

Host defenses against *S. aureus* infection consist of an intact, normal skin barrier and the innate immune system. Conditions in which these defenses are impaired are associated with increased risk of *S. aureus* infection. Among these conditions are injection drug use, presence of vascular access devices, burns, chronic skin diseases, use of systemic steroids, traumatic wounds, minor skin abrasions or trauma, surgical procedures, insulin-dependent and non-insulin-dependent diabetes, peritoneal dialysis, hemodialysis, subcutaneous and intramuscular injections, acupuncture, prosthetic implants, and congenital or acquired neutrophil disorders (e.g., chronic granulomatous disease, Job's syndrome). Once the cutaneous barrier has been breached, the next line of defense is the innate immune system. Neutrophils recruited to the site of infection ingest and kill staphylococci. Staphylococci elaborate numerous virulence factors specifically designed to thwart each step of the host response. If large numbers of organisms are present, the host response is overwhelmed, infection is not contained, and dissemination occurs. Endothelial cell injury and invasion can also occur. Intracellular organisms within phagocytes and endothelial cells may play a role in relapse and persistent bacteremia. High tissue burdens of organisms and bacteremia are usually, but not always, accompanied by fever, tachycardia, and other signs of the systemic inflammatory response syndrome, including frank septic shock.

Three toxin-mediated syndromes, which can occur in the absence of invasive disease, are staphylococcal food poisoning, staphylococcal toxic shock syndrome, and staphylococcal scalded skin syndrome. Staphylococcal food poisoning is caused by the ingestion of a preformed heat-stable enterotoxin. The emetic activity of enterotoxin is mediated by the intestinal release of 5-hydroxytryptamine and the stimulation of receptors present on afferent vagal neurons. Toxic shock syndrome is caused by a specific toxin, TSST-1, or other staphylococcal enterotoxins, acting as superantigens, promiscuously binding to major histocompatibility complex (MHC) class II molecules of antigen-presenting cells and T-cell receptors, stimulating the massive release of cytokines from T cells and resulting in septic shock and death. Staphylococcal scalded skin syndrome and bullous impetigo are caused by either of two exfoliative toxins, A or B. These toxins are serine proteases that specifically cleave desmoglein 1, a desmosomal protein that anchors the overlying superficial epidermis to the stratum granulosum.

CLINICAL MANIFESTATIONS

Skin and Soft Tissue Infections

Skin and soft tissue infections are by far the most common infections caused by *S. aureus*; millions of cases occur annually in the United States. Community MRSA strains have been associated with a 50% increase in the rates of skin and soft tissue infections in the United States. This heterogeneous group of skin diseases includes impetigo, folliculitis, furuncle, abscess, erysipelas and cellulitis, mastitis (cellulitis of the breast), necrotizing fasciitis, and wound infections.

Impetigo, folliculitis, and furuncle are superficial infections; fever and other systemic signs of infection are not present. Impetigo is a focal infection of the epidermis that occurs most commonly in children. The typical lesion, which may be multiple or in clusters, is about 1 cm in diameter, with erythema surrounding a bulla or bullae (caused by the production of exfoliative toxin) containing cloudy fluid or with a crusty or scabbed-over appearance. Gram stain of the fluid or drainage from the lesion shows the organism. Folliculitis is a superficial infection with tender, erythematous, maculopapular or pustular lesions centered around hair follicles. Both impetigo and folliculitis readily respond to local measures such as application of soap and water, topical antibiotics, or antiseptics; systemic antimicrobial therapy may be indicated for extensive or refractory infections.

A furuncle is simply a boil—an erythematous, suppurative infection measuring 1 to 2 cm that extends through the dermis into the subcutaneous tissue. It may drain spontaneously; if not, hot compresses can be applied to encourage drainage, or the furuncle can be incised and drained. Antimicrobial therapy is not needed. The distinction between a furuncle and an abscess is somewhat arbitrary; abscesses tend to be larger and deeper and may be associated with systemic signs of infection and bacteremia. Furuncles may extend to fascia or deeper tissues and coalesce into carbuncles, a more severe form of infection that may be accompanied by bacteremia. Large abscesses and carbuncles, particularly in the presence of fever and the systemic inflammatory response syndrome, require surgical drainage and systemic antimicrobial therapy.

Erysipelas and cellulitis, which are similar in appearance, are painful, warm, indurated, erythematous, nonlocalized infections that may be accompanied by lymphangitis. Cellulitis extends into the dermis and subcutaneous fat; erysipelas is more superficial. Surrounding cellulitis is often associated with an obvious cutaneous abscess, but it may also overlie a deeper abscess; the primary therapy is surgical drainage. Cellulitis without an associated abscess should be treated with systemic antimicrobial therapy. Cellulitis due to streptococci (Chapter 298) cannot reliably be distinguished from that caused by *S. aureus*, owing to their similar appearance; the presence of an associated purulent lesion suggests staphylococcal infection, and culture should be performed to make a microbiologic diagnosis.

Necrotizing fasciitis is an infection of the deep layers of skin and subcutaneous tissues, extending to muscle and along fascial planes. It is associated with systemic toxicity, leukocytosis, and severe pain, often out of proportion to the physical findings. The overlying skin may appear to be uninvolved, belying the serious nature of this infection, which requires immediate surgical intervention for débridement of involved tissue. Necrotizing fasciitis, which is more typically caused by group A streptococci (Chapter 298) or occurs as a mixed infection, has been associated with community MRSA infection.

Pyomyositis (also termed *tropical myositis*) is an infection of the skeletal muscle; *S. aureus* is the most common cause. The patient presents with fever, pain, and swelling and induration that can be felt on deep palpation; the overlying skin and soft tissue may appear normal. There is often a history of trauma to the infected area. Although it can occur in otherwise normal children and adults, acquired immunodeficiency syndrome (AIDS) and other immunocompromising conditions are predisposing factors. This infection is thought to occur as a consequence of metastatic seeding from a subclinical bacteremia; blood cultures may not be positive at the time of diagnosis. The diagnosis is established by culture of pus collected by needle aspirate. Surgical or percutaneous drainage should be performed, and systemic antimicrobial therapy is indicated.

S. aureus causes 30% of surgical site infections overall in the United States, and approximately 50% of those follow neurosurgical or orthopedic procedures. These infections occur at the site of incision, typically after the second or third postoperative day. Signs and symptoms are fever accompanied by erythema, edema, induration, drainage, pain, and tenderness at the surgical site. Superficial infections respond to removal of stitches, débridement of devitalized tissue, opening of the wound to allow drainage, and a short course of antimicrobial therapy. Deeper infections may require more extensive débridement and longer courses of therapy (4 to 6 weeks), particularly if bone or a prosthetic device is involved. Removal of infected prosthetic material or a foreign body greatly increases the chance of cure.

Bacteremia

Bacteremia, the presence of bacteria in the blood stream, exemplifies the pathogenicity of *S. aureus*. It is virtually synonymous with invasive disease, present in approximately 75% of cases. The most common sources of bacteremia are skin and soft tissue infections, central venous catheters and other intravascular devices, bone and joint infections, pneumonia, and endocarditis. Bacteremia can emanate from any source, which may not be obvious in 25% of cases. Invasion of the blood stream allows the organism to disseminate widely throughout the body, establishing multiple metastatic sites of infection and thereby perpetuating bacteremia. Fever is usually, but not always, present. Sepsis syndrome and septic shock are common, and death occurs in 10 to 20% of cases.

The presence of bacteremia dictates the approach to the diagnosis, management, and therapy of *S. aureus* infection. When blood cultures are positive, even if the primary source is known, there is always the possibility of endocarditis or other secondary foci of infection. Echocardiography is recommended to look for evidence of endocarditis. Source control is the cornerstone of management and therapy; both primary and secondary foci of infection should be identified and removed whenever possible, because these may lead to treatment failure or relapse once therapy is discontinued. Computed tomography (CT) or magnetic resonance imaging (MRI) should be considered if signs and symptoms point to deep tissue abscesses or osteomyelitis. Follow-up blood cultures should be obtained to document clearance. Persistent bacteremia is suggestive of endovascular infection, and failure to clear

TABLE 296-2 CRITERIA FOR DIAGNOSIS OF UNCOMPLICATED *STAPHYLOCOCCUS AUREUS* BACTEREMIA*

Resolution of fever and systemic signs of infection by day 3 of therapy
Sterile blood cultures within 2–3 days of initiation of antimicrobial therapy
Presence of an identifiable and easily removable focus of infection
Prompt removal of the primary focus of infection
No echocardiographic or clinical signs of endocarditis
No osteomyelitis
No hematogenous secondary foci of infection
No preexisting valve abnormalities predisposing to endocarditis (e.g., prosthetic valve, rheumatic heart disease, bicuspid aortic valve)
No implanted prosthetic device (e.g., prosthetic hip)

*Uncomplicated *S. aureus* bacteremia can be treated with a shorter course of antibiotics (see text).

blood cultures after 3 to 4 days of appropriate therapy is a strong predictor of complicated bacteremia, necessitating a longer course of therapy. Antimicrobial therapy should always be administered. A shorter duration of therapy (i.e., 14 days) is appropriate for uncomplicated bacteremia (Table 296-2). Longer courses of 4 to 6 weeks are recommended for the treatment of endocarditis or bacteremia complicated by slow resolution or the presence of metastatic infection.

Endocarditis

S. aureus is the leading cause of endocarditis (Chapter 76), accounting for approximately 30% of all cases. Most are community-acquired infections, often occurring as a complication of injection drug use. The number of health care–associated infections has been increasing in recent years; risk factors are diabetes mellitus, hemodialysis, and presence of a prosthetic valve. The presentation is that of an acute febrile illness, with high fever developing over a few days. The patient may appear toxic and septic. A source of infection may not be evident at first; a minority of patients have an associated infection of bone, joint, or skin and soft tissue. The aortic and mitral valves are most commonly involved, except in injection drug users (discussed later); however, a pathologic murmur may not be evident when the patient first presents. Systemic embolization to the brain, kidneys, spleen, gut, or other large vessels is clinically evident in about one third of cases. Peripheral manifestations, including Roth's spots, Osler's nodes, Janeway's lesions, and petechiae, occur with a similar frequency. Morbidity and mortality are high, in part due to the occurrence of this infection in older patients, many of whom have medical comorbidities. Strokes occur in approximately 20% of patients, and congestive heart failure occurs in 40 to 50%; 25 to 30% do not survive the initial hospitalization.

Endocarditis in injection drug users involves the tricuspid valve in approximately three quarters of cases. Patients typically have fever, cough, hemoptysis, and pleuritic chest pain as a consequence of hematogenous seeding of the lung and septic emboli from the valve. The chest radiograph may show pulmonary infiltrates; signs of consolidation or pleural effusion; or multiple, often peripheral nodular pulmonary infiltrates with cavitation, hallmark features of septic embolization (Fig. 296-1). Patients tend to be young and otherwise healthy, so mortality is relatively low—5% or less. Injection drug users can also have aortic valve or mitral valve endocarditis, in which case the presentation is similar to that described earlier. Conversely, patients who are not injection drug users may have tricuspid valve endocarditis with pulmonary findings.

Pericarditis

S. aureus is the most common cause of purulent pericarditis in children and following cardiac surgery in adults. It may occur by contamination at the time of surgery; bacteremic seeding from another site of infection; as a complication of endocarditis, paravalvular abscess, or myocardial abscess; or by direct extension of infection from pneumonia, lung abscess, or empyema. The presentation is that of acute pericarditis (Chapter 77), with fever and severe chest pain, tachycardia, and hemodynamic instability. The clinical course may be extremely rapid, terminating in septic shock or cardiac tamponade. Immediate drainage of the infected pericardial space and administration of systemic antimicrobial therapy are indicated. Needle pericardiocentesis is useful for confirming the diagnosis and providing temporary decompression of the pericardial space, but definitive therapy requires surgical or continuous tube drainage.

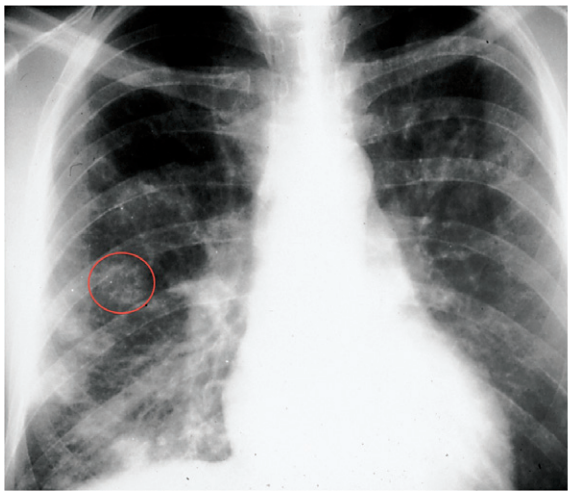

FIGURE 296-1. Chest radiograph shows multiple nodular pulmonary lesions, suggestive of septic embolization, in a patient with tricuspid valve *S. aureus* endocarditis. The red circle shows a lesion with signs of cavitation.

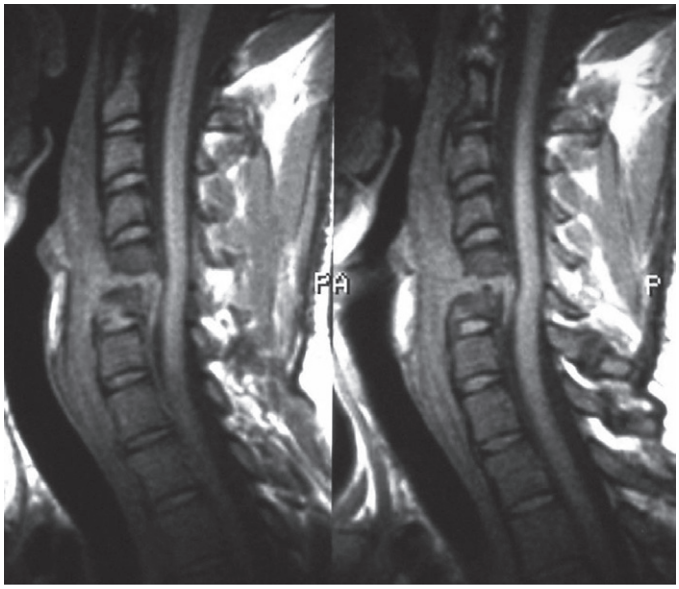

FIGURE 296-2. Noncontrast, non–fat-saturated, T1-weighted, sagittal sequence shows discitis, osteomyelitis, prevertebral and epidural abscess, and cord compression in a patient with *S. aureus* infection of the cervical spine.

Osteomyelitis

S. aureus is the most common cause of osteomyelitis, both acute and chronic (Chapter 280). The primary mode of infection is hematogenous seeding. Up to a quarter of cases of bacteremia are complicated by osteomyelitis, and bacteremia is present in 50 to 75% of osteomyelitis cases. Acute osteomyelitis—defined as an initial episode with a clinical course of days to weeks, but not months—presents with fever and pain at the site of infection. Long bones are more commonly infected in children, whereas vertebrae are more commonly infected in adults. Adults can also have long bone osteomyelitis, however, usually from a contiguous focus of infection or at a site of fracture or prior trauma. Vertebral osteomyelitis is frequently accompanied by paravertebral or epidural abscess (Fig. 296-2). Back pain accompanied by signs of cord compression, such as radicular pain, sensory loss, lower extremity weakness, urinary retention, and bowel or bladder incontinence, is an emergency. MRI should be performed as soon as possible to define the location and extent of infection, and neurosurgical consultation should be obtained in anticipation of surgical decompression and drainage.

Septic Arthritis

S. aureus is the most common cause of septic arthritis (Chapter 280), usually as a consequence of bacteremic seeding, trauma, or a surgical procedure. Risk factors include diabetes, recent joint surgery or joint prosthesis (Chapter

285), and rheumatoid arthritis (Chapter 272). Cardinal features are joint pain, history of joint swelling, and fever. The diagnosis is established by analysis of synovial fluid. The white blood cell count exceeds 25,000/mm^3, with 90% neutrophils. Organisms are usually present on Gram stain, and the culture is virtually always positive. Hip, knee, ankle, and wrist are most commonly affected. *S. aureus* also has a predilection for infecting the sternoclavicular, sacroiliac, and symphysis pubis joints. Multiple joints are involved in 5% of cases. Both antimicrobial therapy and drainage of the infected joint (by repeated needle aspiration, arthrotomy, or arthroscopically) are required to prevent destructive arthritis.

Central Nervous System Infections

S. aureus is an uncommon cause of community-acquired central nervous system infections such as bacterial meningitis, primary brain abscess, or subdural empyema. These infections are often associated with endocarditis or a contiguous focus of infection, such as cavernous sinus thrombosis. Mortality of these infections is as high as 30 to 50%. *S. aureus* is an important cause of nosocomial meningitis following head trauma, craniotomy, or implantation of intraventricular or extraventricular catheters.

Pulmonary Infections

S. aureus is an uncommon cause of community-acquired pneumonia (Chapter 97). It is typically a severe, often fatal, fulminant necrotizing pneumonia accompanied by evidence of cavitation on chest radiographs. Production of Panton-Valentine leukocidin has been associated with severe pneumonia. Community-acquired staphylococcal pneumonia should be considered, and coverage for MRSA strains should be included in the empirical regimen, in two clinical settings: severe pneumonia requiring admission to an intensive care unit, and pneumonia in a patient with influenza.

The most common hospital-acquired and ventilator-associated pneumonias are caused by *S. aureus,* and MRSA in particular. Mortality is in the range of 40 to 50%, reflecting the virulence of the organism and the comorbid conditions that contribute to poor outcomes. The diagnosis is readily established by examination of a Gram stain of sputum, tracheal aspirate, or lavage (obtained to avoid oropharyngeal contamination), which typically shows organisms and numerous neutrophils. The culture is less specific than the Gram stain because it is positive in colonized patients, but it is highly sensitive. Coverage for MRSA can be discontinued if the organism is not isolated in culture or not seen on Gram stain.

Lung abscess and pleural empyema, infections most commonly caused by oral anaerobic bacteria, are occasionally caused by *S. aureus*. The clinical course may be subacute or even indolent. Empyema occurs as a complication of prior chest tube placement, surgery, trauma, staphylococcal pneumonia, or tricuspid valve endocarditis. These infections are treated with drainage and antimicrobial therapy.

Prosthetic Device Infections

Prosthetic device– and implant-associated infections occurring within the first 12 weeks of surgery are most commonly caused by *S. aureus*. *S. aureus* is second only to coagulase-negative staphylococci as a cause of later infections. The presentation may be acute, with joint pain, evidence of arthritis, fever, and systemic signs of infection; alternatively, the infection may run a more chronic course, with pain and loosening of the prosthesis but little or no fever. Formation of biofilm makes treating these infections a challenge. In most cases, the infection is incurable if the infected hardware is not removed. Débridement and removal of the prosthesis or implant in conjunction with antimicrobial therapy offer the best chance of cure. This can be accomplished either as a one-stage procedure, in which the infected prosthesis or implant is removed and immediately replaced, or as a two-stage procedure, in which the device is removed and replaced after completion of a 4- to 6-week course of antimicrobial therapy.

Genitourinary Infections

Genitourinary infections arise by hematogenous dissemination or as an ascending infection, usually as a result of instrumentation, urinary catheterization, or surgery. These infections include cystitis, pyelonephritis, microabscess, perinephric abscess, prostatitis, and prostatic abscess. *S. aureus* can also be a contaminant introduced during the collection of urine from a patient with asymptomatic vaginal or perineal colonization. Contamination should be suspected if the urine colony counts are low, repeat urine cultures are negative, pyuria is absent, and there are no signs or symptoms of urinary tract infection. If contamination seems unlikely and there is no well-documented history of an event that could lead to ascending infection, hematogenous dissemination has to be assumed. Blood cultures should be obtained to determine whether there is ongoing bacteremia, and appropriate imaging studies should be performed to identify a deep focus of infection and the presence of renal and perinephric abscesses.

Toxin-Mediated Diseases

These diseases are caused by the ingestion of preformed toxin or the elaboration of toxin by *S. aureus* from a site of colonization or infection. Staphylococcal food poisoning is a gastroenteritis caused by the ingestion of a preformed enterotoxin produced in food contaminated by *S. aureus* from an infected or colonized food handler. When contaminated food is kept at room temperature for several hours, organisms replicate and produce a heat-stable toxin that is not inactivated by cooking or digestive enzymes. Nausea, vomiting, abdominal pain, and diarrhea occur within 2 to 6 hours of eating the contaminated food. There is no fever, and the illness is self-limited, generally lasting about a day. Antibiotics have no role in therapy, which consists of fluid replacement to prevent dehydration. Infants, small children, and the elderly are more severely affected and may require intravenous fluids.

Toxic shock syndrome is caused by colonization or infection with a strain that elaborates a specific toxin, TSST-1, or certain staphylococcal enterotoxins. TSST-1 is responsible for 100% of menstrual cases due to its ability to cross the vaginal mucosa and achieve systemic concentrations. TSST-1 and the staphylococcal enterotoxins SEA, SEB, and SEC are responsible for nonmenstrual toxic shock syndrome, which is characteristically associated with an identifiable focus of infection, usually of the skin. The diagnosis is clinical, defined by fever, erythroderma, hypotension, involvement of three of more organ systems (renal, hematologic, hepatic, pulmonary, gastrointestinal, muscle, central nervous system, mucous membranes), and desquamation, especially of the palms and soles, 1 to 2 weeks after the onset of illness. Bacteremia is rare, present in only 5% of cases. The case fatality rate is about 5%. Treatment consists of systemic antimicrobial therapy, removal of the source of toxin production, and treatment of septic shock (streptococcal toxic shock syndrome is discussed in Chapter 298).

Colonization or infection with an *S. aureus* strain that produces exfoliative toxin A or B may cause staphylococcal scalded skin syndrome, a disease primarily of infants but occasionally seen in adults (Fig. 296-3), and bullous impetigo, a pustular skin lesion. The appearance is that of a scald, burn, or blister. The differential diagnosis of staphylococcal scalded skin syndrome includes drug reaction (Chapter 448), toxic epidermal necrolysis (Chapter 447), Kawasaki disease (Chapter 447), and pemphigus foliaceus (Chapter 443).

DIAGNOSIS

S. aureus infection is diagnosed by isolating the organism in cultures of blood, tissue, or pus. Non–culture-based methods such as nucleic acid amplification tests are becoming available, but their utility is still being defined; culture remains the "gold standard." Gram stain is very useful for making a presumptive diagnosis of staphylococcal infection and should be performed whenever possible to look for gram-positive cocci in tetrads or clusters in pus, bone or tissue samples, respiratory secretions, or body fluids such as cerebrospinal

FIGURE 296-3. Scalded skin–type lesions with multiple ruptured bullae and desquamation in a patient with aortic valve endocarditis caused by an exfoliative toxin–producing strain of *S. aureus*.

fluid, pleural or pericardial fluid, synovial fluid, or urine. Failure to isolate the organism in culture is strong evidence against *S. aureus* infection unless a patient is being actively treated with an antibiotic; even then, several days of therapy would be needed to render an infected site culture negative. The specificity of isolating *S. aureus* from blood or other sterile body sites is essentially 100%. Because of nasopharyngeal colonization in some uninfected individuals, isolation of *S. aureus* from culture of a respiratory specimen lacks specificity; however, if Gram stain also shows gram-positive cocci in tetrads and clusters and many neutrophils, this is very suggestive of *S. aureus* pneumonia.

Susceptibility Testing

Susceptibility testing should be performed for clinically significant isolates to guide antimicrobial therapy. The critical determination is whether the isolate is methicillin resistant (i.e., resistant to β-lactam antibiotics). Resistance to macrolides and fluoroquinolones is common, and these drugs should not be used to treat suspected staphylococcal infection without confirmation of in vitro susceptibility. Clindamycin is usually active, although macrolide-resistant strains that produce a ribosomal methylase, inducibly or constitutively, are cross-resistant. Tetracyclines and trimethoprim-sulfamethoxazole are active against 80 to 90% of strains. Resistance to vancomycin, daptomycin, telavancin, or linezolid, though rare, may occur, particularly when there has been prior exposure to the drug, making susceptibility testing important for these antibiotics.

TREATMENT Rx

The two principles of therapy for *S. aureus* infections are (1) elimination of focal infection and infected foreign material whenever feasible, and (2) administration of systemic antimicrobial therapy. For boils and cutaneous abscesses, incision and drainage may be all that is required. Antimicrobial therapy is indicated if the infection is not amenable to removal (e.g., cellulitis, pneumonia), drainage is impossible or inadequate, systemic signs and symptoms of infection are present, or there is invasive disease (i.e., secondary sites of infection; involvement of deep tissues, vital organs, sterile sites) and in all cases of bacteremia. An undrained focus of infection or retention of an infected foreign body is the most common reason for unsatisfactory clinical response, treatment failure, or relapse.

The most important consideration when selecting an antibiotic is susceptibility of the *S. aureus* isolate to β-lactams. A penicillinase-resistant penicillin, such as nafcillin (1 to 2 g every 4 to 6 hours IV, depending on the severity of the infection), oxacillin, or flucloxacillin, or a cephalosporin (e.g., cefazolin 1 to 2 g every 8 hours IV) is the agent of choice for the treatment of methicillin-susceptible *S. aureus* (MSSA) infections; no other antibiotic is as safe or as effective as a β-lactam. An orally administered β-lactam (e.g., dicloxacillin 500 mg four times daily or cephalexin 500 mg four times daily) is appropriate for most cutaneous infections; a parenteral agent is recommended, at least initially, for invasive infections. Only if the patient is allergic or has a serious reaction is an agent other than a β-lactam preferred for the treatment of infection caused by an MSSA strain.

Methicillin-resistant strains are cross-resistant to all currently available β-lactams, except for ceftaroline, recently FDA approved at a dose of 600 mg intravenously every 12 hours for treatment of skin and skin structure infections caused by methicillin-resistant strains. Otherwise, a β-lactam should not be used to treat infection caused by a methicillin-resistant strain or as empirical therapy when the prevalence of methicillin-resistant strains is high. The prevalence of methicillin resistance in *S. aureus* isolates from hospital-acquired and health care–associated infections in most hospitals in the United States and in many European countries is 25 to 50% or higher. MRSA also causes a substantial proportion of community-onset infections in individuals lacking other risk factors, especially in the United States. Trimethoprim-sulfamethoxazole (one or two 80/160-mg tablets twice a day), clindamycin (300 mg three times a day), and doxycycline or minocycline (100 mg twice a day) are active in vitro against most community-acquired MSSA and MRSA strains and are effective when administered orally for the treatment of skin and soft tissue infections in outpatients. Fluoroquinolones should not be used because most methicillin-resistant strains are also fluoroquinolone resistant. For invasive infections, vancomycin is still the drug of choice. It must be administered intravenously; doses of 30 to 60 mg/kg/day, adjusted based on creatinine clearance, are recommended to achieve trough serum concentrations of 15 to 20 μg/mL for patients with bacteremia, endocarditis, or other serious infections. Treatment failures are not uncommon; approximately a quarter of patients with bacteremia or endocarditis remain persistently bacteremic (≥7 days) or relapse, even when the strain is susceptible (minimal inhibitory concentration [MIC] ≤2 μg/mL) in vitro. Other than the presence of an undrained focus of infection, the reasons for this are unclear. Possible explanations include vancomycin's slowly bactericidal activity; tolerance, in which the isolate is inhibited at low concentrations but not killed; or so-called heteroresistance, in which a small fraction of the population of organisms has a higher MIC. Treatment failures have also been associated with isolates having MICs of 2 μg/mL. Isolates with intermediate susceptibility to vancomycin (MICs of 4 or 8 μg/mL) in vitro are in fact "nonsusceptible" and should be considered resistant because this is highly predictive of treatment failure. Approximately 1 to 3% of clinical isolates have intermediate susceptibility to vancomycin. Vancomycin-resistant strains (MIC >8 μg/mL) are rare. Alternatives to vancomycin include quinupristin-dalfopristin (7.5 mg/kg every 8-12 hours), linezolid (600 mg every 12 hours), daptomycin (4 mg/kg once daily for complicated skin and soft tissue infections; 6 mg/kg once daily for bacteremia,[1] although some authorities recommended higher doses of 10 mg/kg), and telavancin (10 mg/kg once daily for complicated skin and soft tissue infection).[2]

The role of combination therapy is ill defined. Aminoglycoside combination regimens have not been shown to improve outcomes, but there are good data demonstrating increased toxicity and adverse events with aminoglycoside combinations. Aminoglycoside combinations should not be used routinely; if used at all, they should be reserved for patients who have failed first-line therapy. Rifampin combination therapy may have a role in the treatment of osteomyelitis, particularly that caused by methicillin-resistant strains. Rifampin (300 to 450 mg twice daily) must always be administered in combination with a second active agent because resistance emerges rapidly during therapy.

COAGULASE-NEGATIVE STAPHYLOCOCCI

More than 30 different species of coagulase-negative staphylococci have been identified, and about half of these colonize humans. *Staphylococcus epidermidis* is the species that most commonly causes infection. Coagulase-negative staphylococci rarely cause infection unless there is a foreign body in place, and although bacteremia occurs, metastatic seeding of secondary sites of infection is distinctly uncommon. Coagulase-negative staphylococci are typically resistant to methicillin and multiple other antibiotics, and they are an important reservoir of drug-resistance elements that are horizontally transferrable to *S. aureus*. They are the most common cause of health care–associated infections overall in the United States (Chapter 290); they account for one third of central line–associated blood stream infections; and they are the second most common cause of surgical site infections, particularly when a prosthetic device or other foreign material has been implanted. Infections are often indolent, causing little in the way of fever or systemic signs of infection, but they may also be acute and life-threatening, as in the case of prosthetic valve endocarditis. Coagulase-negative staphylococci are proficient biofilm producers; consequently, débridement and removal of the infected prosthetic device or foreign body are paramount. Antimicrobial therapy of these infections is similar to that for *S. aureus*, except that hematogenous seeding rarely occurs, so attention is focused primarily on source control.

Coagulase-negative staphylococci, because they are normal skin flora, are the most common blood culture contaminant. In approximately 75% of cases, when the blood culture is positive for coagulase-negative staphylococci, this reflects contamination rather than infection. Sorting out whether a positive culture represents contamination or true infection can be a challenge. A single positive blood culture or blood cultures in which more than one strain is present are likely to be due to contamination. Time to blood culture positivity, quantitative blood cultures, and the presence of multiple positive cultures can be useful in determining whether a positive blood culture represents true infection. Isolation of coagulase-negative staphylococci from the blood of a patient with a prosthetic valve, intravenous pacemaker, or vascular graft can be especially problematic because these patients are at high risk for true infection. Unless the patient is hemodynamically unstable or otherwise seriously ill, it is advisable to withhold antibiotics until additional cultures are obtained to document the presence of true bacteremia. Isolation of coagulase-negative staphylococci from cultures of deep tissue, bone, prosthetic devices, or other normally sterile sites, especially if multiple cultures are positive, strongly suggests true infection.

PREVENTION

The emergence of community MRSA and the large burden of hospital-acquired and health care–associated staphylococcal infections have stimulated renewed interest in prevention strategies. The organisms that cause these infections are usually resident flora (either *S. aureus* or coagulase-negative staphylococci), or they are acquired by direct contact with a contaminated source, such as a wound or dressing, the skin or hands of an asymptomatically colonized individual, or a contaminated health care provider. The most effective strategy is adherence to principles of basic infection control, the key component of which is hand hygiene, whether it be

handwashing or use of an alcohol-based hand rub. This disrupts transmission of organisms via the hands of care providers, a well-documented source of bacterial contamination. Barrier precautions (gloves and gowns) are important for minimizing contact with infected wounds, contaminated secretions, and dressings. Isolation precautions and screening for asymptomatic carriage are more controversial and less well documented in terms of their efficacy. For patients undergoing surgical procedures, surgical hand and surgical site antisepsis, aseptic surgical technique, and antimicrobial prophylaxis are important preventive measures.

Screening and decolonization of *S. aureus* carriers is another potentially effective means of preventing infection. Studies to determine whether decolonization actually prevents infection, however, have had mixed results. Nevertheless, decolonization may be considered in two settings: prevention of recurrent infection in individuals who have had several prior episodes, and prevention of surgical site infections. The best-studied regimens are topically applied mupirocin nasal ointment (0.5 g twice daily in each nostril for 5 days), with or without bathing with chlorhexidine soap, and orally administered rifampin (600 mg in one or two divided doses) in combination with another active agent (e.g., a fluoroquinolone if the isolate is susceptible, trimethoprim-sulfamethoxazole, doxycycline). In a recent randomized, double-blind, placebo-controlled, multicenter trial, the number of surgical site *S. aureus* infections acquired in the hospital was reduced by the rapid screening of nasal carriers using a real-time polymerase chain reaction assay and the decolonization of carriers with mupirocin nasal ointment and chlorhexidine soap.■ Several antistaphylococcal vaccine candidates are currently in phase I and phase II clinical trials; the availability of an effective vaccine would be an important tool in preventing staphylococcal infections.

STREPTOCOCCUS PNEUMONIAE INFECTIONS

LIONEL A. MANDELL

DEFINITION

The term *pneumococcal pneumonia* refers to infection of the pulmonary parenchyma and its associated structures by *Streptococcus pneumoniae.* The estimated 500,000 cases that occur annually in the United States result in approximately 50,000 deaths.

The Pathogen

S. pneumoniae is a gram-positive coccus that typically grows in pairs or short chains. Careful examination of the diplococcal form reveals slightly tapered ends that give rise to its lancet-shaped appearance. It is a facultative anaerobe that grows best on blood agar plates in a 5% carbon dioxide ambient environment. The colonies are typically surrounded by a greenish zone of hemolysis resulting from degradation of hemoglobin by a pneumococcal toxin. The organism can be distinguished from other streptococci by its susceptibility to ethyl hydrocuprein (optochin) and bile solubility.

The surface of the pneumococcus consists of a capsule and a cell wall. The capsule, which helps prevent phagocytosis, is composed of polysaccharides that define the 90 pneumococcal serotypes. The cell wall is a dynamic structure composed of more than a dozen distinct glycopeptides.

EPIDEMIOLOGY

The pneumococcus causes about two thirds of cases of community-acquired pneumonia (CAP) and is responsible for a corresponding percentage of deaths; it can cause hospital-acquired and health care–associated pneumonia as well. The false impression that *S. pneumoniae* is uncommon has arisen because at least one third of patients with CAP are unable to produce sputum and, even if they do, often provide an inadequate sample. Moreover, if the patient has recently taken just one dose of a drug to which the pneumococcus is susceptible, it may not be possible to isolate the organism.

The ecologic niche of the pneumococcus is the nasopharynx, and up to 80% of infants and 20% of healthy adults may be colonized. Simultaneous colonization with more than one capsular type has been reported. Asymptomatic colonization is an immunizing experience because homologous anticapsular antibodies may be demonstrated in individuals after colonization with a specific serotype.

A particular serotype may colonize the nasopharynx for varying periods, but the average duration in infants is 7 weeks. Carriage rates are highest during the late fall, winter, and early spring. Although each of the 90 serotypes is potentially pathogenic, the most frequently encountered are types 3, 4, 6, 7, 9, 12, 14, 18, 19, and 23.

Person-to-person transmission results from close interpersonal contact. Although pneumococcal pneumonia is typically a sporadic illness, epidemics can occur in crowded settings such as daycare centers, barracks, nursing homes, or prisons.

The incidence of pneumococcal pneumonia is about 18 per 100,000 people per year. For persons 5 years or younger and 75 years or older, rates are about 23 and 35.8 per 100,000 people, respectively. For pneumococcal bacteremia, the incidence is about 7.5 per 100,000 people per year and increases with age; the case-fatality rate is 21%.

Risk factors for pneumococcal pneumonia include dementia, seizure disorders, heart failure, cerebrovascular disease, chronic obstructive pulmonary disease, human immunodeficiency virus (HIV) infection, previous viral respiratory illness, alcoholism, malnutrition, diabetes, cirrhosis, and renal insufficiency.

Certain ethnic groups such as Native Americans, particularly Alaskan natives, and Australian Aboriginals appear to be particularly susceptible to invasive pneumococcal infection. Any individual who has a defect in immunoglobulin G (IgG) synthesis (Chapter 258) or phagocyte function (Chapter 172) or who has undergone splenectomy is also at increased risk for invasive pneumococcal infection.

PATHOBIOLOGY

Pneumonia is the result of a breakdown in the interplay between colonizer and host. In pneumococcal pneumonia, the microorganism first colonizes the nasopharynx. Aspiration of small amounts of oropharyngeal contents occurs in deep sleep, even in normal individuals, but if the oropharyngeal material includes pneumococcal serotypes associated with invasive infection and if normal clearance mechanisms fail, the colonizers may become pathogens. The risk for infection is increased by any process or condition that exposes the host to the pathogen, that allows oropharyngeal secretions to bypass upper airway defenses, or that interferes with the host's ability to ingest and kill the pneumococci (Table 297-1).

It appears that aspirated pneumococci adhere to type II cells in the alveolus if they are not cleared by normal defense mechanisms. Attachment to resting cells is mediated by two classes of glycoconjugates, but local inflammatory mediators upregulate host cell receptors, such as those for platelet-activating factor (PAF), and provide a site of attachment for the bacteria. This interaction between PAF receptor and pathogen appears to be an important step in internalization of the bacteria by means of an endocytic vacuole and may promote invasion.

Once in the lung, the pneumococci are able to activate complement and stimulate the cytokine response. Initially, the alveoli fill with fluid exudate

Note intact alveolar walls and alveoli filled with edema and thick cellular exudates. **B,** Higher magnification (× 500) H&E stain of same section shown in **A.** Note heavy infiltrate of polymorphonuclear cells and intact alveolar walls.

(Fig. 297-1), which allows the infection to spread to adjacent uninfected alveoli. In healthy lungs, polymorphonuclear leukocytes (PMNs) constitute less than 1 to 2% of alveolar cells and normally reside in the interstitial areas of the lung and in adjacent capillaries. Recruitment of PMNs into alveoli depends on the generation of chemoattractants necessary for the directed migration of neutrophils.

The pneumococcal polysaccharides of the bacterial capsule help the organism resist phagocytosis, and absence of anticapsular antibody limits the ability to opsonize and ingest pathogens. Ultimately, the signs and symptoms of disease are due both to the pathogens themselves and to the body's response to them. The bacterial cytotoxin pneumolysin and pneumococcal cell wall components, such as teichoic acid and peptidoglycan, are able to induce a variety of effects that initiate and then enhance the inflammatory response, thereby resulting in the various signs and symptoms of pneumonia.

The effects of pneumococcal infection are ultimately manifested as changes in lung mechanics secondary to reductions in lung volumes and lung compliance, as well as gas exchange problems resulting from intrapulmonary shunting and subsequent arterial hypoxemia. If severe enough, death may ensue.

Antibiotic Resistance

The phenotypic expression of antibiotic resistance corresponds to genetic alterations resulting from horizontal acquisition of foreign genetic information or from mutations in the microbial genome. With *S. pneumoniae,* resistance may be acquired by direct DNA incorporation and remodeling from closely related oral commensal bacteria by the process of natural transformation. Pneumococcal resistance to β-lactams such as penicillin is due solely to the presence of low-affinity penicillin-binding proteins (PBPs). The PBPs themselves are *trans* and carboxypeptidase enzymes that are involved in bacterial cell wall synthesis and represent the primary sites of action for β-lactam drugs.

Resistance to macrolides, in contrast, can occur through multiple mechanisms, including target site modification or an efflux pump. Target site modification is caused by a ribosomal methylase encoded by the *ermB* gene. A change in 23S recombinant RNA mediated by this gene can result in resistance to macrolides, lincosamides, and streptogramin B–type antibiotics (MLS_B phenotype). The efflux mechanism is encoded by the *mefA* gene, which results in an M phenotype. The former is typically associated with high-level resistance with minimal inhibitory concentrations (MICs) of 64 μg/mL or higher, whereas the latter is usually associated with low-level resistance with MICs of 1 to 32 μg/mL. These two mechanisms account for approximately 45 and 55%, respectively, of resistant isolates. Some pneumococcal isolates have been found with both the *erm* and *mef* gene, but the significance of such a finding is unknown.

Resistance to fluoroquinolones may be mediated by changes in one or both target sites (topoisomerase II and IV), which usually result from mutations in the *gyrA* and *parC* genes, respectively. An efflux pump may have a role as well. Of concern is the fact that the incidence of multidrug-resistant isolates is increasing.

CLINICAL MANIFESTATIONS

The clinical features of pneumococcal pneumonia depend on factors such as whether the patient is immunocompetent or immunosuppressed, the severity of illness, and whether the patient has taken antibiotics. Temperatures can vary from 101° F to higher than 103° F (38 to 39.5°C), can be accompanied by chills and rigors, and are usually associated with a tachycardic response. A cough, typically productive of purulent and occasionally blood-tinged sputum, is often present, and as many as 46% of patients report chest pain. About 20% have gastrointestinal symptoms such as nausea, vomiting, or diarrhea. In elderly people, symptoms and signs may be more subtle; for example, older patients may have predominantly confusion.

On examination, the patient is often listless and may be cyanotic. The respiratory rate is increased; if pleuritic pain is marked, the patient may be splinting the affected side. Dullness to percussion over a lung segment suggests consolidation, whereas a flat percussion note is typically associated with a pleural effusion. Breath sounds may be "distant" if there is an overlying effusion, but they are bronchial in nature if the underlying lung is consolidated. Rales may be noted. If the patient has pleurisy without much pleural fluid, a friction rub may be heard.

No radiographic appearance is characteristic of pneumococcal pneumonia (Chapter 97). Typically, however, involvement is limited to one or more segments within a single lobe. Involvement is unilateral approximately 80% of the time, and the presence of cavitation or lung abscess is uncommon. Forty-five percent of patients have an associated pleural effusion, but only 15% have an effusion of sufficient size to warrant drainage (>10 mm on lateral decubitus views).

Patients with lobar consolidation are more likely to be bacteremic, but there are no consistently significant differences in the radiologic manifestations of bacteremic and nonbacteremic pneumococcal pneumonia. Bacteremic pneumococcal pneumonia may seed distant sites and cause meningitis (Chapter 420), endocarditis (Chapter 76), or septic arthritis (Chapter 280).

With sepsis, sepsis syndrome, or septic shock (Chapter 108), the patient may be hypotensive, and the findings of organ failure vary depending on the target organ involved. For example, oliguria, anuria, and acidosis suggest renal failure; myocardial impairment suggests heart failure; and jaundice is consistent with hepatic failure. Systemic activation of coagulation together with consumption of clotting proteins can result in simultaneous clotting and bleeding (Chapter 178). In some cases, peripheral gangrene and purpura fulminans may be seen.

DIAGNOSIS

Despite extensive testing, a specific etiologic agent is not found in half or more of patients with CAP. The history, physical examination, chest radiograph, sputum Gram stain, and blood and sputum cultures are insensitive and lack specificity, whereas more invasive methods (e.g., endotracheal

TABLE 297-2 INDICATIONS FOR MORE EXTENSIVE DIAGNOSTIC TESTING

Intensive care unit admission for community-acquired pneumonia
Failure of outpatient treatment
Radiographic appearance of cavities on initial evaluation
Infection resulting in neutropenia
Alcohol abuse
Chronic severe liver disease
Severe chronic obstructive lung disease
Asplenia (anatomic or functional)
Recent travel (within 2 weeks)
Positive rapid *Legionella* species or pneumococcal urinary antigen test
Pleural effusion

aspirate, bronchoscopy techniques, pleural fluid aspiration, and lung biopsy) require special expertise and are infrequently indicated. As a general rule, routine diagnostic tests to identify a pathogen are optional for outpatients with CAP, but more extensive testing is recommended for hospitalized patients (Table 297-2).

Ultimately, the diagnosis should be based on suggestive clinical features plus a chest radiograph with or without corroborating microbiologic data. Because *S. pneumoniae* is the most common etiologic agent of CAP, virtually any recommended treatment regimen must provide adequate coverage for it, so documentation of its presence has little or no effect on ultimate clinical outcomes. From the point of view of epidemiology and antimicrobial susceptibility, however, documentation of a pathogen is desirable.

The sputum Gram stain is a relatively simple and inexpensive procedure to document the presence of certain pathogens. The adequacy of the specimen is based on the relative number of PMNs and squamous epithelial cells (SECs). There should be at least 25 PMNs and less than 10 SECs per low-power field (× 100 magnification). The sensitivity of sputum Gram stain for *S. pneumoniae* is 55%, whereas the specificity is higher than 80%. Unfortunately, approximately 30% of patients overall are unable to produce an appropriate sputum sample. In elderly patients, this figure reaches almost 70%. Overall, only 28% at best of sputum samples are of good quality. Sputum cultures are neither sensitive nor specific, particularly when dealing with relatively fastidious pathogens such as *S. pneumoniae.*

Blood cultures are positive in only 5 to 14% of patients with CAP. If patients have taken a previous dose of antibiotic, culture results are even less useful. As a result, sputum Gram stain, sputum culture, and blood cultures are generally recommended only in patients with selected clinical indications (see Table 297-2). In patients with severe CAP, an expectorated sputum sample should be replaced by an endotracheal aspirate sample if the patient is intubated.

Pneumococcus can also be detected by polymerase chain reaction (PCR), but this is not done routinely. An increased pneumococcal bacterial load demonstrated by real-time PCR is associated with an increased risk for septic shock, need for mechanical ventilation, and death, suggesting that such a test may be of help in identifying patients suitable for care in the intensive care unit. Pneumococcal capsular polysaccharide can be detected in urine, and this may occasionally be helpful for diagnosis after antibiotic therapy has been started. The overall sensitivity of the pneumococcal urinary antigen test is less than 80% but can reach 90% or higher in patients with pneumococcal bacteremia and those with high-risk pneumonia. The specificity in adult patients with CAP can exceed 95%. Detection of antibody to pneumococcal polysaccharide is not useful.

PREVENTION

Polysaccharide Vaccine

A polysaccharide vaccine contains 25 µg of each of the 23 capsular polysaccharides that account for 90% of invasive infections (Chapter 17). Polysaccharide vaccines stimulate B-cell responses, thereby resulting in type-specific antibody production that enhances ingestion and killing of the pathogens by phagocytes. The antigens, however, are T-cell independent and therefore do not result in long-lasting immunity. Two types of polysaccharide vaccine have been available—Pneumovax (Merck) and Pnu-Imune (Lederle).

The effectiveness of the pneumococcal polysaccharide vaccine ranges from 56 to 81%. It is not effective in immunocompromised patients, such as those with sickle cell disease, chronic renal failure, immunoglobulin deficiency, Hodgkin's disease, non-Hodgkin's lymphoma, leukemia, and multiple myeloma. It is also not effective in preventing nonbacteremic pneumonia. The vaccine is recommended for (1) persons 65 years or older; (2) persons 2 to 64 years old with chronic illnesses such as cardiovascular disease, chronic pulmonary disease (not asthma), diabetes mellitus, alcoholism, chronic liver disease, or cerebrospinal fluid leaks; (3) persons 2 to 64 years old with functional or anatomic asplenia; and (4) persons 2 to 64 years old living in special environments or social settings (Alaskan natives, certain Native American populations, residents of long-term care facilities).

Although the effectiveness of the vaccine is less in these subgroups, the following immunocompromised patients 2 years or older should also be immunized: (1) persons with HIV infection, leukemia, lymphoma, or Hodgkin's disease; and (2) those with multiple myeloma, generalized malignancy, chronic renal failure, nephrotic syndrome, or organ or bone marrow transplants and individuals being treated with immunosuppressive chemotherapy, including steroids.

The lack of an anamnestic response with polysaccharide vaccines means that antibody levels decrease over time and revaccination is required. Although the exact timing is unclear, most experts suggest revaccination at 5 years. For immunocompetent persons 65 years or older, a second dose is suggested if the patient was given the first vaccine 5 years earlier at an age younger than 65 years. For persons 2 to 64 years of age with asplenia, a single revaccination is suggested 5 years after the initial dose if the patient is older than 10 years. However, if the patient is younger than 10 years, revaccination should be given 3 years after the first dose. For immunocompromised patients, revaccination should be given 5 years after the first dose if the patient is older than 10 years and 3 years after the first dose if the patient is younger than 10 years.

Conjugated Vaccine

A seven-valent pneumococcal conjugate vaccine (Prevenar, Wyeth-Lederle) has also been approved for use. The basis of this newer vaccine is that pneumococcal polysaccharide is conjugated to a carrier protein, thereby producing T-cell-dependent antigens, which results in long-term immunologic memory. In this case, the carrier protein is CRM 197, which is similar to diphtheria toxoid. The seven serotypes (4, 6B, 9V, 14, 18C, 19F, 23F) are found most commonly in children and account for approximately 80% of invasive infections in children younger than 6 years. Use of this vaccine has resulted in an overall decrease in the prevalence of antimicrobial resistant pneumococci and in the incidence of invasive pneumococcal disease in both children and adults. Vaccine use can result in replacement with nonvaccine serotypes such as 19A and 35B. As a result, in 2010 the U.S. Food and Drug Administration licensed a new 13-valent pneumococcal conjugate vaccine to replace the 7-valent vaccine. For recommendations in children, see the policy statement of the American Academy of Pediatrics in Suggested Readings.

TREATMENT Rx

Empirical therapy is usually used for CAP. If pneumococcal infection can be documented, however, antibiotic therapy can be targeted against this specific pathogen.

Treatment Regimens

Directed Therapy against Known *S. pneumoniae*

S. pneumoniae can be treated with a number of antimicrobials, including various β-lactams, macrolides, and selected fluoroquinolones (Table 297-3). Resistance has been described for virtually all these agents. For nonmeningeal infections such as pneumonia, susceptibility is now defined by a penicillin MIC of 2 µg/mL or less, intermediate as an MIC of 4 µg/mL, and resistant as an MIC of more than 8 µg/mL. Multidrug-resistant pathogens, which are resistant to three or more antimicrobial agents with different mechanisms of action, have been seen in a number of countries. Risk factors for drug-resistant pneumococcal infection include recent antimicrobial therapy, age younger than 2 years or older than 65 years, attendance at a daycare center, recent hospitalization, and HIV infection.

If a good-quality Gram stain of sputum reveals sheets of PMNs with lancet-shaped gram-positive diplococci as the only organism, if the patient has no risk factors for infection with resistant *S. pneumoniae,* and if the patient is not living in an area endemic for penicillin-resistant *S. pneumoniae,* it is reasonable to initiate parenteral treatment with penicillin G, 2.4 million U/day. For outpatients, oral therapy is usually given in the form of amoxicillin, 500 mg three times daily. For infection with *S. pneumoniae* with penicillin MICs of up to 1 µg/mL, penicillin is still an appropriate agent. For strains with penicillin MICs of 2 to 4 µg/mL, data regarding efficacy are conflicting, and higher doses may be

TABLE 297-3 ANTIMICROBIAL DOSES AND FREQUENCY OF ADMINISTRATION

ANTIMICROBIAL	DOSE AND ROUTE	FREQUENCY
MACROLIDE		
Azithromycin	500 mg × 1 then 250 mg PO	q24h
Clarithromycin	500 mg PO	q12h
Erythromycin	500 mg PO	q6h

Tobramycin	1.7 mg/kg	q24h
MISCELLANEOUS		
Linezolid	600 mg PO or IV	q12h
Vancomycin	0.75-1 g IV	q12h

better. If the patient is allergic to penicillin, a macrolide such as azithromycin (500 mg on day 1, then 250 mg/day) or clarithromycin (500 mg twice daily) may be used. Five days is the minimal recommended duration of treatment of CAP that is not complicated, severe, or associated with bacteremia.

For patients who are hospitalized because of CAP, higher doses of parenteral antibiotics are generally used: penicillin in the range of 12 million U (2 to 3 million every 4 hours) or ampicillin, 4 g/day (1 g every 6 hours). Third-generation cephalosporins such as ceftriaxone (1 to 2 g every 24 hours) and cefotaxime (1 to 2 g every 8 hours) are other alternatives.

The patient can be switched to an oral regimen when cough and shortness of breath are improving, the white blood cell count is normalizing, and oral intake and gastrointestinal tract absorption are adequate. Febrile patients are frequently treated outside the hospital, so absence of a fever is not a prerequisite for switching to an oral regimen.

Some studies have suggested that initial combination antimicrobial treatment of bacteremic pneumococcal pneumonia that includes a macrolide is associated with lower mortality rates possibly because of an immunomodulatory effect of the macrolides.

Drotrecogin alfa activated (Chapters 108 and 178) used as adjunctive immunomodulatory therapy in selected cases of CAP provides a survival advantage in those with severe sepsis due to pneumococcal infection.

Empirical Treatment

This is discussed in the chapter dealing with CAP (Chapter 97).

PROGNOSIS

In an otherwise well, relatively young patient with no comorbid conditions and with mild to moderate infection, the elevated temperature and white blood cell count usually resolve by days 2 to 4 and 4, respectively. The patient looks and feels better within a few days, but it is important to keep in mind that even in patients younger than 50 years, only 60% of cases will have resolved radiologically by 1 month. In patients older than 50 years or those with more severe infection or chronic obstructive pulmonary disease, only 25% may clear radiographically by 1 month.

A patient who fails to respond or deteriorates after initial treatment must be carefully reassessed with a detailed review of the history and treatment course, plus appropriate radiographic studies and cultures. If the diagnosis is incorrect, other infectious causes of pneumonia, such as *Haemophilus influenzae* (Chapter 308) or the atypical agents (Chapter 97), must be considered. Noninfectious illnesses must also be considered: heart failure (Chapter 58), pulmonary embolism (Chapter 98), neoplasm (Chapter 197), radiation injury (Chapter 19), drug reaction (Chapter 262), and inflammatory lung disease, to name a few. If the original diagnosis was correct, metastatic infection, lung abscess (Chapter 90) or empyema, and unsuspected drug resistance must be considered. Drug factors such as errors in selection, dose, or route of administration are possible explanations, especially in patients who receive oral medication.

NONPNEUMOCOCCAL STREPTOCOCCAL INFECTIONS, RHEUMATIC FEVER

DONALD E. LOW

THE PATHOGENS

The *Streptococcus* genus contains a number of species that inhabit a broad range of hosts, including humans and domesticated animals, where they often colonize as part of the normal flora and cause infection. They are gram-positive cocci that grow in chains. The two most useful methods of classifying streptococci are by the type of hemolytic reaction displayed on blood agar on which they are grown and the serologic reactivity of the cell wall polysaccharide antigens as originally described by Rebecca Lancefield (Table 298-1). On blood agar plates, streptococci may cause complete (β), incomplete (α), or no (γ) hemolysis. Hemolytic streptococci from humans can be classified into Lancefield groups A, B, C, F, G, and L on the basis of carbohydrate antigens of the cell wall and can be subdivided into large-colony and small-colony (<0.5 mm in diameter) formers. The β-hemolytic group A and group B streptococci are considered the major pathogenic β-hemolytic

streptococci. The β-hemolytic large-colony-forming species, *Streptococcus dysgalactiae* subspecies *equisimilis,* may possess Lancefield group A, C, G, or L antigens. The small-colony-forming β-hemolytic strains with Lancefield group A, C, F, or G or no group antigens belong to the anginosus (or previously termed *Streptococcus milleri*) group. Members of the anginosus group (*Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*) are considered part of the viridans group streptococci, most of which display α-hemolytic or nonhemolytic reactions.

STREPTOCOCCUS PYOGENES (GROUP A STREPTOCOCCUS)

The most clinically significant of the streptococcal human pathogens are *Streptococcus pyogenes* (also referred to as group A streptococci), which contain the Lancefield group A antigen on their cell surface. Group A streptococcus (GAS) causes primarily infections of the upper respiratory tract and the skin. It is also responsible for a toxic shock–like syndrome, necrotizing fasciitis, and delayed nonsuppurative sequelae including acute rheumatic fever and poststreptococcal glomerulonephritis. The major virulence factor of the organism is the M protein. This protein, a stable dimer, is anchored to the cell membrane and traverses and penetrates the cell wall. The proximal portion of the molecule is highly conserved among GAS, whereas the distal portions contain type-specific epitopes localized on the tips that protrude from the cell surface. This variation in the distal region of the M proteins provides the basis of widely used epidemiologic typing schemes that employ serologic methods (M type) or nucleotide sequence analysis of the M protein gene (*emm* type). There are more than 150 distinct *emm* and *emm*-like genes recognized. Epidemiologic studies have revealed that certain disease manifestations are commonly associated with particular M types, such as M1 and M3 types, which are associated with the most severe invasive manifestations such as toxic shock syndrome and necrotizing fasciitis. Humans are the natural host, and there is no animal or environmental reservoir. The throat and skin of the human host are the principal reservoirs for GAS. GAS is transmitted primarily person to person by either contact or droplet transmission.

EPIDEMIOLOGY

All GAS infections have the highest incidence in children younger than 10 years. The asymptomatic prevalence is also higher (15 to 20%) in children than in adults. Age is not the only factor; crowded conditions in temperate climates during the winter months are also associated with epidemics of pharyngitis in school children as well as in military recruits. The peak incidence for streptococcal pharyngitis and impetigo varies with season and locale. In many temperate regions of the world, the incidence of pharyngitis peaks in winter, whereas impetigo, although less common, peaks during the summer months. In contrast, for many tropical host populations, impetigo is hyperendemic year round, whereas throat infection, whether pharyngitis or asymptomatic carriage, ranges from very low to moderate levels.

CLINICAL MANIFESTATIONS

Respiratory Tract Infections

Pharyngitis

GAS is a major cause of pharyngitis and remains the only agent of this syndrome requiring etiologic diagnosis and treatment. The burden and economic costs of GAS pharyngitis are great. It has been estimated that in the United States alone more than 7 million cases of acute pharyngitis are diagnosed by pediatricians annually. *S. pyogenes* is the cause in only 15% to 30% of them, but antibiotics are prescribed in 55% to 75% of the cases. Although a major consequence of GAS pharyngitis, acute rheumatic fever (see later), is much less common now than in the past, it is still a considerable problem in the developing world. The World Health Organization (WHO) estimates that there are about half a million cases of acute rheumatic fever worldwide annually. On clinical grounds, streptococcal pharyngitis (Fig. 298-1) is strongly suggested by the presence of fever, tonsillar exudate, tender enlarged anterior cervical lymph nodes, and absence of cough.

TABLE 298-2 SCORE FOR USE IN BOTH CHILDREN AND ADULTS WITH SORE THROAT TO ESTIMATE PROBABILITY OF POSITIVE CULTURE AND GUIDE MANAGEMENT APPROACH

Diagnostic Criteria		*Management*		
FINDINGS	POINTS	SCORE	RISK FOR STREPTOCOCCAL INFECTION	RECOMMENDATION
Temperature >38° C	+1	≤0	1 to 2.5%	No culture or antibiotics
Absence of cough	+1	1	5 to 10%	
Swollen, tender anterior cervical nodes	+1	2	11 to 17%	Culture: antibiotics only if culture positive
Tonsillar swelling or exudate	+1	3	18 to 35%	
Age		≥4		Antibiotics
3 to 14 yr	+1			
>44 yr	−1			

Adapted from McIsaac WJ, Kellner JD, Aufricht P, et al. Empirical validation of guidelines for the management of pharyngitis in children and adults. *JAMA*. 2004;291:1587-1595.

Because these findings are nonspecific and commonly found in cases of viral origin, however, even experienced physicians may accurately diagnose streptococcal pharyngitis based on the clinical findings alone in no more than 75% of the cases. Treatment of suspected GAS pharyngitis at the time of initial clinical evaluation has only a modest effect on relieving acute symptoms and perhaps on preventing suppurative complications. However, antibacterial treatment may be delayed for several days and still achieve the goal of preventing rheumatic fever and spread of disease. Prospective studies to compare the impact of various pharyngitis management strategies on clinically relevant outcomes have been recommended. A particular focus of recent guidelines has been to reduce overall use of antibiotics for treatment of pharyngitis in both children and adults in order to limit antibiotic resistance (Table 298-2).

Throat culture is the conventional method for establishing the diagnosis of GAS pharyngitis. In an untreated patient with GAS pharyngitis, a properly obtained throat culture (by vigorous swabbing of both tonsils and posterior pharynx) is almost always positive; however, a positive throat culture may reflect chronic colonization by GAS, and the acute illness may

be caused by another agent. Quantitation of GAS from the throat swab culture cannot be used to differentiate carriage from infection because sparse growth may be associated with true infection. A negative throat culture permits the physician to withhold antibiotic therapy from most patients with sore throats.

Many GAS antigen detection tests are available commercially. These tests vary in method. Most of these tests have a high degree of specificity, but their sensitivity in clinical practice can be unacceptably low. Therefore, treatment is indicated for the patient with acute pharyngitis who has a positive rapid antigen detection test.

Otitis Media and Rhinosinusitis

During the past several decades, a number of studies have reported isolation of GAS from 2 to 5% of cultures of middle ear fluid specimens obtained from children with acute otitis media (AOM). Thus, in contrast to the very striking role of GAS as the major bacterial agent of acute pharyngitis, GAS has been fairly consistently the fourth most predominant pathogen causing pediatric AOM, after *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.* GAS AOM is associated with increased risk for development of mastoiditis. Although the risk is small (<1%), it is much greater than with AOM due to *S. pneumoniae, H. influenzae,* or *M. catarrhalis.* GAS is the etiologic agent of acute bacterial rhinosinusitis in 2 to 7% of cases.

Pneumonia

The occurrence of pneumonia has increased with the resurgence of invasive GAS disease during the past several decades, with 10% of patients with invasive GAS disease presenting with pneumonia. Small outbreaks of GAS pneumonia have been described in chronic care facilities and within families, as well as sporadic cases occurring in the community. GAS pneumonia now occurs with a frequency similar to that of other well-recognized causes, such as *Staphylococcus aureus* or *Klebsiella pneumoniae*. A Canadian population-based surveillance program of invasive GAS disease confirmed that GAS pneumonia is a severe illness of sudden onset frequently associated with local and systemic complications, particularly empyema (19%), toxic shock (32%), and death (38%).

Skin and Soft Tissue Infections

Scarlet Fever

Scarlet fever is a diffuse erythematous eruption that generally occurs in association with pharyngitis, most commonly in children 5 to 15 years of age. Development of the scarlet fever rash requires prior exposure to *S. pyogenes* and occurs as a result of delayed-type skin reactivity to pyrogenic exotoxin (erythrogenic toxin, usually types A, B, or C) produced by the organism. The rash of scarlet fever is a diffuse erythema that blanches with pressure, with numerous small (1 to 2 mm) papular elevations, giving a sandpaper quality to the skin. It usually starts on the head and neck and is accompanied by circumoral pallor and a strawberry tongue. Subsequently, the rash expands rapidly to cover the trunk, followed by the extremities, and then ultimately desquamates; the palms and soles are usually spared. The rash is most marked in the skinfolds of the inguinal, axillary, antecubital, and abdominal areas and about pressure points. It often exhibits a linear petechial character in the antecubital fossae and axillary folds, known as Pastia's lines.

Erysipelas

Erysipelas is an acute, superficial, non-necrotizing dermal or hypodermal infection that is mainly caused by streptococci. The definitive diagnosis is based on clinical findings that usually include a sharply demarcated shiny erythematosus plaque associated with pain, swelling, and fever. Erysipelas affects predominantly adult patients in the sixth or seventh decade and is located on the lower limb in more than 80% of cases. A female predominance exists, except in young patients. Risk factors include disruption of the cutaneous barrier (leg ulcer, wound, fissured toe-web intertrigo, and pressure ulcer), lymphedema, chronic edema, or local surgical operations (lymph node dissection, saphenectomy). Toe-web intertrigo appears to be a major portal of entry whether or not due to dermatophytes. Erysipelas is less commonly caused by group B, C, or G streptococci and rarely by staphylococci. Bulla formation is considered as a relatively severe but frequent local complication of the disease. Although most cases of erysipelas are caused by β-hemolytic streptococci, many other bacteria can produce non-necrotizing cellulitis, which can often occur in particular circumstances, such as *Pasteurella multocida* following cat or dog bites, *Aeromonas hydrophila* following immersion in fresh water, *Vibrio* species after saltwater exposure, or *H. influenzae* in periorbital cellulitis in children. Recurrence is the main complication of erysipelas; it occurs in about 20% of cases. Measures to reduce recurrences of erysipelas include treatment of any predisposing factor, such as toe-web intertrigo or wound, and reducing any underlying edema. If frequent infections occur despite such measures, prophylactic antibiotics may be warranted.

Impetigo

Impetigo is a highly contagious infection of the superficial epidermis that most often affects children 2 to 5 years of age, although it can occur in any age group. Impetigo is classified as bullous or nonbullous impetigo; the latter is the most common form. Bullous impetigo simply means that the skin eruption is characterized by bullae (blisters). The infection usually heals without scarring, even without treatment. *S. aureus* is the most important causative organism, especially in bullous impetigo. GAS causes fewer cases, either alone or in combination with *S. aureus,* and is more often found in nonbullous impetigo. The diagnosis usually is made clinically and can be confirmed by Gram stain and culture, although this is not usually necessary. Culture may be useful to identify patients with nephritogenic strains of GAS during outbreaks of poststreptococcal glomerulonephritis. Impetigo usually is transmitted through direct contact. Patients can further spread the infection to themselves or others after excoriating an infected area. Infections often spread rapidly through schools and daycare centers.

The Cochrane Collaboration reviewed interventions for impetigo. There was little evidence found for the use of disinfecting measures, such as chlorhexidine. There was good evidence that topical mupirocin and topical fusidic acid are equally or more effective than oral antibiotics for people with limited disease. Fusidic acid and mupirocin were of similar efficacy. It was found to be unclear whether oral antibiotics are superior to topical antibiotics for people with extensive impetigo.

Cellulitis

Bacterial cellulitis refers to a diffuse, spreading skin infection. Associated regional lymphadenopathy and lymphatic streaking are variable, and local complications (abscesses, necrosis) are more frequent than in erysipelas. Petechiae and ecchymoses with frequent bullae may develop in inflamed skin resulting in hemorrhagic cellulitis. Cellulitis usually refers to a more deeply situated skin infection than erysipelas. However, the distinction between these entities is not clear-cut, and the two conditions share the typical clinical features, including sudden onset, usually with a high fever, and the tendency to recur. GAS has been considered the main causative agent of cellulitis, although groups B, C, and G streptococcus and *S. aureus* can also be a cause.

The predominant infection site for cellulitis is on the lower extremities. Lymphedema and disruption of the cutaneous barrier, which serves as a site of entry for the pathogens, are risk factors for infections. Twenty to 30% of patients have a recurrence during a 3-year follow-up period. Blood cultures are positive for β-hemolytic streptococci in less than 5% of cases.

Invasive Group A Streptococcus Disease

Invasive disease is defined as the isolation of GAS from an otherwise sterile site. Since the late 1980s, a resurgence of severe invasive infections due to GAS, including streptococcal toxic shock syndrome and necrotizing fasciitis, has been reported worldwide. Both manifestations are associated with high morbidity and mortality. The clinical spectrum of disease may vary from mild to severe, resulting in streptococcal toxic shock or necrotizing fasciitis, or both.

Toxic Shock Syndrome

Streptococcal *toxic shock syndrome* is defined as hypotension accompanied by multiple organ failure, indicated by two of the following signs: renal impairment, coagulopathy, liver involvement, adult respiratory distress syndrome, a generalized rash, and soft tissue necrosis. In contrast to the other major form of toxic shock syndrome that is caused by toxin-producing *S. aureus* (Chapter 296), in which blood cultures are positive in less than 5% of cases, most (60%) patients with streptococcal toxic shock syndrome have positive blood cultures. A focus of infection in staphylococcal toxic shock syndrome, if present at all, tends to be superficial, a complication of surgical wounds or burns or a foreign body (e.g., tampons). Streptococcal toxic shock syndrome can originate from an unknown focus or from a deep-seated soft tissue infection (e.g., necrotizing fasciitis, myositis, cellulitis). Mortality rates are much

higher with streptococcal than staphylococcal toxic shock, reported at up to 80% when associated with myositis.

Necrotizing Fasciitis

Necrotizing fasciitis is defined by infection of the subcutaneous tissue and fascia that often results in necrosis with relative sparing of the underlying muscle. Histopathology demonstrates both necrosis of superficial fascia and polymorphonuclear infiltrates as well as edema of the reticular dermis, subcutaneous fat, and superficial fascia. GAS organisms in this disorder secrete proteases that disrupt host tissue and exotoxins that can cause local tissue injury or systemic manifestations as the result of an excessive and inappropriate inflammatory response leading to a life-threatening infection.

In the early stages of necrotizing fasciitis due to GAS, the clinical findings can be nondescript, with as many as one third of patients initially being given a diagnosis other than necrotizing fasciitis. The only feature that might alert the clinician is a complaint of pain out of proportion to that expected on examination, even for those patients who report previous trauma to the area. Necrotizing fasciitis has been found to occur more frequently during the winter months and in older men. More then half of patients give a history of an antecedent skin lesion or injury at the site of infection. In adults, most cases occur in persons with at least one chronic underlying illness, and in children, the most frequent underlying illness is an infection due to varicella-zoster virus (Chapter 383). The most common primary site of infection is the lower extremity, followed by the upper extremity, trunk, and groin or perineum.

Streptococcal exotoxins, which are superantigens, have been recognized as central mediators of the systemic effects associated with severe GAS infections. As superantigens, they have the ability to stimulate a large proportion of the T-cell population and yield an intense, uncontrolled immune response with excessive amounts of cytokines, leading to hyperinflammation, tissue destruction, and shock syndrome. Twelve distinct superantigens produced by GAS have been identified, and many GAS strains harbor genes encoding four to six different superantigens. The magnitude of the inflammatory response is determined by the patient's human leukocyte antigen (HLA) class II type. Another important risk factor for invasive GAS infections is lack of opsonic anti-M1 protein and neutralizing antisuperantigen antibodies.

Treatment of either streptococcal toxic shock or necrotizing fasciitis has not been critically studied because of the low incidence of disease and difficulty in patient recruitment for clinical trials. The importance of aggressive surgical treatment with adequate débridement or amputation has been based on observational studies of patients with necrotizing fasciitis due to a number of different etiologies and underlying diseases. The finding that lack of protective antibodies against streptococcal M protein and superantigens correlates with risk for developing invasive streptococcal diseases, highlights the importance of antibodies in protection against these infections, and suggests that intravenous immune globulin might be a potential adjunctive therapy. Intravenous immune globulin exhibits high polyspecificity generated by antibodies pooled from several thousands of donors and has been shown to contain broad-spectrum antibodies against streptococcal superantigens and M proteins. In addition, intravenous immune globulin has a general anti-inflammatory effect due in large part to Fc receptor–mediated mechanisms. The documentation of clinical efficacy of intravenous immune globulin includes several case reports and two observational cohort studies, one case-control study, and one multicenter placebo-controlled trial.

Nonsuppurative Sequelae of Streptococcal Infections

Acute Rheumatic Fever

Acute rheumatic fever is a delayed, nonsuppurative sequela of a pharyngeal infection with the GAS. Following the initial pharyngitis, a latent period of 2 to 3 weeks occurs before the first signs or symptoms of acute rheumatic fever appear. The disease presents with various manifestations that may include arthritis, carditis, chorea, subcutaneous nodules, and erythema marginatum. In developing areas of the world, acute rheumatic fever and rheumatic heart disease are estimated to affect nearly 20 million people and are the leading causes of cardiovascular death during the first five decades of life. Worldwide, there are 470,000 new cases of rheumatic fever and 233,000 deaths attributable to rheumatic fever or rheumatic heart disease each year; most occur in developing countries and among indigenous groups. The observation in some studies that only a few M serotypes (types 3, 5, 6, 14, 18, 19, 24, and 29) were implicated in outbreaks of rheumatic fever suggested a particular "rheumatogenic" potential of certain strains of GAS. The decrease in the incidence of acute rheumatic fever in developed countries with the replacement of rheumatogenic types by nonrheumatogenic types is not solely responsible for the decrease in acute rheumatic fever, and the issue of potential rheumatogenic strains remains unresolved. A streptococcal strain capable of causing a well-documented pharyngitis almost always is potentially capable of causing rheumatic fever. The lack of specific rheumatogenic strains also can explain the relatively high risk for recurrent disease with new streptococcal infections, in contrast to poststreptococcal glomerulonephritis, in which only a few "nephritogenic" strains appear to be capable of inducing the disease (e.g., type 12 with pharyngitis and type 49 with impetigo), and recurrent disease is uncommon.

Modified Jones criteria were first published in 1944 to be able to define persons with acute rheumatic fever. They have been periodically revised by the American Heart Association in collaboration with other groups. According to revised Jones criteria, the diagnosis of rheumatic fever can be made when two of the major criteria, or one major criterion plus two minor criteria, are present along with evidence of streptococcal infection. Exceptions are chorea and indolent carditis, each of which by itself can indicate rheumatic fever. Major criteria include the following:

1. Migratory polyarthritis: a temporary migrating inflammation of the large joints, usually starting in the legs and migrating upward
2. Carditis: inflammation of the heart muscle, which can manifest as congestive heart failure, pericarditis with a rub, or a new heart murmur
3. Subcutaneous nodules: painless, firm collections of collagen fibers over bones or tendons, commonly appearing on the back of the wrist, the outside elbow, and the front of the knees
4. Erythema marginatum: a long-lasting rash that begins on the trunk or arms as macules and spreads outward to form a snakelike ring while clearing in the middle. This rash never starts on the face, and it is made worse with heat.
5. Sydenham's chorea (St. Vitus's dance): a characteristic series of rapid movements of the face and arms without purpose, generally occurring late in the disease

Minor criteria include the following:

1. Fever
2. Arthralgia: joint pain without swelling
3. Raised erythrocyte sedimentation rate or C-reactive protein
4. Leukocytosis
5. Electrocardiogram showing features of heart block, such as a prolonged PR interval
6. Supporting evidence of streptococcal infection: elevated or rising antistreptolysin O titer or anti-DNAse B
7. Previous episode of rheumatic fever or inactive heart disease

The pathogenic mechanisms that lead to the development of acute rheumatic fever remain incompletely understood. Clearly, streptococcal pharyngeal infection is required, and genetic susceptibility may be present. On the other hand, evidence is sparse that toxins produced by the streptococcus are important. Molecular mimicry is thought to play an important role in the initiation of the tissue injury. As a result of molecular mimicry, antibodies directed against GAS antigens cross-react with host antigens. In addition to the role of antibody, observations suggest a role for cellular immunity in molecular mimicry.

Primary prevention of acute rheumatic fever is accomplished by proper identification and adequate antibiotic treatment of GAS tonsillopharyngitis. Diagnosis of GAS pharyngitis is best accomplished by combining clinical judgment with diagnostic test results, the criterion standard of which is the throat culture. Penicillin (either oral penicillin V or injectable benzathine penicillin) is the treatment of choice because it is cost-effective, has a narrow spectrum of activity, and has long-standing proven efficacy. In addition, GAS resistant to penicillin has not been documented. For penicillin-allergic individuals, acceptable alternatives include a narrow-spectrum oral cephalosporin, oral clindamycin, or various oral macrolides. The individual who has had an attack of rheumatic fever is at very high risk of developing recurrences after subsequent GAS pharyngitis and needs continuous antimicrobial prophylaxis to prevent such recurrences (secondary prevention). The recommended duration of prophylaxis depends on the number of previous attacks, the time elapsed since the last attack, the risk for exposure to GAS infections, the age of the patient, and the presence or absence of cardiac involvement. Penicillin is again the agent of choice for secondary prophylaxis, but sulfadiazine or a macrolide is an acceptable alternative in penicillin-allergic individuals.■

Post-streptococcal Reactive Arthritis

The term *poststreptococcal reactive arthritis* was first used to describe patients with arthritis after documented GAS infection but who failed to meet the Jones criteria for the diagnosis of acute rheumatic fever. Since then, the differentiation of post-streptococcal reactive arthritis from acute rheumatic fever has remained unsettled. Compared with acute rheumatic fever, the arthritis of post-streptococcal reactive arthritis is more likely to occur within 10 days after infection, be symmetrical and nonmigratory, last longer than 3 weeks, and be poorly responsive to aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs). Periarticular findings, such as tenosynovitis, have not been considered to be part of the clinical spectrum of acute rheumatic fever but have been described with poststreptococcal reactive arthritis. However, some studies have reported that an additive and prolonged pattern of arthritis, as well as aspirin unresponsitivity, may be seen in 19 to 36% of patients with acute rheumatic fever. Some have suggested that patients with higher erythrocyte sedimentation rate, C-reactive protein, and shorter duration of joint symptoms after NSAID therapy, and without relapse when NSAIDs were stopped, were diagnosed as having acute rheumatic fever rather than post-streptococcal reactive arthritis. Although all patients with post-streptococcal reactive arthritis have serologic evidence of a recent GAS infection, no more than half of these patients who have a throat culture performed have GAS isolated. Because a small proportion of patients with poststreptococcal reactive arthritis have been reported to develop subsequent valvular heart disease, these patients should be observed carefully for several months for clinical evidence of carditis. If valvular disease is detected, the patient should be classified as having had acute rheumatic fever and should continue to receive secondary prophylaxis.

Post-streptococcal Glomerulonephritis

Acute post-streptococcal glomerulonephritis (PSGN) is a disease characterized by the sudden appearance of edema, hematuria, proteinuria, and hypertension (Chapter 123). It is now known to follow infection by nephrogenic strains of GAS; M types 1, 2, 4, 12, 18, 25, 49, 55, 57, and 60. These may cause skin or throat infections, but specific M types, such as 49, 55, 57, and 60, are most commonly associated with skin infections. In addition, nontypeable GAS is frequently isolated from the skin or throat of patients with glomerulonephritis, representing presumably unclassified nephritogenic strains. The overall risk of developing acute PSGN after infection by these nephritogenic strains is about 15%. The risk for nephritis may also be related to the M type and the site of infection. The risk of developing nephritis infection by M type 49 is 5% if it is present in the throat. This risk increases to 25% if infection by the same organism is present in the skin. The time lapse between infection and onset of PSGN symptoms is typically 1 to 3 weeks following a throat infection and 3 to 6 weeks after a skin infection.

The pathogenic mechanism of PSGN remains largely unknown (Chapter 123). Diffuse glomerular hypercellularity, C3 and immunoglobulin G (IgG) deposition, as well as proteinuria and hematuria are cardinal features. However, it can occur without all these signs present concurrently. For a reliable diagnosis of PSGN, clear evidence that a streptococcal infection preceded the glomerulonephritis is required. However, streptococcal infection has often cleared by the time the patient appears in the clinic because the symptoms generally arise 1 to 3 weeks after the patient was infected. Acute PSGN most often follows upper respiratory tract GAS infections in colder climates and skin infections in warmer climates. Occasionally, it may also be seen following group C or G streptococcal infections. A high incidence of PSGN is noted in other parts of the world, especially in areas with tropical climates where skin infections are common. Epidemic episodes tend to occur in highly populated areas where poor hygiene, malnutrition, anemia, and parasites are common, and episodes are separated by periods of 5 to 7 years in certain communities. Epidemics occur also in the Western world, especially in closed communities. Acute PSGN affects all age groups but most commonly children and young adults. Males are affected more often than females, often in the ratio of 2 : 1. Acute PSGN rarely strikes the same individual twice. Thus, it appears likely that protective immunity is acquired as a result of an infection with a nephritogenic strain.

Although penicillin treatment of the antecedent streptococcal infections is highly efficacious in preventing acute rheumatic fever, it does not appear to be the case in PSGN. Studies carried out during epidemics of nephritis found that prior antibiotics had little, if any, effect in preventing PSGN. Penicillin is, nevertheless, effective in epidemiologic attempts to eradicate nephritogenic strains by treatment of acute glomerulonephritis patients and their colonized family contacts. Because recurrent episodes of acute glomerulonephritis are so rare, continuous antibiotic prophylaxis, such as is used in the secondary prevention of rheumatic fever, is unnecessary.

The ultimate prognosis in persons with acute glomerulonephritis depends largely on the severity of the initial insult. In an extremely small proportion of patients, the initial injury is so severe that either persistent renal failure or progression to renal failure occurs. However, in most patients, histologic regression of the disease is the rule, and the ultimate prognosis is good.

DIAGNOSIS

Streptococcal Antibody Tests

Antistreptococcal antibody titers reflect past and not present immunologic events and therefore cannot be used to determine whether an individual with pharyngitis and GAS in the pharynx is truly infected or merely a streptococcal carrier. When present, elevated or rising antistreptococcal antibody titers provide reliable confirmation of a recent GAS infection and are of value in identifying a preceding GAS infection in a patient suspected of having rheumatic fever. The most commonly used and commercially available antibody assays are antistreptolysin O and anti-DNAse B. These tests are valuable in patients who have possible nonsuppurative complications of GAS infections (acute rheumatic fever or acute glomerulonephritis). The antistreptolysin O test is usually obtained first, and if it is not elevated, an anti-DNAse B test may be performed. Antistreptolysin O titers begin to rise approximately 1 week and peak 3 to 6 weeks after the infection. Anti-DNAse B titers begin to rise 1 to 2 weeks and peak 6 to 8 weeks after the infection. Elevated titers for both tests may persist for several months after even uncomplicated GAS infections.

It is not uncommon for laboratory personnel and physicians to misinterpret streptococcal antibody titers because of a failure to appreciate that the normal levels of these antibodies are higher among school-aged children than among adults. Single antibody titers are often misleading. Sequential samples more accurately define infection, allowing correlation of titer increases with temporal confirmation of GAS acquisition.

TREATMENT Rx

Antimicrobial Susceptibility

Penicillin and the cephalosporins continue to be the drugs of first choice for the treatment of most GAS infections. The continued susceptibility of *S. pyogenes* to β-lactams is remarkable, especially when compared with the emergence of resistance to β-lactams among pneumococci and viridans group streptococci over the past decade. A limited ability to acquire foreign DNA and a physiologic fitness cost associated with β-lactam resistance are possible explanations for this organism's continued susceptibility to penicillin. The macrolides are the second-line drug of choice and are used in penicillin-hypersensitive patients. Clindamycin is also the drug of choice for chronic, recurrent pharyngitis. However, resistance has emerged in this organism. Elevated rates of macrolide resistance (>25%) among GAS reported in Korea, Taiwan, Spain, and Italy are causes of concern. Limited surveillance data suggest that the overall rate of macrolide-resistant GAS in North America is 3 to 9%. There are two primary mechanisms of macrolide resistance in GAS: efflux (encoded by *mefA*) and target modification due to ribosomal methylation (encoded by *ermB* or *ermA*). Isolates with the *mefA* gene have a pattern of resistance known as the M phenotype: they are macrolide resistant but clindamycin susceptible. GAS isolates with the *ermB* gene are usually resistant to macrolides and clindamycin. Isolates with the *ermA* gene typically have an inducible phenotype that requires exposure to a macrolide inducer before clindamycin resistance becomes evident. There are rare reports of L4 ribosomal protein and 23S recombinant RNA mutations in macrolide-resistant GAS isolates.

Fluoroquinolones are a useful therapeutic alternative for the treatment of skin and soft tissue infections in adults. Although strains of GAS nonsusceptible to the fluoroquinolones have been reported, they are rare. The mechanisms of decreased susceptibility to the fluoroquinolones among *Streptococcus* species are mainly mediated by point mutations in the quinolone resistance–determining region of the bacterial topoisomerase II enzymes, namely, DNA gyrase and topoisomerase IV. DNA gyrase and topoisomerase IV enzymes are homologues, with each enzyme consisting of a tetramer with two subunits (two *gyrA* and two *gyrB* molecules in DNA gyrase, two *parC* and two *parE* molecules in topoisomerase IV). In the last few years, *S. pyogenes* isolates that are resistant or have reduced susceptibility to fluoroquinolones have been reported by several authors, but isolates with a high level of resistance have been detected very infrequently.

PREVENTION

Tetracycline resistance in GAS is quite common. In gram-positive organisms, resistance to tetracycline is typically conferred by ribosome protection genes, such as *tet*(M) and *tet*(O). Tetracycline resistance is usually acquired by GAS through horizontal gene transfer. A global sample of GAS revealed 80 or more separate acquisitions of tetracycline resistance. Of 244 clones, 38 and 25% displayed resistance to tetracycline and erythromycin, respectively; a relatively high proportion (15%) were resistant to both classes of drugs. *tet*(M) displayed a highly significant association with *erm*(B). Trimethoprim-sulfamethoxazole is not active against GAS and therefore should not be used as monotherapy for infections potentially caused by GAS.

STREPTOCOCCUS AGALACTIAE (GROUP B STREPTOCOCCUS)

EPIDEMIOLOGY

Group B streptococcus (GBS), also known as *Streptococcus agalactiae*, was once considered a pathogen of only domestic animals, causing mastitis in cows. Although asymptomatic vaginal carriage of GBS was described in 1935, the first report of GBS sepsis in a neonate was not reported until 1964. Since the 1970s, GBS is recognized as one of the most common causes of neonatal infectious morbidity and mortality in developed countries. GBS causes significant maternal and perinatal morbidity, asymptomatic bacteriuria in pregnancy, and urinary tract and other infections in the adult nonpregnant population. The virulence of *S. agalactiae* is related to the polysaccharide toxin it produces. Immunity is mediated by antibodies to the capsular polysaccharide and is serotype specific. Several serotypes are known, including Ia, Ib, Ic, II, III, IV, V, VI, VII, and VIII.

CLINICAL MANIFESTATIONS

Neonatal Group B Streptococcus Disease

GBS colonizes the vaginal and gastrointestinal tracts in healthy women, with carriage rates ranging from 15 to 45%. Neonates can acquire the organism vertically in utero or during delivery from the maternal genital tract. Although the transmission rate from mothers colonized with *S. agalactiae* to neonates delivered vaginally is approximately 50%, only 1 to 2% of colonized neonates go on to develop invasive GBS disease. Neonatal GBS disease is divided into early and late disease. Early GBS neonatal sepsis often presents within 24 hours of delivery but can become apparent up to 7 days postpartum. Pneumonia with bacteremia is common, whereas meningitis is less likely. Late GBS neonatal sepsis is defined as infection that presents between 1 week postpartum and age 3 months. Late disease commonly involves GBS serotype III, typically characterized by bacteremia and meningitis.

PREVENTION

The current approach to the prevention of early-onset GBS infection in pregnancy requires intrapartum antimicrobial prophylaxis in term women with culture evidence of recent vaginal or rectal GBS infection.■ Women without a known GBS status delivering before 37 weeks' gestation with premature rupture of the membranes or intrapartum fever are also candidates for intrapartum antimicrobial prophylaxis. Penicillin or ampicillin is the initial approach. Clindamycin and macrolides are standard in individuals with penicillin allergy, but GBS infections are no longer always sensitive to these two drugs. Despite these recommendations, there is lack of evidence from well-designed and well-conducted trials to recommend intrapartum antibiotic prophylaxis to reduce neonatal early-onset GBS disease.

Invasive Group B Streptococcus Disease

S. agalactiae infection is extremely rare in healthy adults and is almost always associated with underlying abnormalities. Bacteremia with an unknown source accounts for approximately 25% of all cases of invasive GBS disease. Diabetes mellitus and malignancy are the most common underlying diseases associated with infection. Urinary tract infections are a common manifestation of GBS disease and are observed in both pregnant and nonpregnant adults. Other presentations of GBS infection include pneumonia, skin and soft tissue infections, septic arthritis, osteomyelitis, meningitis, peritonitis, and endo-ophthalmitis.

Invasive GBS disease is a major cause of illness and death in older adults and is even more frequent among long-term care facility residents, possibly because of concurrent conditions such as advanced age, diabetes, cirrhosis, and stroke, which are known risk factors for GBS infection. Case-fatality rates are about 13% for persons 65 years and older. An increased prevalence of serogroup V has been reported in adult populations. Serotype V has been associated with higher rates of antimicrobial drug resistance.

TREATMENT Rx

Although β-lactams remain the preferred therapy for GBS infections, strains with elevated penicillin minimal inhibitory concentrations have been reported but are rare.

STREPTOCOCCUS DYSGALACTIAE SUBSPECIES *EQUISIMILIS* (HUMAN GROUP C AND G STREPTOCOCCI)

EPIDEMIOLOGY

Non–group A or B β-hemolytic streptococci that are frequently normal inhabitants of the oropharynx, skin, and gastrointestinal and genitourinary tracts are also capable of causing significant disease. These include groups C, G, F, and L, of which the most common are groups G and C (see Table 298-1). According to recent taxonomic studies, large-colony-forming human groups C and G streptococci are currently classified as *Streptococcus dysgalactiae* subspecies *equisimilis* (SDSE). Few laboratories identify groups C and G streptococci to the species level; therefore, exact numbers of human SDSE infections are not available. Infections due to SDSE are transmitted person to person; an animal reservoir for these strains has not been reported. Zoonotic group C or G streptococcal infections are comparatively rare and are mostly caused by other streptococcal species after animal contact or are associated with the consumption of unpasteurized dairy food products. Nonhuman large-colony-forming β-hemolytic group G streptococci usually belong to *Streptococcus canis,* an animal pathogen that has been found only rarely in humans.

CLINICAL MANIFESTATIONS

A population-based study carried out in North America demonstrated a substantial morbidity and mortality associated with infections due to SDSE, comparable to that caused by invasive GAS infection during the same study period. Both SDSE and GAS affected similar adult populations, tended to be community acquired, and affected primarily persons with underlying medical conditions. The mortality rate was similar to that (8 to 21%) reported in other studies. SDSE primarily presented as skin and soft tissue infection in older patients, whereas individuals with invasive *S. anginosus* group infections were more likely to be younger patients with intra-abdominal infections; these were typically polymicrobial and represented sequelae of perforated appendicitis and associated peritonitis. This finding is supported by the fact that *S. anginosus* group isolates have been recovered from 20 to 40% of healthy appendices.

Pharyngitis is a classic presentation in adult patients, and SDSE has clearly been responsible for epidemic outbreaks of pharyngitis in children. The etiologic role of SDSE in pharyngitis is supported by reports on acute poststreptococcal glomerulonephritis and, more recently, on acute rheumatic fever after SDSE isolation from the upper respiratory tract.

In a 1-year study of 90 patients presenting with 98 disease episodes of acute bacterial cellulitis in Finland, SDSE instead of GAS was strikingly the most common finding. Some patients and household members also carried SDSE in the pharynx, whereas it was not detected in the control subjects. SDSE was isolated either from skin lesion or blood from 22% of patients, whereas GAS was isolated from 7% of patients.

TREATMENT Rx

The non–group A or B β-hemolytic streptococci are typically susceptible to penicillins and cephalosporins, although α-hemolytic viridans group streptococci have shown increasing resistance to penicillin and other β-lactams. In contrast, the resistance to erythromycin and tetracycline among SDSE is similar to rates found in GAS.

VIRIDANS GROUP STREPTOCOCCI

There are more than 20 streptococcal species that have the phenotypic characteristics of typical viridans streptococci and are divided into the mutants

group, salivarius group, anginosus group, sanguineous group, and mitis group. Although often found as commensals whose pathogenic abilities appear to be much more subtle than those of the pyogenic streptococci, they may also participate in various infections such as subacute bacterial endocarditis, catheter-related and neutropenia-related blood stream infections, and purulent abdominal, hepatobiliary, brain, and dental infections. Antimicrobial resistance is substantial in the viridans streptococci as a group. Penicillin resistance is from 30 to 50% in strains isolated from patients in North America. *S. mitis* and *S. oralis* are the most common strains found in blood cultures of cancer patients and are commonly resistant to β-lactam antimicrobials. *S. sanguinis*, *S. oralis*, and *S. gordonii*, in descending order, are the most common strains isolated from cultures of blood of endocarditis patients. In the *S. anginosus* group, resistance to ß-lactam antimicrobial is only at the intermediate level, but resistance to macrolides has been found in 17% of the strains. In addition, *S. anginosus* plays a significant role as a reservoir of antimicrobial resistance genes, transferring different resistance traits to more pathogenic organisms such as *Streptococcus pneumoniae* and *S. pyogenes*.

ZOONOTIC STREPTROCOCCI

Streptococcus suis

S. suis is a pathogen in pigs that can cause severe infection in humans. *S. suis* was first reported by veterinarians in 1954, after outbreaks of meningitis, septicemia, and purulent arthritis occurred among piglets. Fourteen years later, the first human *S. suis* cases were diagnosed in Denmark, and subsequently, other cases were reported in more than 30 countries, including Canada, the United States, Japan, Vietnam, and Thailand. It can be clinically manifested with meningitis, arthritis, and septicemia. *S. suis* is the name assigned to streptococci that were formally called Lancefield groups R, S, and T. Of the 35 known serotypes, the most frequent serotype identified from humans has been serotype 2 (group R). Human *S. suis* infections are most often reported from countries where pig rearing is common. The relatively high mean patient age (47 to 55 years) and almost complete absence of children in case series, as well as the high male-to-female patient ratio (3.5 : 1 to 6.5 : 1), support the notion that infection with *S. suis* is generally an occupational disease. The annual risk of developing *S. suis* meningitis among abattoir workers and pig breeders has been estimated to be 3 cases per 100,000 population; the risk is lower for butchers, at 1.2 cases per 100,000 population in developed countries. The incubation period of *S. suis* is from hours to 14 days (median, 2.2 days). A very short incubation time is consistent with direct entry of *S. suis* into the blood through skin wounds. Patients have generally been healthy before infection with *S. suis,* although predisposing factors, such as splenectomy, diabetes mellitus, alcoholism, malignancy, and structural heart diseases have been reported. An outbreak in China was associated with an overall case-fatality rate of 18%, but this reached 63% among patients with septicemia and septic shock.

Data from Vietnam show that *S. suis* is susceptible to penicillin, ceftriaxone, and vancomycin. Resistance was seen to tetracycline (83%), erythromycin (20%), and chloramphenicol (3%). In a European study, 384 *S. suis* strains from diseased pigs were susceptible to penicillin, but resistance was detected to gentamicin (1.0%), trimethoprim-sulfamethoxazole, (6.0%), and tetracycline (75%). There may be a role for the use of dexamethasone as an adjunctive treatment to reduce mortality and improve the outcome of bacterial meningitis due to *S. suis*. In a randomized, double-blind, placebo-controlled clinical trial in Vietnam, dexamethasone (0.4 mg/kg twice daily for 4 days) resulted in a significant reduction in the risk for death at 1 month and in the risk for death and disability at 6 months in patients with confirmed bacterial meningitis: *S. suis* accounted for 25% of pathogens.■

Currently, a human vaccine is not available, but simple preventive measures, such as wearing gloves during processing pig meat or slaughtering, hand washing after handling raw pork meat, and thorough cooking of pork, should prevent most cases. Travelers should be aware that dietary habits in some countries may pose a risk for infectious diseases, including *S. suis* infection.

Streptococcus canis

S. canis is an organism that was described in 1986 as having the Lancefield group G antigen and was isolated from animals, most frequently dogs. Extensive phenotypic testing of isolates from dogs was described in 1994, and the isolation of *S. canis* from a human with sepsis was reported in 1997. Despite its name, *S. canis* has been isolated from animals other than dogs, including cats, harbor porpoises, cows, mice, rats, and rabbits. In healthy dogs, *S. canis* is found as commensal flora of the skin, oropharynx, genital urinary tract, and anus. Rare cases of *S. canis* infection in humans have been reported in the literature. Resistance to erythromycin and tetracycline is common. In the clinical laboratory, group G streptococci are not usually identified to the species level. In addition, laboratory tests have only recently been able to identify *S. canis* accurately. Thus, the true incidence of *S. canis* infection is unknown.

Streptococcus bovis Group

Members of the *Streptococcus bovis* group have long been regarded as opportunistic pathogens in humans causing up to 11 to 14% of all endocarditis cases and 24% of streptococcal endocarditis. *S. bovis* group isolates from human infections are divided into three biotypes, designated biotype I, biotype II/1, and biotype II/2. Most *S. bovis* group endocarditis isolates belong to biotype I, for which a reclassification as *Streptococcus gallolyticus* subspecies *gallolyticus* was recently proposed. The human intestinal tract is a major natural reservoir of *S. bovis* group strains with a reported carriage rate of about 10%. There is a strong association between the presence of malignant or premalignant lesions in the gastrointestinal tracts of patients and isolation of *S. bovis* as a causative agent of bacteremia or endocarditis.

Streptococcus iniae

S. iniae is a β-hemolytic streptococcus without a group antigen. It is a major fish pathogen in many regions of the world. These bacteria are also zoonotic, with infections in humans associated with the handling and preparation of infected fish. The first human infections were reported in 1996. Most cases of human *S. iniae* infections have been in persons of Asian descent, who are elderly and commonly have underlying conditions such as diabetes mellitus, chronic rheumatic heart disease, cirrhosis, or other conditions.

Carrier fish have been implicated in fish-to-fish transmission of *S. iniae*, and these carriers may be responsible for human infection because fish with overt signs of disease are unmarketable. Soft tissue injuries that occur during the preparation of fresh fish from wet markets usually result in bacteremic cellulitis of the hand, followed by one or more of the following conditions: endocarditis, meningitis, arthritis, sepsis, pneumonia, osteomyelitis, and toxic shock. *S. iniae* is susceptible to penicillin and other antimicrobials. The expression of a suite of virulence factors, many of them similar to those found in GAS, is responsible for successful entry, propagation, and evasion of immune defenses of the host by this bacterium. Underreporting of human cases is likely because identification of *S. iniae* is based on biochemical testing of isolates with commercial kits; the use of kits is associated with problems because *S. iniae* is not listed in commercial or clinical databases, and many atypical strains are assigned low matches.

ENTEROCOCCAL INFECTIONS

ELI N. PERENCEVICH AND TRISH M. PERL

DEFINITION

Enterococci, formerly called group D streptococci, are endogenous human flora that had been considered pathogens with low virulence. However, more recently they have emerged as increasingly important health care–associated (nosocomial) pathogens. This emergence is primarily due to their inherent resistance to commonly used antimicrobials, acquisition of high-level resistance to vancomycin, persistence in the environment, and transmission from patient to patient by way of the contaminated hands of health care workers. The emergence of vancomycin-resistant enterococci (VRE) has limited therapeutic options in confirmed enterococcal infections and in empirical therapy for infections in severely ill hospitalized patients. One third of enterococcal isolates from hospitalized patients are now reported to be highly resistant to vancomycin. Additionally, there have been several reported cases of vancomycin-resistant *Staphylococcus aureus* (VRSA). In each case, the staphylococcus acquired a vancomycin resistance gene (*VanA*) from a VRE isolate that colonized the same VRSA-infected patient. This highlights that resistance in one species can affect the evolution of resistance in another pathogenic species and that failure to control one species can negatively affect patient outcomes in those infected with another bacteria.

Enterococci are common residents of the human gastrointestinal tract and the female genitourinary tract and act as opportunistic pathogens in severely ill patients. They are known to cause urinary tract infections, intra-abdominal abscesses, bacteremia, including catheter-associated blood stream infections, and endocarditis; less commonly, they cause osteoarticular infections and meningitis.

The Pathogen

Members of the genus *Enterococcus* were long classified within group D of the genus *Streptococcus*. However, in the past 25 years, they have been reclassified based on new molecular and genetic analyses. Enterococci are catalase-negative gram-positive cocci that can appear singly or in pairs or short chains. They are facultative anaerobes that grow optimally at 35° C in broth containing 6.5% NaCl and hydrolyze esculin in the presence of 40% bile salts (bile-esculin medium). Demonstration of the group D antigen may assist the identification of enterococci; however, it is not a particularly sensitive test because it is present in about 80% of enterococcal strains. *Enterococcus faecalis,* the most common cause of enterococcal infections in humans, is the causative agent for 80 to 90% of the enterococcal infections, followed by *Enterococcus faecium,* which is found in 5 to 10% of the infections. *Enterococcus casseliflavus* and *Enterococcus raffinosus* have been reported in clusters of infections. Other species reported to cause infections in humans include *Enterococcus avium, Enterococcus cecorum, Enterococcus dispar, Enterococcus durans, Enterococcus gallinarum, Enterococcus glivus, Enterococcus hirae, Enterococcus mundtii,* and *Enterococcus pallens.*

EPIDEMIOLOGY

The proportion of infections caused by enterococci in hospitalized patients has been increasing over the past several decades. Overall, urinary tract infections (UTIs) are the most common clinical condition caused by enterococci. *Enterococcus* species are now the third most common isolate from UTIs in hospitalized patients, causing 14 to 16% of these infections in North America and can be involved in both complicated and uncomplicated UTIs. Enterococci are the second most common cause of central line–associated blood stream infections and are involved in approximately 5 to 15% of all cases of infective endocarditis. They are also the third most frequent pathogen recovered in surgical site infections. Overall, they are the third most common pathogen in the United States, causing 12% of all health care–associated infections.

Enterococci are part of the normal human gut flora, and infections in both hospitalized and nonhospitalized patients can arise from an endogenous source. However, most infections are health care associated and appear to result from an exogenous source, meaning that transmission from the environment, another patient, or on the hands of a health care worker has occurred before infection. Nearly all infections are preceded by some period of colonization, and although most colonized patients do not develop infections, they are still able to shed and transmit bacteria to other hospitalized patients. The organism, including VRE, contaminates the hospital environment and equipment and has been associated with outbreaks. Increasingly, hospitalized patients, if they are colonized or infected with an *Enterococcus* species, tend to have a strain resistant to vancomycin (i.e., VRE).

VRE was first reported in Europe in 1986. Since the mid-1990s, the proportion of enterococcal strains resistant to vancomycin has risen steadily. According to the Centers for Disease Control and Prevention (CDC) National Healthcare Safety Network (NHSN), 80% of *E. faecium* isolates and 7% of *E. faecalis* isolates were resistant to vancomycin in 2006 to 2007. There are two major phenotypes for acquired vancomycin resistance, VanA and VanB. The genes encoding the VanA phenotype result in high-level resistance to vancomycin and teicoplanin and are carried on a transposon usually found on a plasmid that is transferable to other gram-positive cocci, including *Staphylococcus aureus*. VanB is associated with variable resistance to vancomycin, but isolates are usually susceptible to teicoplanin. Linezolid resistance is increasingly reported even in patients without previous exposure to the antibiotic. Daptomycin resistance is also reported in both *E. faecalis* and *E. faecium* after prolonged courses of therapy. *E. faecalis* is intrinsically resistant to the streptogramin combination quinupristin-dalfopristin, and resistance exists in *E. faecium* or can develop during therapy.

The epidemiology of VRE differs between Europe and North America. In Europe, VRE is often detected in farm animals, likely due to the use of the antibiotic avoparcin in animal feeds until it was banned in 1997. The proportion of VRE among enterococcal clinical isolates in hospitalized Europeans has been historically lower than in the United States; however, these rates are increasing. In the United States, avoparcin was never used in animal feeds, and therefore VRE is not usually found in farm animals or healthy humans. In contrast, the proportion of enterococcal isolates resistant to vancomycin is higher in U.S. hospitals than European hospitals.

The most common mode of nosocomial transmission of VRE is patient-to-patient cross-transmission by the hands of health care workers who become transiently colonized with the organism. Enterococci with genetic relatedness by pulse-field gel electrophoresis (PFGE) have been cultured on the hands of health care workers caring for infected patients. A study in a U.S. hospital's medical intensive care unit (ICU) found that the number of patients already colonized with VRE in a defined geographic area ("colonization pressure") was the most significant variable in predicting new acquisition of VRE. This finding was significant in that it highlights the important role that patient-to-patient transmission has had in the emergence of VRE. Similarly, a study on hemodialysis patients found the only significant predictor of VRE colonization was hospitalization in the prior year, suggesting the importance of nosocomial transmission in VRE acquisition. A study of hospitalized patients recently admitted to non-ICU wards found that the most sensitive factor for predicting VRE colonization on surveillance culture was previous admission to an acute care hospital in the past year. Importantly, once colonized with VRE, patients may harbor the strain in their gastrointestinal tract for years.

Apart from preexisting gastrointestinal colonization, risk factors for enterococcal infections, particularly VRE infections, include severe underlying conditions such as renal failure, previous solid organ or bone marrow transplantation, solid and hematologic malignancy, diabetes mellitus, and neutropenia. Other factors associated with infection include prior surgical or gastrointestinal procedures, presence of a vascular or urinary indwelling catheter, hospital factors such as location in the ICU or oncology ward, proximity to colonized patients, prolonged length of hospitalization, and recent antimicrobial exposure.

Numerous epidemiologic investigations have revealed that most classes of antimicrobials have been associated with VRE infections. In particular, vancomycin, cephalosporins, and drugs with anaerobic organism coverage use have been linked to VRE acquisition. However, measuring the attributable impact of a particular antibiotic on VRE acquisition is difficult. Increasingly, an association between VRE colonization and *Clostridium difficile* infection is reported in high-risk patients such as those with hematologic malignancies.

PATHOBIOLOGY

Enterococci are commensal organisms that colonize the human gastrointestinal tract and female genital tract. Although they are not as intrinsically virulent as other gram-positive pathogens, under certain conditions, the

commensal relationship is disrupted, and serious infections occur. Several adhesion factors have been identified, including aggregation substance, which allow binding to epithelial surfaces and enhance the ability for colonization. The ability to adhere to heart valves and urinary tract epithelium enables the enterococcus to cause endocarditis and UTIs. Enterococci are also known to secrete potential virulence factors. These include cytolysin/hemolysin, which is a bacterial toxin that is produced in a higher proportion of infecting strains compared with stool-colonizing strains. Infecting strains also possess the ability of intestinal translocation, although the exact mechanisms of this process have yet to be determined. To this point, little is known about the host defense mechanisms in enterococcal infections. In addition, the exact role of capsular polysaccharides in colonization or infection is unknown. Strains have been shown to survive within phagocytic cells, yet it is unclear whether this represents successful host defense or evasion by the enterococci. The intrinsic resistance to multiple antimicrobials that enterococci possess, along with their ability to acquire new resistance mechanisms through mutation or acquisition of new genes, enhances their ability to survive and multiply in the many hospitalized patients treated with broad-spectrum antimicrobials.

CLINICAL MANIFESTATIONS

There are no specific clinical manifestations to help distinguish enterococcal infections from infections caused by other bacteria. Enterococci are not thought to cause lower respiratory tract infections or ventilator-associated pneumonia and, if found in these settings, likely represent colonization and not infection.

Urinary Tract Infections

UTIs are the most frequent type of infection caused by enterococci. Most infections are nosocomial in origin and include uncomplicated cystitis, pyelonephritis, prostatitis, and perinephric abscess. These infections are typically secondary to urinary catheterization or instrumentation. In contrast to nosocomial UTI, enterococci cause less than 5% of uncomplicated cystitis or pyelonephritis cases in otherwise healthy nonhospitalized women. Patients with diabetes mellitus appear to be at increased risk for enterococcal UTI. Bacteremia is only infrequently associated with enterococcal UTI.

Bacteremia

The incidence of bacteremia caused by enterococci continues to increase. Specific risk factors include prolonged hospitalization, preexisting urethral catheters or intravascular lines, recent surgery, malignancy, neutropenia, and biliary pathology. Secondary bacteremia without endocarditis usually arises from the urinary tract, hepatobiliary tract, or soft tissue infection. Bacteremia secondary to an intra-abdominal source carries a high mortality rate. Risk factors for VRE bacteremia parallel those mentioned previously but additionally include severe preexisting comorbid conditions, including hematologic malignancy, human immunodeficiency virus (HIV) infection, chronic renal insufficiency, and liver transplantation. Prior exposure to broad-spectrum antimicrobials, including those with antianaerobic activity such as clindamycin or metronidazole and exposure to multiple and prolonged antimicrobial therapy are consistent risk factors. Enterococcal bacteremia is frequently polymicrobial, and the clinical picture is often influenced by whether it is isolated alone or with other bacteria. When enterococci are isolated alone, the course is typically indolent, and frequently fever is the only sign. In contrast, polymicrobial bacteremia is more severe, often presenting with shock or disseminated intravascular coagulation. VRE bacteremia is associated with higher mortality rates than bacteremia due to vancomycin-susceptible strains, and early treatment with an appropriate antibiotic within the first 48 hours of presentation has been associated with improved outcomes.

Endocarditis

Enterococci, particularly *E. faecalis*, are an increasingly frequent cause of endocarditis even though most enterococcal bacteremias are not complicated by endocarditis. The disease occurs most frequently in older patients, with a male predominance. Most cases appear to arise in the community. Patients with preexisting valvular heart disease, including prosthetic valves, are at highest risk, yet many patients lack underlying heart disease. Enterococci more commonly cause left-sided endocarditis primarily affecting the mitral valve. Clinically, these patients present with symptoms that closely resemble a subacute bacterial endocarditis caused by viridans streptococci. Many patients have symptoms for weeks or months before seeking medical care.

Intra-abdominal Infections

In intra-abdominal infections, enterococci are often detected as part of a polymicrobial process. These infections typically arise from a hepatobiliary source, including postoperative infection in liver transplantation, and are complicated by secondary bacteremia.

Skin and Soft Tissue Infections

Enterococci rarely cause cellulitis or other soft tissue infections alone but are often isolated in mixed surgical site infections, diabetic foot infections, and decubitus ulcers along with other gram-negative bacilli, gram-positive cocci, and anaerobic bacteria. Their clinical significance in these situations has not been adequately determined. Enterococci are not thought to be primary pathogens in chronic osteomyelitis. When they are identified, it is thought they may solely represent superinfection, and thus adequate therapy may not require antibiotics directed at enterococcal eradication.

DIAGNOSIS

The diagnosis of an *Enterococcus* infection is made by isolating the organism through culture of a sterile site, such as blood culture or urine culture. The diagnosis and differential diagnosis of specific conditions are the same as discussed for UTIs (Chapter 292) and endocarditis (Chapter 76).

TREATMENT Rx

Therapy for enterococcal infections is complicated by the fact that strains exhibit inherent resistance to many commonly used antibiotics, including cephalosporins. In addition, enterococci have acquired resistance to a wide-range of antibiotic classes, including aminoglycosides, β-lactams, fluoroquinolones, lincosamides, macrolides, oxazolidinones (linezolid), quinupristin/dalfopristin, rifampin, tetracyclines, and vancomycin. Thus, effective directed therapy for any severe enterococcal infection requires susceptibility testing by experienced microbiology laboratories, with therapy adjusted based on the results. However, even when enterococcus appears susceptible to trimethoprim-sulfamethoxazole in vitro, it should not be used in therapy because clinical failures have been reported secondary to the ability of enterococci to utilize exogenous folate. Recently, there has been increasing isolation of *E. faecium* strains with intrinsic resistance to penicillins. Importantly, *E. faecalis* is intrinsically resistant to quinupristin/dalfopristin, which therefore should not be used in therapy for infections caused by this species. However, most *E. faecalis* strains remain susceptible to ampicillin and the related piperacillin, in contrast to most *E. faecium* strains, which are resistant to ampicillin. Optimal therapy for most infections includes intravenous ampicillin, penicillin, or vancomycin. Given the resistance or tolerance to cell wall–targeting antibiotics, including penicillins and vancomycin, standard therapy with these antibiotics, except in UTIs, should include the addition of a synergistic aminoglycoside (i.e., streptomycin or gentamicin), as long as high-level resistance is not detected. This strategy of two-drug therapy has been associated with improved outcomes. If the VRE strains are known to be susceptible, potential therapy in these infections includes linezolid, quinupristin/dalfopristin, and daptomycin. Although daptomycin is not approved by the U.S. Food and Drug Administration (FDA) to treat VRE, it has been used to treat skin and soft tissue infections and bacteremia. Newly licensed tigecycline is FDA approved to treat complicated skin and soft tissue infections and complicated intra-abdominal infections caused by vancomycin-susceptible isolates of *E. faecalis*. Quinupristin/dalfopristin use is associated with myalgias and arthralgias, and linezolid use is associated with bone marrow suppression including thrombocytopenia; both have only bacteriostatic activity against the enterococci. Linezolid, when used in combination with selective serotonin reuptake inhibitors, can be associated with serotonin syndrome (Chapter 442). Given the complexity of enterococcal infections, an infectious disease consult should be considered for therapeutic guidance.

Urinary Tract Infections

A single agent can usually be used to treat enterococcal UTIs, including ampicillin, amoxicillin, penicillin, or vancomycin. Vancomycin is typically reserved for penicillin-allergic patients or if the strain has high-level penicillin resistance. β-Lactam/β-lactamase inhibitor combinations are usually reserved for polymicrobial infections. Nitrofurantoin is also occasionally used because most strains remain susceptible.

Bacteremia without Endocarditis

Many cases of enterococcal bacteremia are transient or self-limited, yet antibiotic therapy with penicillin or ampicillin has been shown to improve outcomes. Unlike in endocarditis therapy, it is not known whether patients benefit from combination therapy (penicillin or ampicillin or vancomycin plus an aminoglycoside), except perhaps when an indwelling intravascular catheter is present. In the setting of an indwelling intravascular catheter, especially for VRE, removal of the catheter is recommended.

Endocarditis

Combination therapy (intravenous penicillin, ampicillin, or vancomycin plus an aminoglycoside) is the standard therapy for enterococcal endocarditis. Doses and durations are found in Chapter 76. Importantly, the aminoglycoside is used to provide synergistic killing of the organism. Duration of therapy is typically 4 weeks, with 6-week duration given to patients who had prolonged symptoms before seeking therapy, prosthetic valve infection, or relapsed after initial treatment. If the causative enterococcal strain is highly resistant to both gentamicin and streptomycin, then alternative agents and durations must be explored, and surgery to excise infected valves should be considered. Optimal therapy of VRE strains that are resistant to ampicillin is not known but includes combination therapy under the guidance of an infectious disease consultant. Several newly approved agents, including quinupristin/dalfopristin, linezolid, and daptomycin, could be considered if the strain is found to be susceptible. VRE endocarditis may require early surgery because outcomes with antibiotic therapy can be poor. Careful microbiologic and clinical assessment of all patients with enterococcal endocarditis and VRE in particular is helpful in deciding when surgery is necessary. If repeated blood cultures grow for more than 7 days after the initiation of medical therapy or other signs of uncontrolled infection (persistent fever or leukocytosis) are present, surgical repair of the valve or valve replacement should be considered early in the treatment course if there are no absolute contraindications for surgery.

PRIMARY PREVENTION

Optimal infection prevention for VRE, like many multidrug-resistant bacteria, includes proper use and compliance with hand hygiene, proper management and timely removal of urinary and vascular catheters, reduction of antibiotic selective pressure through antimicrobial stewardship, use of Contact Precautions, and environmental cleaning of equipment and patient rooms. The latter is particularly important for VRE. Decontamination of patients' skin, called source control, may broadly control transmission of resistant pathogens and reduce device-related infections such as central venous catheter–associated blood stream infections. Source control using daily bathing of patients with chlorhexidine gluconate (CHG)-saturated cloths has been associated with reduced VRE contamination of patients' skin and health care workers' hands. A multicenter quasi-experimental study in six ICUs found daily bathing with CHG solution reduced VRE acquisition by 50% and decreased the risk for VRE bacteremia in known VRE-colonized patients by one third.

The methods for VRE-specific prevention are directed at preventing incident colonization in high-risk hospitalized patients. Nearly all enterococcal infections, including VRE infections, are preceded by gastrointestinal colonization, and although most colonized patients do not develop infections, they are still able to shed and transmit bacteria to other hospitalized patients. At least with VRE, a colonization-to-infection ratio of 10:1 has been reported, suggesting for every 1 clinical infection in an ICU, there may be 10 colonized patients lurking undetected in the unit. Thus, the unrecognized colonized patients represent the target population for infection prevention and control efforts such as active surveillance. Active surveillance programs use rectal or perirectal surveillance swabs to detect previously unrecognized, colonized patients and isolate them to prevent further transmission. Currently, surveillance cultures are recommended at the time of hospital admission for patients at high risk for carriage of VRE, and colonized patients or infected patients should be placed in isolation using Contact Precautions. Contact Precautions typically entail private rooms, dedicated equipment such as stethoscopes, and gloves and gowns for all patient contact. Implicit in this is the continued use of standard precautions that requires cleaning and disinfection of equipment that is used in patient rooms. Many hospitals do use active surveillance in the ICU and other wards with a high prevalence of VRE, although the overall adoption of this strategy has been hindered by the perceived high costs of surveillance programs and lack of available randomized control trial data.

PROGNOSIS

Enterococcal bacteremia is associated with prolonged hospitalization and added costs compared with similar patients without enterococcal bacteremia. Still, apart from enterococcal endocarditis, the attributable mortality of enterococcal infections is difficult to quantify owing to its predilection to infect patients with preexisting comorbid conditions and high levels of illness severity. In certain patient populations, including those with liver and bone marrow transplants, studies have suggested increased morbidity, length of stay, and mortality associated with vancomycin resistance. Furthermore, a recent meta-analysis reported that the odds of dying from a vancomycin-resistant enterococcal blood stream infection were 2.5 times higher than dying from an infection caused by a susceptible enterococcus. The unadjusted mortality in susceptible enterococcal bacteremia was 20%. It is unclear why resistance is associated with higher mortality, although it is thought that delayed adequate empirical therapy may play a role. These studies should be interpreted cautiously because the clinical impact of resistance in enterococci was assessed before the availability of newer antimicrobials with activity against VRE.

DIPHTHERIA AND OTHER CORYNEBACTERIA INFECTIONS

ROLAND W. SUTTER

DIPHTHERIA

DEFINITION

Diphtheria is an acute infectious disease caused by *Corynebacterium diphtheriae,* a gram-positive bacillus. The organism infects primarily the respiratory tract, where it causes tonsillopharyngitis, laryngitis, or both (typically with a pseudomembrane), as well as the skin, where it is responsible for a variety of indolent lesions. If the infecting strain produces exotoxin, myocarditis and neuritis may ensue.

The Pathogen

C. diphtheriae is a member of a group of aerobic, nonmotile, unencapsulated, nonsporulating, pleomorphic gram-positive bacilli. Its name comes from the Greek *korynee* (meaning "club"), which describes the shape of the organism on stained smears—with one end usually being wider—and *diphtheria* (meaning "leather hide"), for the characteristic adherent membrane. The genus *Corynebacterium* is characterized by bacilli that line up in parallel groups and bend when dividing to create "Chinese character" arrangements. Both nontoxigenic and toxigenic *C. diphtheriae* strains exist. Toxigenicity is conferred when a nontoxigenic organism is infected with a beta-phage carrying the gene for the toxin (*tox*). *C. diphtheriae* has three biotypes—*gravis, mitis,* and *intermedius*—that are distinguished by colonial morphology and varying biochemical and hemolytic reactions. Strains can be distinguished for epidemiologic purposes by molecular techniques. Diphtheria toxin–producing strains of *Corynebacterium ulcerans* can produce classic diphtheria, including local respiratory tract and distal toxic complications.

EPIDEMIOLOGY

Humans are the only natural reservoir of *C. diphtheriae,* although the organism has occasionally been isolated from a variety of domestic and other

animals. Spread occurs in close-contact settings through respiratory droplets or by direct contact with respiratory secretions or skin lesions. The organism survives for weeks and possibly months on environmental surfaces and in dust, and fomite transmission may occur. The majority of nasopharyngeal *C. diphtheriae* infections result in asymptomatic carriage, with clinical disease developing in only about one in seven individuals. However, asymptomatic carriers are important in maintaining transmission.

Diphtheria immunization protects against disease but does not prevent carriage. In the prevaccine era, respiratory disease dominated in temperate climates, with a fall/winter peak in incidence. Most individuals acquired natural immunity by the midteen years. Cutaneous disease was the predominant form of the disease in tropical countries, but the current contribution of cutaneous diphtheria in inducing or maintaining diphtheria immunity in tropical countries is not known. Over the past 3 decades, outbreaks of this form of diphtheria have occurred in the United States and Europe, typically in homeless and alcoholic inner-city adults.

Vaccination with diphtheria toxoid (formalin-treated toxin) was introduced in the 1920s. Immunization of children in an era when the majority of older individuals had natural immunity resulted in a dramatic drop in the incidence of diphtheria and an even more rapid decline in the proportion of toxigenic strains isolated, presumably because the selective advantage of the *tox* gene—promotion of greater replication and spread of the organism—is lost in an immune host. In most Western countries, toxigenic *C. diphtheriae* has been virtually eliminated. In the United States, reported cases fell from 147,991 in 1920 to 15,536 in 1940 to a total of 40 cases from 1980 to 1993. The absence of reported diphtheria cases in the United States in recent years, however, does not indicate that circulation of toxigenic *C. diphtheriae* has ceased. Investigations in a Northern Plains Indian community in North Dakota and First Nations communities in Ontario, Canada, suggest that *C. diphtheriae* strains might have circulated independently for more than 2 decades in these communities, despite the absence of reported respiratory diphtheria cases.

Vaccine-induced immunity to diphtheria wanes with time, and there is a growing cohort of individuals with no natural diphtheria immunity. Serosurveys indicate that 20 to 60% of adults in industrialized countries have diphtheria antitoxin levels below minimal protective levels. A level of 0.01 IU/mL from an in vitro neutralization assay, the "gold standard" test, is considered the lower limit of protection. Long-term protection against diphtheria requires a level of greater than 0.1 IU/mL. As long as a high proportion of the population remains susceptible, the danger of reintroduction or reemergence of toxigenic strains exists.

Large outbreaks of diphtheria have occurred in the vaccine era. In the 1990s there was a major resurgence of diphtheria in several countries of the former Soviet Union. In Russia, the number of reported cases rose from 593 in 1989 to 39,582 in 1994, with more than two thirds of cases occurring in adults. Large-scale campaigns to administer diphtheria toxoid to virtually the entire population in the affected states of the former Soviet Union led to significant decreases in the incidence of diphtheria, from a peak of 50,449 cases in 1995 to 7197 cases in 1997 to pre-resurgence levels by the later 1990s (Fig. 300-1). In general, outbreaks of diphtheria may occur in susceptible populations due to clonal spread of the organism or transfer of the bacteriophage to nontoxigenic strains of *C. diphtheriae.*

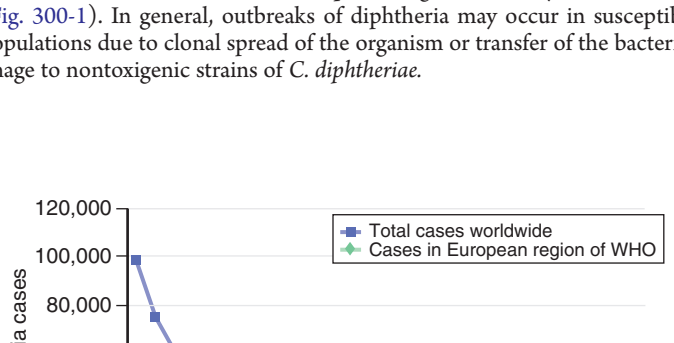

FIGURE 300-1. Reported diphtheria cases worldwide and by European region of the World Health Organization (WHO), 1980 to 2008. (Data from the World Health Organization.)

PATHOBIOLOGY

In classic respiratory diphtheria, *C. diphtheriae* colonizes the mucosal surface of the nasopharynx and multiplies locally without blood stream invasion. Released toxin causes local tissue necrosis, with the formation of a tough, adherent pseudomembrane composed of a mixture of fibrin, dead cells, and bacteria. The membrane usually begins on the tonsils or posterior to the pharynx. In more severe cases, it spreads by progressively extending over the pharyngeal wall, fauces, and soft palate into the larynx, which may result in respiratory obstruction. Toxin entering the blood stream causes tissue damage at distant sites, particularly the heart (myocarditis), nerves (demyelination), and kidney (tubular necrosis). Nontoxigenic strains may cause mild local respiratory disease, sometimes including a membrane.

Diphtheria toxin is an extremely potent inhibitor of protein synthesis, and the estimated human lethal dose is 0.1 mg/kg. The extent of toxin absorption varies with the site of infection, being much less from the skin or nose than from the pharynx.

CLINICAL MANIFESTATIONS

Respiratory Diphtheria

Infection limited to the anterior nares manifests as a chronic serosanguineous or seropurulent discharge without fever or significant toxicity. A whitish membrane may be observed on the septum. The faucial (pharyngeal) form is most common. After an incubation period of 1 to 7 days, the illness begins with a sore throat, malaise, and mild to moderate fever. Initially there is mild pharyngeal erythema, usually followed by progressive formation of a whitish tonsillar exudate; over 24 to 48 hours, this exudate changes into a grayish membrane that is tightly adherent and bleeds on attempted removal. In more severe cases, the patient appears toxic, and the membrane is more extensive. Cervical adenopathy and soft tissue edema may occur and result in the typical "bull neck" appearance and stridor. Laryngeal involvement, which may develop on its own or as a result of membrane extension from the nasopharynx, manifests as hoarseness, stridor, and dyspnea. The following clinical classification has been proposed by the World Health Organization: (1) catarrhal form (erythema of pharynx, no membrane); (2) follicular form (patches of exudate, no pharyngeal or tonsillar involvement); (3) spreading form (membranes covering the tonsils and the posterior pharynx); and (4) combined form (more than one anatomic site involved, such as the throat and skin). The more severe clinical manifestations are associated with increasing toxin absorption levels.

The likelihood of toxic complications depends primarily on the interval between disease onset and administration of antitoxin. The severity of disease at the initial evaluation closely predicts the likelihood of a severe clinical course, complications, and death. Myocarditis typically occurs in the first or second week after the onset of respiratory symptoms and develops either suddenly or insidiously with signs of low cardiac output and congestive failure. Conduction disturbances, which may occur without other signs of myocarditis, include ST-T wave abnormalities, arrhythmias, and heart block. Neurologic impairment manifests as cranial nerve palsies and peripheral neuritis. Palatal or pharyngeal paralysis (or both) occurs during the acute phase; peripheral neuritis, which is symmetrical and predominantly motor, occurs 2 to 12 weeks after the onset of the disease. Motor deficits may range from minor proximal weakness to complete paralysis. Complete recovery is the rule. In fulminant, sometimes called "hypertoxic," diphtheria, toxic circulatory collapse with hemorrhagic features occurs.

Cutaneous Diphtheria

Cutaneous diphtheria lesions are classically indolent, deep, punched-out ulcers that may have a grayish white membrane. However, the lesions may be indistinguishable from impetigo, or *C. diphtheriae* may infect chronic dermatoses such as stasis dermatitis. Coinfection with *Streptococcus pyogenes, Staphylococcus aureus,* or both occurs frequently. Toxic complications of only cutaneous diphtheria are rare.

DIAGNOSIS

The decision to initiate therapy should be based on clinical grounds because delayed treatment, especially delay in the administration of antitoxin, is associated with worse outcomes. A high index of suspicion is required. Specimens for culture should be taken from beneath the membrane, from the nasopharynx, and from any suspicious skin lesions. Because special media are required, the laboratory should be alerted to the possibility of diphtheria. *C. diphtheriae* is best isolated on selective media that inhibit the growth of other

nasopharyngeal organisms; one containing potassium tellurite is generally used. Based on colonial morphology and Gram stain appearance, a presumptive diagnosis may be possible within 18 to 24 hours. Cultures may be negative if the patient previously received antibiotics. Toxigenicity testing should be performed on all *C. diphtheriae* isolates. Because both nontoxigenic and toxigenic strains may be isolated from the same patient, more than one colony should be tested. Traditional methods include guinea pig inoculation and the Elek test, in which the isolate and appropriate controls are streaked on a culture plate in which a filter strip soaked with antitoxin has been embedded; toxin production is confirmed by an immunoprecipitation line in the agar. Identification of the diphtheria *tox* gene has allowed the development of rapid and accurate polymerase chain reaction–based methods for identifying toxigenic strains.

Differential Diagnosis

The differential diagnosis includes streptococcal and viral tonsillopharyngitis, infectious mononucleosis, Vincent's angina, candidiasis, and acute epiglottitis. A history of travel to a region with endemic diphtheria or a history of contact with a recent immigrant from such an area increases the possibility of diphtheria, as does a serum antitoxin level of less than 0.01 IU/mL before antitoxin treatment.

TABLE 300-1 GOALS AND PROPOSED INTERVENTIONS FOR THE MANAGEMENT OF SUSPECTED DIPHTHERIA CASES

GOALS	PROPOSED INTERVENTIONS
Neutralize toxin as soon as possible to reduce severe complications, including death	After a presumptive diagnosis of diphtheria, immediately obtain and administer antitoxin, initiate antimicrobial treatment, and arrange for appropriate supportive care
Prevent further spread of *C. diphtheriae* to close contacts, including hospital staff	Isolate the patient; strictly observe respiratory barrier procedures Notify the health department Review the vaccination status of the family and other close contacts, and initiate postexposure prophylaxis
Confirm the diagnosis	Collect appropriate specimens for culture (alert the laboratory to ensure that it can prepare specific culture media)
Induce long-term protection against *C. diphtheriae* in case and close contacts	Complete the primary series with diphtheria toxoid as needed

TREATMENT

Rx

The goals of treatment are to neutralize the toxin rapidly, eliminate the infecting organism, provide supportive care, and prevent further transmission (Table 300-1). The mainstay of therapy is equine diphtheria antitoxin. Because only unbound toxin can be neutralized, treatment should commence as soon as the diagnosis is suspected because each day of delay in administration increases the likelihood of a fatal outcome. A single dose is given, ranging from 20,000 units for localized tonsillar diphtheria to 100,000 units for extensive disease with severe toxicity. Antitoxin can be administered intramuscularly or intravenously; particularly for more severe cases, the intravenous route is preferred. Tests for sensitivity to antitoxin should be performed according to package insert instructions before administering it, and desensitization should be carried out if necessary. Antibiotic therapy, by eliminating the organism, halts toxin production, limits local infection, and prevents transmission. Parenteral penicillin (4 to 6 million U/day) and erythromycin (40 mg/kg/day in four divided doses to a maximum of 2 g/day, usually orally if the patient can swallow) are the drugs of choice. General supportive care includes ensuring a secure airway (with tracheotomy, if necessary), monitoring the electrocardiogram for evidence of myocarditis, treating heart failure and arrhythmias, and preventing secondary complications of neurologic impairment such as aspiration pneumonia. The patient should be in strict isolation until follow-up cultures are negative. Convalescing patients should receive diphtheria toxoid.

The local health department must be notified. Close contacts should have cultures performed and should be given prophylactic antibiotics. A positive culture in a contact may confirm the diagnosis if the patient is culture negative. All contacts without full primary immunization and a booster within the preceding 5 years should receive diphtheria toxoid. Because U.S. manufacturers discontinued diphtheria antitoxin production, no licensed product is available. However, diphtheria antitoxin for therapeutic purposes can be obtained from the Centers for Disease Control and Prevention (CDC; call the National Immunization Program at 1-404-639-8257 during working hours and 1-770-488-7100 at other times), which distributes a Brazilian-produced antitoxin (Instituto Butantan, Sao Paulo, Brazil) under an investigational new drug protocol.

PREVENTION

Immunization with diphtheria toxoid is the only effective means of primary prevention. The primary series is four doses of diphtheria toxoid (given with tetanus toxoid and pertussis vaccine) at 2, 4, 6, and 15 to 18 months of age; a preschool booster dose is given at 4 to 6 years of age. Thereafter, a booster should be given as part of the adolescent immunization schedule (i.e., between 11 and 13 years of age), followed by doses administered every 10 years. Since 2005, the CDC recommends the routine use of tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis vaccine, adsorbed (Tdap), in adolescents aged 11 to 18 years in place of tetanus and diphtheria toxoid (Td) vaccines. In addition, the CDC recommends the routine use of a single

TABLE 300-2 CORYNEBACTERIA AND RELATED ORGANISMS ASSOCIATED WITH HUMAN DISEASE

SITE OF INFECTION	PATHOGEN	CLINICAL SYNDROME	COMMENT
Respiratory tract	*C. diphtheriae*	Classic diphtheria	
	C. ulcerans	Diphtheria	Zoonotic infection; may produce diphtheria toxin
	C. pseudodiphtheriticum	Pharyngitis Rarely, pneumonia in patients with advanced AIDS	
	Arcanobacterium haemolyticum	Pharyngitis, tonsillar abscess, rash	Clinically indistinguishable from streptococcal pharyngitis
Skin and soft tissue	*C. pseudotuberculosis*	Granulomatous lymphadenitis	Zoonotic infection, especially in sheep; occupational risk for veterinarians and butchers
	C. minutissimum	Erythrasma	
	C. kroppenstedtii	Granulomatous breast abscess	
Genitourinary tract	*C. glucuronolyticum*	Urinary tract infection in men; chronic prostatitis	
	C. urealyticum	Chronic and recurrent urinary tract infection	More common in the elderly, chronically ill, immunosuppressed patients and those with indwelling catheters
	C. riegelli	Encrusted cystitis	
Health care–associated infections	*C. jeikeium* and, less commonly, many others, including *C. amycolatum*, *C. striatum*, and *C. urealyticum*	Catheter- and device-associated infection Postprocedure wound and soft tissue infection Prosthetic valve, joint infection Nosocomial pneumonia Cerebrospinal fluid shunt infection	*C. jeikeium* is the most common corynebacterial pathogen in hospitals and causes severe infections in immunosuppressed patients and those with indwelling devices

dose of Tdap for adults 19 to 64 years of age to replace the next booster dose of Td.

Genetically altered, fully immunogenic mutants of diphtheria toxin have been created (e.g., CRM197) and could be used as potentially less reactogenic alternatives to immunization with the toxoid. CRM197 is used as a protein carrier in several polysaccharide-protein conjugate vaccines.

PROGNOSIS

In the 21st century, diphtheria remains a serious disease associated with a high case-fatality rate. In the United States, the diphtheria case-fatality rate has remained virtually unchanged (between 5 and 10%) over recent decades.

OTHER *CORYNEBACTERIUM* SPECIES

Corynebacteria other than *C. diphtheriae* are ubiquitous in the environment and are among the normal flora colonizing humans and animals. The pathogenic potential of many of these organisms was not appreciated in the past, but many are now known to be associated with specific and often serious infectious diseases, especially in immunosuppressed, chronically ill, and hospitalized patients (Table 300-2). In general, these organisms remain susceptible to vancomycin, but resistance to other classes of antimicrobials is not uncommon and varies among species.

LISTERIOSIS

BENNETT LORBER

DEFINITION

Listeriosis is a food-borne infection caused by the gram-positive rod *Listeria monocytogenes*. Most patients have impaired cell-mediated immunity and are seen with life-threatening bacteremia or meningitis, although a self-limited, febrile gastroenteritis in healthy persons also occurs.

The Pathogen

Widely distributed in nature, *L. monocytogenes* may be found in soil, on vegetation, and in the stool of healthy mammals, including humans. It causes disease in animals, especially herd animals, and in humans. The organism has been isolated from many foods, including raw vegetables, raw milk, fish, poultry, and meat.

EPIDEMIOLOGY

Ingestion of contaminated foods appears to be the source of most human infection. Outbreaks have been documented in association with coleslaw, milk, soft cheese, pâté, ready-to-eat pork products, deli counter meats, smoked fish, and butter. Sporadic cases have been traced to contaminated cheese, milk, deli counter meats, turkey frankfurters, and alfalfa tablets. Molecular epidemiologic tools such as pulsed-field gel electrophoresis are important resources when tracking outbreaks.

Information on annual incidence comes from active surveillance studies performed by the Centers for Disease Control and Prevention. The annual incidence of listeriosis in the United States decreased by 44% between 1989 and 1993, possibly related to more stringent regulations in the food-processing industry. Presently, the annual incidence of listeriosis is 3 cases per million population, and it accounts for 1800 cases per year and about 400 deaths. Neonates and adults older than 60 years have the highest infection rates. Pregnant women represent 30% of all affected individuals; other adults at increased risk for invasive listeriosis (bacteremia, meningitis) include those with hematologic malignancy, advanced acquired immunodeficiency syndrome (AIDS), a solid organ transplant, or iron overload and anyone treated with corticosteroids or an anti–tumor necrosis factor (TNF) agent. However, as many as a fourth of all cases of invasive listeriosis occur in apparently healthy persons, particularly those older than 60 years.

PATHOBIOLOGY

L. monocytogenes enters the human body through the intestine, most often after the ingestion of contaminated food. The bacterium induces its own uptake by gastrointestinal cells and macrophages. Mother-to-child transmission occurs transplacentally or through an infected birth canal. Within the host cell the bacterium is enclosed in a phagolysosome, but through the production of an exotoxin called listeriolysin O, it destroys the phagolysosome membrane and gains access to the cytoplasm. All pathogenic strains of *L. monocytogenes* produce listeriolysin O, the major virulence factor. Listeriae actively divide in the cytoplasm, migrate to the periphery of the cell by polymerization of host cell actin, and then push out the cell membrane to form pseudopods, which are taken up by adjacent host cells. The bacteria move from cell to cell in this fashion and repeat their life cycle.

After invasion through the gastrointestinal tract, listeriae may disseminate hematogenously to any body site but show a particular tropism for the central nervous system (CNS). Less commonly, listeriae may spread intra-axonally through cranial nerves to reach the CNS.

Immunity to listerial infection is handled through the cell-mediated arm of the immune system; persons with abnormalities solely of humoral immunity or leukocytes are not at increased risk for infection.

CLINICAL MANIFESTATIONS

The incubation period for invasive listeriosis (time from ingestion of contaminated food to illness) averages about 30 days. Invasive listeriosis in an immunocompromised adult is most often manifested as bacteremia without an obvious focus. In such cases, patients have nonspecific complaints such as fever, malaise, myalgia, and back pain. Bacteremia is the form of invasive listeriosis that complicates pregnancy; CNS infection is extremely rare in the absence of other risk factors. Listeriosis during pregnancy may lead to spontaneous abortion or neonatal sepsis, but early antimicrobial therapy may result in the birth of a healthy child. Endocarditis with *L. monocytogenes* can occur on both native and prosthetic valves and carries a high rate of septic complications. Endocarditis, but not bacteremia per se, may be a clue to underlying colon cancer; colonoscopy should be considered in all cases of listerial endocarditis.

Persons in whom *L. monocytogenes* bacteremia develops may progress to CNS infection, most commonly manifested as meningitis. *Listeria* has a predilection for infecting brain tissue, as well as the meninges, and unlike other common bacterial causes of meningitis, it not infrequently causes encephalitis or brain abscess. Brain abscess as a result of infection by *L. monocytogenes* exhibits unusual features when compared with other bacteria: listerial brain abscess coexists with bacteremia in nearly all cases and with meningitis in a fourth; in addition, abscesses are often subcortical.

L. monocytogenes is the most common cause of bacterial meningitis in patients with lymphomas, organ transplant recipients, and patients treated with corticosteroids for any reason. Affected persons usually have the classic acute symptoms of meningitis but may also have a subacute disease course more characteristic of tuberculous meningitis. Most have a stiff neck, but 25% may not. Focal neurologic findings, including ataxia, tremors, myoclonus, and seizures, may be seen consistent with the tropism of *Listeria* for brain parenchyma. The glucose content in cerebrospinal fluid (CSF) is normal in more than 60% of cases. Gram stain of CSF reveals *L. monocytogenes* in only

about 40% of cases, and even when seen, the organisms may be mistaken for pneumococci.

Listerial rhombencephalitis is an unusual form of listerial encephalitis that involves the brain stem. Unlike other listerial CNS infections, rhombencephalitis usually occurs in healthy adults. The typical clinical picture is one of a biphasic illness with a prodrome of fever, headache, nausea, and vomiting lasting about 4 days, followed by the abrupt onset of asymmetrical cranial nerve deficits, cerebellar signs, and hemiparesis or hemisensory deficits, or both. Respiratory failure develops in about 40% of patients. Nuchal rigidity is present in about half, and CSF findings are only mildly abnormal, with a positive CSF culture in about 40%. Almost two thirds of patients are bacteremic. Magnetic resonance imaging is superior to computed tomography for demonstrating rhombencephalitis. Mortality is high, and serious sequelae are common in survivors.

Localized infection may occur after hematogenous seeding (e.g., liver abscess, septic arthritis) or, rarely, after direct inoculation (e.g., conjunctivitis, cellulitis).

Well-documented reports of food-borne outbreaks have demonstrated that ingestion of *L. monocytogenes* in a sufficiently large inoculum can result in a self-limited illness consisting of fever, chills, diarrhea, abdominal cramps, and sometimes nausea and vomiting. Symptoms follow exposure by 1 to 2 days and last for about 2 days.

DIAGNOSIS

Differential Diagnosis

Clinical situations in which a diagnosis of listeriosis should be considered include (1) neonatal sepsis or meningitis; (2) meningitis or parenchymal brain infection in the following: patients with hematologic malignancies, AIDS, organ transplantation, corticosteroid immunosuppression, treatment with anti-TNF agents, and age older than 50 years; (3) simultaneous infection of the meninges and brain parenchyma; (4) subcortical brain abscess; (5) fever during pregnancy, particularly in the third trimester; (6) blood, CSF, or other normally sterile specimen reported to have "diphtheroids" on Gram stain or culture; and (7) food-borne outbreak of febrile gastroenteritis when routine cultures fail to identify a pathogen. The differential diagnosis of listerial CNS infection includes the more common causes of bacterial meningitis and brain abscess; indolent listerial meningitis or rhombencephalitis may mimic CNS tuberculosis.

Laboratory Findings

The diagnosis of listeriosis is best made by routine bacterial culture of specimens from usually sterile sites such as blood or CSF. The laboratory must exercise caution because *L. monocytogenes* may be mistaken for diphtheroids, streptococci, enterococci, or *Haemophilus influenzae*. Specific stool culture is recommended only when routine stool cultures are negative in the setting of an outbreak of gastroenteritis; many people have enteric colonization with *L. monocytogenes* without invasive disease. The laboratory must be advised that listerial infection is suspected because the organism is unlikely to be identified with routine stool culture media.

Serologic testing (antibody to listeriolysin O) is not useful for invasive disease but may be helpful in the retrospective identification of food-borne outbreaks of febrile gastroenteritis when routine cultures are negative.

PREVENTION

Guidelines for preventing listeriosis are similar to those for preventing other food-borne illnesses. In general, one should thoroughly cook raw food from animal sources, wash raw vegetables thoroughly before eating, keep uncooked meats separate from vegetables and from cooked and ready-to-eat foods, avoid raw (unpasteurized) milk or foods made from raw milk, and wash hands, knives, and cutting boards after each handling of uncooked foods.

People at high risk for listeriosis (those immunocompromised by illness or medications, pregnant women, and the elderly) may choose to avoid soft cheeses such as feta, Brie, Camembert, blue-veined, and Mexican-style cheese such as queso fresco. Hard cheeses, processed cheeses, cream cheese, cottage cheese, and yogurt are safe. Leftover foods or ready-to-eat foods such as hot dogs should be cooked until steaming hot. It is best to avoid foods from delicatessen counters, such as prepared salads, meats, and cheeses, or at least to reheat cold cuts thoroughly until they are steaming hot before eating.

Listeriosis is effectively prevented by trimethoprim-sulfamethoxazole given as *Pneumocystis* prophylaxis to organ transplant recipients or to individuals infected with human immunodeficiency virus. In areas with a high prevalence of AIDS, the widespread use of trimethoprim-sulfamethoxazole for *Pneumocystis* prophylaxis appears to have resulted in a marked decline in nonperinatal listeriosis.

Second episodes of neonatal listerial infection are virtually unheard of, and intrapartum antibiotics are not recommended for women with a history of perinatal listeriosis.

Except from infected mother to fetus, human-to-human transmission of listeriosis does not occur; patients do not need to be isolated.

TREATMENT Rx

Recommendations for the treatment of infection with *L. monocytogenes* derive from in vitro data, animal models, and clinical experience with small numbers of patients; no controlled trials have been performed to prove the efficacy of one drug over another. Many antimicrobials show in vitro activity against *L. monocytogenes*. Clinical utility is more relevant than in vitro susceptibility test results because cephalosporins and other drugs to which the bacterium appears to be susceptible are inadequate to treat infection.

Twenty percent of cases of bacterial meningitis in those older than 50 years are due to *L. monocytogenes*. Therefore, empirical therapy for bacterial meningitis in all adults older than 50 years should include either ampicillin or trimethoprim-sulfamethoxazole, especially in the absence of associated pneumonia, otitis, sinusitis, or endocarditis, which would suggest a cause other than *L. monocytogenes*. Cephalosporins, commonly used for the treatment of bacterial meningitis, should not be used alone when *Listeria* is a diagnostic consideration.

Ampicillin is generally considered the drug of choice for treating confirmed cases of listeriosis. In cases of meningitis and endocarditis and in patients with severely impaired T-cell function, many authorities recommend the addition of gentamicin to ampicillin for synergy based on in vitro testing and animal models. For meningitis, therapy should be continued for at least 3 weeks; bacteremic patients without CNS involvement may be treated for 2 weeks. Endocarditis and brain abscess should be treated for at least 6 weeks. Meningitis doses should be used to treat all cases of invasive listeriosis, even in the absence of CNS or CSF abnormalities.

In patients with penicillin hypersensitivity, trimethoprim-sulfamethoxazole is the preferred agent. It is bactericidal and appears to be as effective as the combination of ampicillin and gentamicin. Drugs that should be avoided because of treatment failure and relapse include cephalosporins, chloramphenicol, tetracycline, and erythromycin.

Corticosteroids appear to be important adjunctive agents in treating the most common forms of bacterial meningitis. Their role in the treatment of listerial CNS infection is unknown.

Iron is a virulence factor for *L. monocytogenes,* and clinically, iron overload states are risk factors for listerial infection. Therefore, in patients with listeriosis and iron deficiency, it may be prudent to withhold iron replacement until antimicrobial therapy is complete.

PROGNOSIS

Listeria meningitis carries a mortality of about 25%, and mortality is higher in those with underlying malignancy. Mortality from brain abscess and endocarditis is about 50%; survivors of brain abscess commonly have significant neurologic residua.

302 ANTHRAX

DANIEL R. LUCEY

DEFINITION

Anthrax is caused by *Bacillus anthracis*, a spore-forming, gram-positive rod that is aerobic or facultatively anaerobic. The name comes from the Greek word for "coal," a reference to the black eschar that eventually forms in the cutaneous form of anthrax. Anthrax is primarily a disease of animals, but it has also been developed in past decades by some nations as a biowarfare weapon and was used by one or more persons as a bioterrorist weapon in 2001 in the United States.

The Pathogen

The bacterium is a large (1 to 1.5 by 3 to 5 µm), gram-positive rod. It has a "ground-glass appearance" of growth on sheep blood agar, with 2- to 5-mm, nonhemolytic, tenacious ("beaten egg white") colonies after 15 to 24 hours of culture; oval, central to subterminal spores; and a capsule that can be visualized by India ink staining and that may also be seen in smears of blood or cerebrospinal fluid.

EPIDEMIOLOGY

Human infection with *B. anthracis* is usually linked to a zoonotic source such as goats, sheep, cattle, antelope, kudu, pigs, horses, zebu, and other animals. Animal-related products that can transmit the infection include meat, wool, hides, bones, and hair. Soil contaminated with spores, which can persist for many years, is also a source of infection. The spores can infect humans or animals, after which they germinate into the vegetative form of the bacterium and then cause clinical disease.

The World Health Organization makes available online an extensive global epidemiology database for anthrax and offers guidelines on epidemiologic and ecologic control issues in both humans and animals. From 1900 to 2005, at least 82 patients with inhalational anthrax were reported in detail in the worldwide medical literature, including 18 from the United States with naturally acquired disease diagnosed before 1977. Many of these 18 patients had environmental exposure to spores, such as in goat hair–processing plants in New England. In 2006, the first patient with naturally acquired inhalational anthrax in the United States in 30 years was hospitalized in Pennsylvania; the source was dried African animal hides used in making drums. Of note, this patient was the first to have a component of anthrax toxin, specifically "lethal factor," assayed for and found in high concentration in pleural fluid. In 2009 the first case of naturally acquired, culture-confirmed, gastrointestinal anthrax in the United States was diagnosed in a patient in New Hampshire. Again, the source of the infection was linked to drums.

Between December 2009 and June 2010, anthrax, mainly severe soft tissue infection, was diagnosed in at least 48 patients in the United Kingdom, primarily Scotland. Approximately 30% (15/48) of infections were fatal, including some patients with central nervous system (CNS) hemorrhage. The source was linked to the injection of heroin contaminated by *Bacillus anthracis*.

Clinical experience with inhalational anthrax in the United States is primarily related to events in 2001, when 11 persons were infected after spores were sent in letters that arrived in several locations, including Florida, New York, New Jersey, Washington, DC, and Virginia (Chapter 20). A previous attempt to use anthrax as a bioterrorist weapon, by releasing it from a Tokyo rooftop in 1993, failed to cause any human illness.

In 1979, accidental release of anthrax from a military facility in Sverdlovsk (now Yekaterinburg), Russia, resulted in the deaths of many dozens of humans and animals. Eventually, epidemiologic and clinical data revealed that the deaths followed the probable airborne path ("plume") of the anthrax spores downwind from the military facility. At autopsy, 50% of 42 patients who died had anthrax meningitis in addition to inhalational anthrax.

Some of the largest outbreaks of anthrax in humans have involved the cutaneous form. For example, an estimated 10,000 human infections with cutaneous anthrax occurred in Zimbabwe from 1979 to 1985, primarily attributed to human exposure to an outbreak in cattle that had not been vaccinated against anthrax. In the United States, bioterrorism via anthrax in mailed letters caused 11 cases of cutaneous anthrax in addition to the 11 inhalational cases.

Notably, *B. anthracis* is not transmitted from person to person through the air. There is, however, evidence of spores being able to re-aerosolize under some experimental indoor and outdoor conditions.

PATHOBIOLOGY

The major virulence factors of *B. anthracis* include its two binary toxins, "edema factor" (EF) and "lethal factor" (LF), and its antiphagocytic poly-D-glutamic acid capsule. Both EF and LF must first bind a third anthrax toxin component, "protective antigen" (PA), following binding of PA to a cellular "anthrax toxin receptor" (ATR). For example, edema toxin consists of EF bound to PA (EF-PA binary toxin), and lethal toxin consists of LF bound to PA (LF-PA binary toxin). EF, LF, and PA are all encoded on one plasmid ("pX-01"), and the immune system–evading, antiphagocytic capsule is encoded on a second plasmid ("pX-02").

The pathogenesis of anthrax is linked to its two binary toxins. Two cellular receptors serve as the ATR: tumor endothelial marker 8 (TEM-8) and capillary morphogenesis protein 2 (CMG-2). Once the PA component of edema toxin and lethal toxin binds to a cellular receptor, the toxin complex can enter the target cell, first going into the acidic endosome and then the cytosol.

EF is a calmodulin-dependent, adenylate cyclase enzyme that catalyzes excessive production of cyclic adenosine monophosphate from adenosine triphosphate and results in water and calcium dysregulation, which is manifested as the characteristic edema of anthrax (sometimes described as "gelatinous"). Edema toxin is also reported to impair the function of polymorphonuclear leukocytes.

LF is a zinc-dependent metalloproteinase that impairs the immune system by interfering with the function of macrophages and other antigen-presenting cells, such as dendritic cells, that are essential for normal T-cell function. Dendritic cell function is inhibited by blockade of costimulatory molecules that are required for the presentation of antigen to T cells, such as CD40, CD80, and CD86, and by blockade of the activation of cytokines that help prime naïve T cells, such as interleukin-12.

The primary mechanism of action of lethal toxin is to inhibit the mitogen-activated protein kinase (MAP kinase) intracellular signal transduction pathway. Lethal toxin is linked to excessive production of inflammatory cytokines and dysregulation of the cytokine network, possibly leading to a "cytokine storm" that contributes to rapid multiorgan clinical failure, shock, and death. Lethal toxin is also reported to impair platelets, again by inhibiting MAP kinase pathways, such as p38 MAP kinase. In addition, lethal toxin can impair human whole blood clotting in vitro. Thus, lethal toxin may contribute in several ways to the striking bleeding diathesis, including bleeding into lymph nodes, the pleural space, the meninges, the intestines, and ascitic fluid.

CLINICAL MANIFESTATIONS

Four major clinical manifestations of anthrax infection—inhalational, cutaneous, gastrointestinal, and meningeal—are related to the three routes by which *B. anthracis* can enter the body: inhalation, ingestion, or via the skin. An apparent fifth major clinical manifestation, "injection anthrax," which causes "serious soft tissue infection," has been described in 2010 in heroin-injecting drug users in the United Kingdom.

Inhalational anthrax typically causes mediastinal adenopathy that results in mediastinal widening (Fig. 302-1), as well as pleural effusions that are often bloody, can expand rapidly, recur if drained by thoracentesis rather than by chest tube, and can be rapidly fatal if not treated with multiple antibiotics and pleural drainage. In 2005, a new clinical staging system for inhalational anthrax (Table 302-1) added an "intermediate progressive stage" based on clinical, microbiologic, and radiologic information acquired from the 11 patients in 2001. Radiography demonstrated either pulmonary infiltrates or consolidation in 8 of the 11 patients. The incubation period of inhalational anthrax is generally 3 to 14 days, with a range of 2 to 43 days in humans. In all six of the patients who survived the anthrax attacks in 2001, anthrax was diagnosed during the "intermediate progressive stage," and prompt therapy prevented progression of disease beyond this stage.

Cutaneous anthrax is the most common form of the disease (95%). The incubation period is usually 1 to 12 days. Cutaneous anthrax typically progresses from a papule that is pruritic, to a central vesicular or bullous lesion with surrounding nonpitting edema, and finally to a necrotic and hemorrhagic central lesion that evolves into the classic painless black eschar with surrounding edema (Fig. 302-2). This sequence of progressive cutaneous

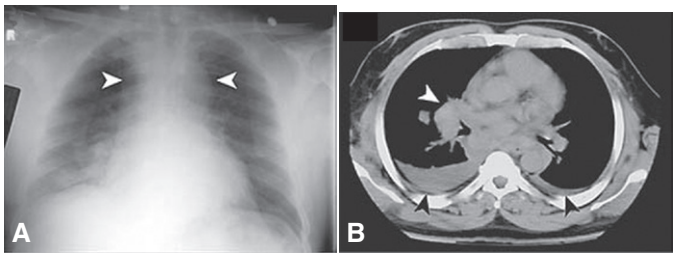

FIGURE 302-1. Clinical features of anthrax. A, A portable chest radiograph in a 56-year-old man with inhalational anthrax depicts a widened mediastinum *(arrowheads)*, bilateral hilar fullness, right pleural effusion, and bilateral perihilar air space disease. **B**, A non–contrast-enhanced spiral computed tomography scan depicts an enlarged and hyperdense right hilar lymph node *(white arrowhead)*, bilateral pleural effusions *(black arrowheads)*, and edema of mediastinal fat. (From Mayer TA, Bersoff-Matcha S, Murphy C, et al. Clinical presentation of inhalational anthrax following bioterrorism exposure. *JAMA.* 2001;286: 2549-2543.)

TABLE 302-1 CLINICAL STAGING SYSTEM FOR INHALATIONAL ANTHRAX

I. EARLY PRODROMAL STAGE

Nonspecific illness sometimes described as "flulike" and including any of the following: fever, cough, headache, chills, nausea, chest pain, or abdominal pain. Laboratory tests and radiographs are nondiagnostic. The prognosis for cure is good with appropriate therapy, but the diagnosis is difficult to confirm acutely in this stage.

II. INTERMEDIATE PROGRESSIVE STAGE

Any of the following findings are defining inclusion criteria for this stage:

1. Positive blood cultures (typically positive in <24 hours)
2. Mediastinal adenopathy
3. Pleural effusions: bloody, often large, require drainage, and may recur

Findings in this stage may include high fever, dyspnea, confusion or syncope, or increasing nausea and vomiting. Exclusion criteria for this stage include the following:

1. Meningitis
2. Respiratory failure requiring intubation and mechanical ventilation or
3. Shock

Importantly, patients in the "intermediate-progressive" stage can still be cured with appropriate antibiotics *and* drainage of pleural effusions by thoracentesis and/or chest tube to reduce the adverse mechanical effect on respiration by large-volume effusions and to remove potentially toxin-producing *Bacillus anthracis* from the pleural space.

III. LATE FULMINANT STAGE

Inclusion criteria include any one of the following findings:

1. Meningitis
2. Respiratory failure requiring intubation and mechanical ventilation
3. Shock: end-organ hypoperfusion

Findings in this stage may also include any of those from previous stages, so there are no exclusion criteria. The probability of survival is lowest in this stage. Novel therapeutics that safely and effectively neutralize anthrax toxin may be needed to increase survival.

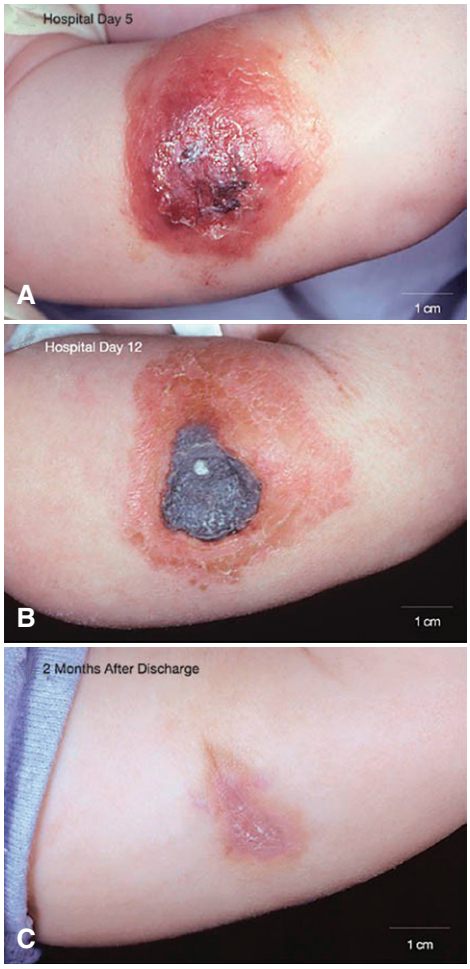

FIGURE 302-2. The lesion of cutaneous anthrax. (From Freedman A, Freedman A, Afonja O, et al. Cutaneous anthrax associated with micro-angiopathic hemolytic anemia and coagulopathy in a 7-month-old infant. *JAMA.* 2002;287:869-874.)

lesions can still occur even if appropriate antibiotics are given, and total resolution can take up to 2 months. The differential diagnosis includes brown recluse spider bites (which typically cause a painful lesion, unlike the painless anthrax lesion; Chapter 367), cutaneous leishmaniasis (Chapter 356), plague (Chapter 320), tularemia (Chapter 319), typhus (Chapter 335), and warfarin (Coumadin) or heparin necrosis (Chapter 37), among others.

Gastrointestinal anthrax can be divided into an oropharyngeal form and an intestinal form. Extremely rare in the United States, gastrointestinal anthrax in other nations is often linked to consumption of the meat of infected animals, thereby suggesting that the vegetative form of the bacteria can cause gastrointestinal disease in humans. The oropharyngeal form is accompanied by painful cervical adenopathy and fever. The incubation period ranges from 2 to 144 hours. Oral lesions can ulcerate and progress to cause a white pseudomembrane, hoarseness, and dysphagia. Three phases of intestinal disease have been noted: an initial prodromal phase with fever, malaise, and syncope; a second progressive phase with abdominal pain, nausea, vomiting, abdominal distention, ascites, and severe weakness; and a fulminant third phase with suddenly increasing abdominal girth and expanding ascites, paroxysmal abdominal pain, and shock.

Anthrax meningoencephalitis can occur in association with inhalational, cutaneous, or gastrointestinal anthrax, and in rare cases it occurs without a known portal of entry. Anthrax meningitis is nearly always fatal. Cerebral edema, parenchymal brain hemorrhages, vasculitis, and subarachnoid hemorrhages can be seen.

DIAGNOSIS

Most importantly, if anthrax is suspected, blood should be obtained immediately for culture before any antibiotics are started; blood from patients with inhalation anthrax will grow the typical large, gram-positive rods in less than 24 hours. Surprisingly, even one dose of an effective antibiotic can sterilize the blood cultures. Nasal cultures should not be performed as a clinical diagnostic test for individual patients but might be useful as part of an epidemiologic investigation. If the initial culture is suggestive, three additional tests that should be performed in a biosafety cabinet are motility (nonmotile), catalase (positive), and hemolysis (negative). If these characteristics are found, *B. anthracis* is suspected but not proved until a sample is sent to a reference laboratory where polymerase chain reaction can identify *B. anthracis* and gamma-phage lysis of the encapsulated bacteria can provide confirmation. In addition, the Anthrax Quick ELISA (enzyme-linked immunosorbent assay) test can detect the eventual presence of antibodies to anthrax in blood.

A non–contrast-enhanced computed tomography scan can be a valuable adjunctive diagnostic tool for inhalational anthrax and is better than chest radiography for demonstrating the characteristic hyperattenuating mediastinal adenopathy and pleural effusions seen with inhalational anthrax. The

hyperattenuation is consistent with bleeding into lymph nodes and thus is helpful in distinguishing anthrax from tularemia (Chapter 319), histoplasmosis (Chapter 340), tuberculosis (Chapter 332), sarcoidosis (Chapter 95), and most other causes of hilar or mediastinal adenopathy.

Anthrax meningitis is typically bloody and neutrophilic. Large gram-positive rods distinguish it from other causes of gram-positive rod meningitis, such as the smaller *Listeria monocytogenes* (Chapter 301).

TREATMENT Rx

Treatment of clinical anthrax includes antibiotics and, in the case of inhalational anthrax, pleural fluid drainage. The Centers for Disease Control and Prevention (CDC) recommendations for treatment include a multidrug regimen with either ciprofloxacin (400 mg intravenously every 12 hours) or doxycycline (100 mg intravenously every 12 hours) plus one or more additional antimicrobials for inhalational or gastrointestinal anthrax: rifampicin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, or clarithromycin. Penicillin (or ampicillin) should not be used as a single agent in the initial therapy for inhalational anthrax because of the risk that resistance will develop. A detailed algorithm for the management of cutaneous anthrax is posted on the website of the American Academy of Dermatology (available at *www.aad.org/professionals/educationcme/bioterrorism/CutaneousAnthrax.htm*). Initial treatment of suspected anthrax meningitis should be combination therapy with a fluoroquinolone given intravenously and one or two other antibiotics that penetrate well into the CNS and are active against *B. anthracis*, such as penicillin, ampicillin, meropenem, vancomycin, or rifampicin.

If persons are potentially exposed to aerosolized anthrax spores, they should also receive three doses of anthrax vaccine at 0, 2, and 4 weeks under a Food and Drug Administration (FDA) Investigational New Drug (IND) or Emergency Use Authorization (EUA) protocol, according to CDC recommendations.

A 60-day course of antibiotic therapy is recommended for inhalational anthrax because of concern that residual spores may germinate into vegetative bacteria if antibiotic therapy is stopped sooner. When clinically appropriate, intravenous therapy can be changed to oral therapy, and multiple antibiotics might be reduced to only ciprofloxacin or doxycycline. Cutaneous anthrax is usually treated for 7 to 10 days rather than 60 days if inhaled spores are not an issue.

Adjunctive corticosteroids have been used historically for anthrax meningitis and for severe airway compromise caused by cutaneous anthrax of the neck. However, steroids have not been shown in a randomized clinical trial to be beneficial in any clinical forms of anthrax.

Another critical treatment modality for inhalational anthrax is pleural drainage via chest tube or by thoracentesis initially performed when the patient is still in the intermediate progressive stage, if possible. Thoracentesis may need to be repeated if the typically bloody fluid reaccumulates.

As of 2009, there are two types of anthrax toxin antibodies in the Strategic National Stockpile (SNS). One is polyclonal, called Anthrax Immune Globulin (AIG), and is derived from the plasma of persons who have received the anthrax vaccine. The other is a humanized monoclonal antibody called raxibacumab. Neither is licensed by the FDA as of June 2010. AIG has been given as adjunctive therapy to several patients, including two in the United States in 2006 and 2009 and several in the U.K. heroin-contaminated outbreak in 2009-2010.

PREVENTION

Clinical anthrax can be prevented by pre-exposure vaccination or by postexposure antibiotic prophylaxis. The current FDA-licensed anthrax vaccine contains PA as the vaccine antigen and alum as an adjuvant. It requires five shots over an 18-month period when given before exposure. In contrast, postexposure prophylaxis, which is an off-label use of this same vaccine and thus needs an IND or EUA protocol, requires only three shots given over a 1-month period. This vaccine is in limited supply and is dedicated primarily to use by the military, so it is not available for routine use by civilian populations.

Antibiotics that are approved by the FDA for postexposure prophylaxis include ciprofloxacin, doxycycline, and procaine penicillin G, as well as levofloxacin. In addition, in certain situations (children, pregnant women, and breast-feeding mothers), the CDC has advised that amoxicillin is another option for postexposure prophylaxis. Either doxycycline or ciprofloxacin is recommended by the CDC for initial prophylaxis when the antibiotic susceptibility of an anthrax strain is unknown. The CDC website on anthrax (available at *http://www.bt.cdc.gov/agent/anthrax*) is the best source for detailed recommendations regarding the choice of antibiotics, doses, and durations for both prevention and treatment of anthrax. Recommendations currently include either ciprofloxacin, 500 mg orally every 12 hours, or doxycycline, 100 mg orally every 12 hours, for a total of 60 days. Levofloxacin has the potential for once-daily 500-mg dosing, but safety data beyond 28 consecutive days in adults are very limited. The 2001 recommendations from the CDC on antibiotic use for prevention and treatment have not yet been officially updated as of May 2010. The CDC did, however, convene a multidisciplinary conference to address updating the clinical guidelines in March 2006 and published the conference report in April 2008 in their journal *Emerging Infectious Diseases*.

Prevention of anthrax secondary to bioterrorism remains a priority. Evolving approaches for detecting and responding to any future bioterrorism attacks with anthrax include the BioWatch antiterrorist system and the Autonomous Detection System. The "Cities Readiness Initiative" was initially described on the CDC website in June 2004 as a program for multiple U.S. cities and metropolitan areas to help prepare them for large-scale public health emergencies, including bioterrorism attacks (e.g., with aerosolized anthrax or another organism). Large volumes of medical supplies, including but not limited to antibiotics, could be delivered rapidly from the SNS to one or multiple locations across the nation, followed by local and regional distribution.

PROGNOSIS

The inhalational anthrax of all six patients who survived the attacks of 2001 was diagnosed during the "intermediate progressive stage," and prompt therapy prevented progression beyond this stage. The 45% case-fatality rate in 2001 was much improved over the 88% rate seen in the United States from 1900 to 1976. Survival is more likely in patients who undergo pleural drainage, receive multidrug antibiotic regimens, do not require intubation or tracheotomy, and do not progress to anthrax meningoencephalitis. The mortality from cutaneous anthrax is approximately 20% if untreated, including patients in whom upper airway compression develops from a lesion on the neck or in whom secondary bacteremic anthrax meningitis develops. In 2009-2010, an approximate 30% mortality (15/48 cases) in U.K. heroin-injecting drug users with serious soft tissue infections occurred despite surgical débridement, multiple antibiotics, and in some cases antitoxin (AIG). Anthrax meningitis remains fatal in more than 95% of victims, and thus better, more rapid therapies are needed.

FUTURE DIRECTIONS

Research is ongoing in an attempt to develop a commercially available, clinically validated, rapid test for the diagnosis of infection with *B. anthracis*, either before symptoms start, in the early prodromal stage of the illness, or in later clinical stages if the patient may have received antibiotics before blood or cerebrospinal fluid was obtained for culture. Anthrax toxin inhibitors, in conjunction with antibiotics, could be particularly useful in treating patients who have progressed into the systemic stages of anthrax as a result of inhalational, gastrointestinal, or injection anthrax causing serious soft tissue infection; however, whether antitoxins cross the blood-brain barrier and can treat human neurologic anthrax remains to be determined.

In addition, antitoxin could be useful in the setting of infection with an engineered form of multidrug-resistant (MDR) or extremely drug-resistant (XDR) anthrax. Currently, however, the best hope for the treatment of MDR/XDR anthrax is to find licensed or investigational antibiotics (or both) to which such an organism is susceptible. New anthrax vaccines are also still being tested.

303 *ERYSIPELOTHRIX* INFECTIONS

ANNETTE C. REBOLI

DEFINITION

Erysipelothrix rhusiopathiae causes three well-defined patterns of human infection: (1) erysipeloid, a cellulitis of the fingers and hands (also known as whale finger or pork finger), which is the most common manifestation of infection with *E. rhusiopathiae;* (2) a diffuse cutaneous form; and (3) a bacteremic form, with or without cutaneous involvement, usually complicated by endocarditis.

The Pathogen

E. rhusiopathiae is a thin, pleomorphic, nonsporulating, microaerophilic gram-positive rod. It may be confused with other gram-positive bacillary organisms, particularly *Listeria monocytogenes* and *Corynebacterium* species. It can be differentiated from *L. monocytogenes* by its lack of motility, lack of catalase and coagulase production, and resistance to neomycin. Most strains of *E. rhusiopathiae* produce hydrogen sulfide on triple sugar iron agar slants, a feature that distinguishes *E. rhusiopathiae* from *L. monocytogenes* and from corynebacteria. Because α-hemolysis may be seen after 48 hours of incubation of *E. rhusiopathiae,* confusion with streptococci may also occur. The term *erysipeloid* refers to cutaneous infection by *E. rhusiopathiae* and should not be confused with erysipelas, which is a superficial cellulitis caused by streptococci or staphylococci.

EPIDEMIOLOGY

E. rhusiopathiae is found worldwide as a commensal or as a pathogen in a variety of wild and domestic animals, including swine, sheep, cattle, horses, dogs, rodents, chickens, ducks, turkeys, penguins, and parrots, as well as in flies, ticks, mites, and lice. The greatest commercial impact of *E. rhusiopathiae* infection is due to disease in swine, but infection of sheep and poultry is also important economically. Environmental surfaces in contact with infected animals or their products are potential sources of *E. rhusiopathiae.* It can persist for prolonged periods in contaminated soil. *E. rhusiopathiae* is killed within 15 minutes by heating to 55° C and by several commercially available home disinfectants.

The incidence of cutaneous infection in humans seems to be decreasing because of technologic advances in animal industries. It is usually the result of contact with infected animals or their products. Persons at greatest risk for infection include fishers, fishmongers, farmers, butchers, slaughterhouse workers, and veterinarians. The organism gains entry through cuts and abrasions on the skin. The seasonal incidence of erysipeloid parallels that of swine erysipeloid and is highest in the summer and early fall. The rare instances of systemic infection that do not have an occupational link tend to occur in immunocompromised hosts, suggesting that oropharyngeal or gastrointestinal colonization with the organism may occur. Chronic alcoholism has been acknowledged as a common underlying condition. Erysipeloid and erysipeloid with bacteremia have been reported rarely after cat and dog bites, suggesting that *E. rhusiopathiae* may be part of the oral flora of these animals.

PATHOBIOLOGY

The virulence of *E. rhusiopathiae* is associated, at least in part, with resistance to phagocytosis by polymorphonuclear leukocytes. This antiphagocytic ability results from the organism's possession of a capsule. In the absence of specific antibodies, *E. rhusiopathiae* evades phagocytosis, but even if phagocytized, it is able to replicate intracellularly in these cells. Other virulence factors include enzymes (neuraminidase and hyaluronidase) and surface proteins.

CLINICAL MANIFESTATIONS

Because of the mode of acquisition (contact with infected animals or their products, with organisms inoculating abrasions on the skin), lesions are usually confined to the fingers and hands (Fig. 303-1). A well-defined, slightly elevated, violaceous lesion accompanied by a very painful, throbbing, burning, or itching sensation develops within 2 to 7 days of traumatic dermal inoculation. The infected area is swollen. Vesicles may be present, but suppuration is absent. The lesion spreads slowly to other fingers but rarely involves the fingertips or the skin above the wrist. As the lesion spreads peripherally, the central area clears. Systemic signs and symptoms are rare. There may be sterile arthritis of an adjacent joint. Regional lymphadenopathy or lymphadenitis occurs in about 20% of cases, and low-grade fever develops in approximately 10%. Lesions usually resolve within 3 weeks without treatment. Relapse occurs in 1% of cases.

FIGURE 303-1. Erysipeloid with its characteristic purple, nonpurulent swelling of the finger. Also known as whale finger or pork finger, this form of cellulitis caused by *Erysipelothrix rhusiopathiae* should not be confused with streptococcal or staphylococcal erysipelas (see Fig. 449-4 in Chapter 449). (From Farrar WE, Wood MJ, Innes JUA, Tubbs H. *Infectious Diseases: Text and Color Atlas,* 2nd ed. New York: Gower Medical Publishing, 1992.)

The diffuse cutaneous form is rare. The cutaneous lesion progresses proximally from the site of inoculation or appears at remote areas. Patients often have fever and arthralgias, but blood cultures are generally negative.

Systemic infection with *Erysipelothrix* is uncommon. Approximately 90 cases of bacteremia have been reported; most of the patients had endocarditis. Although cases of prosthetic valve endocarditis have been reported, most cases have involved native valves. In 60% of cases, infection developed on apparently normal heart valves. One third of patients had an antecedent or concurrent skin lesion of erysipeloid. The clinical manifestations of endocarditis secondary to *E. rhusiopathiae* and other microorganisms are similar. *E. rhusiopathiae* endocarditis correlates highly with occupation, exhibits a tropism for the aortic valve, affects more males than females, and is associated with high mortality. The latter may reflect a delay in appropriate therapy because of the empirical use of vancomycin, which is not an effective treatment of *E. rhusiopathiae.* Cases of *E. rhusiopathiae* endocarditis have been complicated by paravalvular and myocardial abscess formation, cerebral emboli, congestive heart failure, valve perforation, and acute renal failure. *E. rhusiopathiae* bacteremia without endocarditis occurs more frequently than was previously believed. Bacteremia is occurring with increased frequency in immunocompromised patients, whereas endocarditis usually occurs in immunocompetent patients. Focal infections, including brain abscess, meningitis, endophthalmitis, osteomyelitis, septic arthritis, liver abscess, necrotizing fasciitis, intra-abdominal abscess, and peritonitis, have been reported. Some of these infections were complications of bacteremia. Septic arthritis has occurred in native joints, in prosthetic joints, and after arthroscopic surgery. Peritonitis has complicated peritoneal dialysis.

DIAGNOSIS

E. rhusiopathiae grows on routine laboratory media. Because *E. rhusiopathiae* is located only in deeper parts of the skin in cases of erysipeloid, biopsy of the entire thickness of the dermis from the edge of the lesion yields maximal recovery of the organism. Routine blood culture techniques are adequate for growth and isolation of the organism in suspected cases of bacteremia or endocarditis. Various selective media have been used to improve the isolation of *E. rhusiopathiae* from contaminated specimens. Molecular techniques such as polymerase chain reaction with primers specific for *E. rhusiopathiae* have been developed and improve the efficiency of detection and identification.

TREATMENT

Rx

Most isolates of *E. rhusiopathiae* are susceptible to penicillin, cephalosporins, imipenem, clindamycin, ciprofloxacin, ofloxacin, and daptomycin. Some resistance has been observed with erythromycin, tetracycline, and chloramphenicol. *E. rhusiopathiae* is resistant to vancomycin, aminoglycosides, trimethoprim-sulfamethoxazole, and sulfonamides. Penicillin G is the treatment of choice. Uncomplicated cutaneous lesions generally respond well to a 5- to 7-day course of oral penicillin. Treatment hastens healing, although relapse may still occur. Bacteremia should be treated with intravenous penicillin; cases of endocarditis should be treated with 12 million to 20 million units of penicillin G daily or ceftriaxone 1 g daily for 4 to 6 weeks. Two weeks of intravenous therapy followed by 2 weeks of oral therapy has been successful. The use of quinolones or daptomycin may be considered for *Erysipelothrix* infections when the patient is allergic to β-lactams. Oral linezolid was used to complete therapy in a case of bacteremia complicated by endophthalmitis. Valve replacement may be necessary in patients with endocarditis.

PREVENTION

Proper cleaning and disinfection of work surfaces and attention to hygienic work practices, including the use of gloves and hand hygiene, reduce the risk for infection. Vaccines are available for commercial use in animals only.

304 CLOSTRIDIAL INFECTIONS

DALE N. GERDING AND STUART JOHNSON

Clostridial infections are characterized by disease produced by toxins. They include tetanus and botulism, both caused by neurotoxins, and clostridial myonecrosis or gas gangrene, caused by the toxins of *Clostridium perfringens* as well as those of other clostridial species. Although these clostridial infections remain important clinically, their frequency has declined markedly with the advent of vaccines and better public health measures. Several previously little known species of clostridia that produce very large clostridial cytotoxins (LCCs) that vary in size from 250 to 308 kD have become increasingly prominent. They include, in particular, *Clostridium difficile,* which is responsible for one of the most common health care–associated infections and for increasing mortality among elderly patients. Another LCC-producing organism, *Clostridium sordellii*, has caused devastating infections in young women in association with pregnancy and medical abortion, in injection drug users, and in patients with traumatic wounds. *Clostridium novyi* type A is a third LCC organism that has also caused severe infections in injection drug users.

CLOSTRIDIUM DIFFICILE INFECTION

DEFINITION AND PATHOGEN

C. difficile infection (CDI) is a gastrointestinal infection characterized by diarrhea (three or more loose or unformed stools in ≤24 hours) and a positive test for *C. difficile* toxin A or toxin B in stool, evidence of a toxin-producing strain of *C. difficile* in stool, or evidence of pseudomembranous colitis on direct visualization of the colon. *C. difficile* is a spore-forming, anaerobic, gram-positive organism that survives well in water, soil, and animals and has a worldwide distribution.

EPIDEMIOLOGY

CDI occurs most frequently in health care settings, particularly in long-term care facilities and acute care hospitals, and is most frequent and lethal among the elderly, especially those older than 75 years. Rates in U.S. hospitals have nearly tripled in the decade since 2000, and it is now estimated that there are 500,000 to 750,000 CDIs each year. A specific strain of *C. difficile*—identified as the restriction endonuclease group BI, pulse field gel type NAP1, PCR ribotype 027 (BI/NAP1/027) strain—is thought to be responsible for much of the epidemic that has extended to Canada and Europe. Rates of CDI in the community have also increased somewhat during the past decade, in association with the rising rates in hospitals and nursing homes. However, it is unlikely that community cases account for more than 15 to 20% of all CDIs. Risk factors for CDI include antimicrobial use, advanced age, and stay in an acute or chronic care facility. Hospitals are considered a particularly high-risk environment because patients are elderly, antimicrobial use is frequent, the environment is contaminated with *C. difficile* spores (which are difficult to eradicate), asymptomatic patients carry *C. difficile* in their stools, and health care workers carry *C. difficile* on their hands if they do not practice good hand hygiene. In about 2 to 3% of healthy adults, *C. difficile* can be cultured from their stools, but the frequency in asymptomatic hospitalized patients increases with the duration of hospitalization and may reach 20% or more. Exposure to nearly all antimicrobials has been associated with subsequent CDI, but those with the highest risk are clindamycin, the cephalosporins, and the fluoroquinolones. CDI is rare in children and young adults, despite their frequent exposure to antimicrobials. However, children younger than 1 year are commonly colonized with *C. difficile* but remain asymptomatic, an observation that remains largely unexplained.

PATHOBIOLOGY

CDI risk appears to be minimal in the absence of antimicrobial therapy. When antimicrobials are administered, they have the unintended consequence of disrupting the normal protective bowel flora, which may persist for days to weeks after the antimicrobial is stopped. If *C. difficile* is ingested during this time, the spores germinate in the gut, and the vegetative form of the organism multiplies and begins to make toxins. At this point, whether the patient will develop diarrhea is dictated by the status of his or her immunity to the toxins, which is best correlated with serum immunoglobulin G (IgG) antibodies directed at toxin A and toxin B of *C. difficile*. Those with good antibody responses will be asymptomatic but will remain colonized with *C. difficile,* whereas those with little or no antibody response will develop diarrhea and CDI. Toxin A is primarily an enterotoxin, and toxin B is a cytotoxin. Both act by glucosylation that disrupts the cell cytoskeleton, resulting in colonic epithelial cell rounding, fluid leakage, and cell death. In the presence of pseudomembranous colitis, the colon appears to be covered in yellow to white pseudomembranes that vary in size from punctate to completely confluent and covering the entire colon in advanced cases. Histologically, the colon demonstrates a marked neutrophil infiltration throughout the colon wall, with mucosal necrosis and volcano-like lesions from which the pseudomembrane is seen to "erupt." The pseudomembrane is composed of proteinaceous material and cellular debris.

CLINICAL MANIFESTATIONS

Clinical symptoms of CDI range from asymptomatic carriage to severe and sometimes life-threatening pseudomembranous colitis complicated by major fluid losses and systemic complications. With mild CDI, patients may simply have "nuisance diarrhea" that resolves when the implicated drug is discontinued. Others with more severe CDI have substantial fluid and protein losses combined with fever, cramps, hypoalbuminemia, leukocytosis, and hypotension. Leukocytosis is common (occurring in up to 50% of patients) and is a marker of severe CDI when it exceeds 15,000/mm^3. Extremely high levels greater than 50,000/mm^3 are an indication of fulminant and potentially fatal illness. Other factors that may be indicative of severe or late-stage disease include toxic megacolon, high fever, renal failure, hypotension, and a lactic acidosis greater than 5.0 mmol/L.

DIAGNOSIS

The diagnosis should be suspected in any patient who has otherwise unexplained diarrhea (three or more loose or unformed stools in ≤24 hours) in association with recent or concurrent antibiotic use. Only about 10 to 20% of patients in this category actually have CDI, but this is the patient group that should be tested. The standard test to establish the diagnosis is to detect toxins A and B in stool or to detect a toxin-producing strain of *C. difficile* in stool. Tests that detect only toxin A are not acceptable because about 1 to 3% of strains that cause CDI produce toxin B but not toxin A. The most common laboratory method is an enzyme immunoassay (EIA), but its sensitivity is only 50 to 80%. Repeat testing does not improve the diagnostic accuracy because EIAs also have specificity deficiencies that increase the rate of false-positive test results with repeated testing. A number of polymerase chain reaction (PCR) tests for *C. difficile* in stool are available commercially and markedly improve test sensitivity to 90 to 95% (compared with the "gold standard" of culture for a toxigenic strain). The PCR tests are more expensive, but when they become more widely used, they should increase the sensitivity and specificity of diagnosis and eliminate the common practice of ordering *C. difficile* tests "times 3," which has no justification. When a negative test result does not confirm the diagnosis in a patient whose clinical symptoms are highly suggestive of CDI, empirical treatment for CDI should be given rather than repeating the test. The standard cell cytotoxin assay is more sensitive than EIA but has the disadvantages of a 24- to 48-hour turnaround and the requirement for tissue culture facilities, which may not be available in clinical laboratories. Stool culture for *C. difficile*, which is the most sensitive test available, is likewise slow and requires confirmation of toxin production by the organism before reporting. Testing stools for glutamate dehydrogenase, or "common antigen," can be used as a screening test, but it is only about 50% specific and requires confirmation with a toxin test, which increases the turnaround time for reporting positive results. CDI can also be diagnosed by observing pseudomembranous colitis directly via sigmoidoscopy or colonoscopy or at surgery. The cause of diarrhea in an adult patient with an onset longer than 48 hours after hospital admission is almost always CDI because other infectious enteric pathogens are extremely rare in the hospital setting. Also common in the differential diagnosis are noninfectious causes of diarrhea, such as antibiotic or other drug-associated diarrhea, ischemic colitis, and idiopathic inflammatory bowel disease. For patients with antibiotic-associated diarrhea and no evidence of colitis, the cause of diarrhea with a negative *C. difficile* toxin assay is usually not defined.

PREVENTION

Two major prevention strategies are employed. The first is traditional infection control in which barriers to transmission (gowns, gloves, isolation, hand

hygiene, environmental cleaning) are used to prevent the spores of *C. difficile* from reaching the patient. The second strategy is to reduce the likelihood of infection if the patient does encounter *C. difficile* while in the hospital. The most efficacious strategy, also known as *antimicrobial stewardship*, is to avoid or minimize exposure to antimicrobials, especially those with a high CDI risk such as clindamycin, cephalosporins, and fluoroquinolones. Interventions to restrict exposure to clindamycin and to cephalosporins have been highly effective in interrupting outbreaks of CDI in hospitals.

TREATMENT

Rx

Treatment of CDI begins with discontinuation of the implicated antibiotic, supportive care, and avoidance of antiperistaltic agents. Mildly ill patients may recover with these simple conservative measures, but most require specific treatment. Continuation of the offending antibiotics while treating CDI with vancomycin and other agents results in lower cure rates and higher CDI recurrence rates in patients. Metronidazole, at a dose of 500 mg orally three times a day for 10 to 14 days, is the recommended treatment for patients with mild CDI. It provides response rates comparable to those for vancomycin, is much less expensive, and avoids some of the concern about vancomycin-resistant enterococcus colonization.[1,2] Patients with severe CDI (variously defined as a white blood cell count >15,000 or a creatinine increase to >1.5-fold over baseline) should be treated with vancomycin 125 mg orally four times a day for 10 days.[1,2] Vancomycin can be substituted for metronidazole if there is a delayed response in patients with mild illness. A newer option is fidaxomicin (200 mg twice daily), which is as efficacious as vancomycin.[3] The anticipated response to these drugs is rapid defervescence, with gradual normalization of bowel habits. Mean time to resolution of diarrhea is about 3 days; if symptoms have not resolved by day 5 or 6 of treatment, a change in therapy should be considered. However, there are no data to support the use of more than one drug at a time to treat CDI. Failure to respond often means that either the disease has progressed too far or another condition is causing the symptoms. For patients with severe complicated or fulminant CDI, medical management includes vancomycin at a higher dose (500 mg four times a day) orally or by nasogastric tube; if ileus is present, metronidazole (500 mg IV every 8 hours) is added, with vancomycin administered by enema. If symptoms progress with this therapy, colectomy may be life-saving and should be performed before the white blood cell count reaches 50,000/mm^3 or lactate reaches 5.0 mmol/L.

Other antibiotic options include oral fusidic acid, teicoplanin, nitazoxanide, rifaximin, and bacitracin, but most of these drugs have been evaluated in only a small number of patients, and none (like metronidazole) has Food and Drug Administration approval for the treatment of CDI. There is no convincing evidence that toxin-binding agents such as cholestyramine or probiotics such as lactobacillus are useful in preventing or treating CDI. About 20% of patients treated with either vancomycin or metronidazole have a recurrence of symptoms when treatment is stopped because of the persistence of *C. difficile* spores or acquisition of a new strain. Treatment is readministration of either vancomycin or metronidazole, depending on the severity of the recurrence. Patients with multiple recurrences of CDI are extremely difficult to treat and may benefit from consultation with an infectious disease specialist or gastroenterologist.

PROGNOSIS

The majority (≈70%) of patients respond to simple withdrawal of the implicated antibiotic combined with a single course of metronidazole or vancomycin. Some patients with fulminant disease eventually require colectomy. The attributable mortality rate is as high as 7% in large series, and the majority of lethal cases occur in patients older than 65 years. Patients with multiple recurrences require repeated courses of antibiotics, usually vancomycin with tapering and pulse-dose regimens that may need to be continued for weeks to months.

NECROTIZING CLOSTRIDIAL TISSUE INFECTION
Clostridium sordellii

DEFINITION AND PATHOGEN

C. sordellii is another clostridial species that produces LCCs, and it has become more common as a cause of septic shock and necrotizing fasciitis in association with trauma, childbirth, medical abortion, and injection drug use. *C. sordellii* antitoxin cross-neutralizes the cytotoxic effect of *C. difficile* toxins, indicating the similarity of these LCCs.

EPIDEMIOLOGY

The organism is commonly found in soil and in the intestines of animals and occasionally humans worldwide. Soil contamination of wounds is the usual suspected route of infection. Infections have been described following traumatic wounds, childbirth, medical abortion, and intramuscular or subcutaneous injection drug use.

PATHOBIOLOGY

C. sordellii produces up to seven identified toxins; of these, lethal toxin and hemorrhagic toxin, which are both LCCs, are considered major virulence factors. The toxins produce local necrosis, progressive edema, and shock that results in high mortality. The toxins are glycosyltransferases that glycosylate the Rho, Rac, or Ras proteins, causing impaired cytoskeletal organization and massive capillary leakage, leading to the progressive edematous state.

CLINICAL MANIFESTATIONS

Initial symptoms are nonspecific and include nausea, lethargy, dizziness, and tenderness at the infection site. Tachycardia and hypotension follow within hours. Laboratory tests show a marked leukocytosis or leukemoid reaction. Hypotension and tachycardia are refractory to treatment. Edema secondary to capillary leakage is prominent, resulting in hemoconcentration but little or no fever. Peritoneal and pleural effusions are common. White blood cell elevations greater than 75,000/mm^3 are associated with a fatal outcome.

INFECTION ASSOCIATED WITH CHILDBIRTH AND MEDICAL ABORTION. This is a rare infection in which patients present 4 to 7 days following the administration of oral mifepristone and vaginal misoprostol for medical abortion with nausea, vomiting, weakness, abdominal pain, hypotension, and tachycardia but little or no fever and, often remarkably, a lack of findings on pelvic examination. The presentation is similar to toxic shock syndrome. There is rapid progression to vascular collapse and cardiac arrest. Leukocytosis is dramatic, with white blood cell counts near 100,000/mm^3 in most patients. Following delivery, the presentation is similar, but localized swelling and discoloration of the labia and perineum may be evident if the episiotomy site is infected. All patients to date have died.

INFECTION ASSOCIATED WITH INJECTION DRUG USE. Black tar heroin (a dark, gummy, less refined, and cheaper form of heroin) has been associated with necrotizing fasciitis at the subcutaneous or intramuscular injection site, presumably a result of the contaminants mixed with the heroin. Patients present with 2 to 7 days of symptoms of necrotizing fasciitis of the upper or lower extremity where they injected heroin, in some cases accompanied by hypotension. Aggressive surgical débridement is required at the infection site, together with fluids and pressors. Cultures of débrided tissue reveal multiple organisms in addition to *C. sordellii*. Mortality in these patients is 50%.

DIAGNOSIS

Diagnosis is difficult due to the lack of specific symptoms, but it is usually made by identifying the likely source of infection and isolating *C. sordellii* from the infection site or blood cultures. PCR for *C. sordellii* in infected tissues may be required to make the diagnosis when cultures are negative. Other bacteria are also commonly found at the infection site. Computed tomography or magnetic resonance imaging may be helpful in identifying localized infections, which can then be excised or drained surgically, providing material for microbiologic diagnosis.

PREVENTION

C. sordellii infections are very rare, and the exact mechanism of infection, especially following medical abortion, is not known. However, careful attention to wound cleansing, avoidance of injecting drugs into skin or muscle, and good hygiene during childbirth are likely to help prevent *C. sordellii* infection.

TREATMENT

Rx

Definitive treatment information is lacking. The infection progresses so rapidly that therapeutic interventions are rarely successful. Surgery to remove necrotic sites of infection and administration of intravenous fluids and pressors to treat hypotension and tachycardia are supportive. Antibiotic susceptibility suggests that β-lactams, clindamycin, tetracyclines, and chloramphenicol are active, but no clinical treatment efficacy data are available. Theoretically, use of an antibiotic such as clindamycin to suppress toxin synthesis could be a useful adjunct to treatment. At present, there is no antitoxin available.

PROGNOSIS

Infections following childbirth or medical abortion have been uniformly fatal. Mortality in injection drug users or patients following trauma or surgery is about 50%.

Clostridium novyi Infection in Injecting Drug Users

C. novyi α-toxin causes an LCC-producing disease in humans. *C. novyi* has long been recognized as a cause of fatal toxemia in animals with contaminated wounds. An extended outbreak of human infections occurred in Scotland, Ireland, and elsewhere in the United Kingdom in 2000 among persons injecting heroin extravascularly (skin or muscle popping). A localized necrotizing infection with sepsis and significant mortality was recognized. The findings include soft tissue inflammation, edema and necrosis at the injection sites, circulatory collapse, leukocytosis, and pleural effusions. Treatment usually involves débridement and antibiotic administration (gentamicin, flucloxacillin, penicillin, metronidazole, and clindamycin were used during this outbreak).

Clostridial Myonecrosis

DEFINITION

Clostridial myonecrosis, or gas gangrene, can be caused by several *Clostridium* species, most commonly *C. perfringens* following trauma or tissue injury and *Clostridium septicum* following dissemination from a colonic source.

EPIDEMIOLOGY

Gas gangrene has historically been a complication of battlefield injuries and of trauma in noncombat settings. The estimated number of cases in the United States is about 1000 per year. Traumatic injuries account for about 50% of cases, with vehicular accidents accounting for the majority; the remaining cases develop in patients after crush injuries, industrial accidents, gunshot wounds, and burns. Minor injuries such as puncture wounds, intramuscular injections, simple lacerations, and subcutaneous injections with epinephrine may occasionally precipitate clostridial myonecrosis. Postoperative complications account for about 30% of cases and are most frequently associated with surgery on the appendix, biliary tract, or intestine. Approximately 20% are "spontaneous" or nontraumatic and are invariably associated with an occult colonic malignancy.

PATHOBIOLOGY

Clostridia are widely distributed in nature and can be cultured from nearly all soil samples, from environmental sites in the hospital, and from the human intestine. A critical factor is a physiologic state of the wound with conditions that support germination and toxin production by toxigenic clostridia. Particularly critical are a low oxidation-reduction potential, hypoxia, appropriate substrates, and calcium ions. The probability of infection is substantially increased by devitalized muscle and the presence of foreign material such as dirt. *C. perfringens* elaborates at least 12 recognized toxins, most importantly α-toxin and θ-toxin of *C. perfringens* type A. Although the interaction is complex, good evidence supports a central role for α-toxin, a phospholipase C, and θ-toxin or perfringolysin O, a cholesterol-dependent cytolysin, in the extensive cell death and disruption of microvascular perfusion that are characteristic of clostridial myonecrosis. The vascular perfusion changes are likely mediated by toxin-induced platelet aggregation and leukocyte margination. The α-toxin of *C. septicum*, a spore-forming cytolysin unrelated to α-toxin of *C. perfringens*, also causes cell death and microvascular perfusion changes.

CLINICAL MANIFESTATIONS

Initial symptoms of traumatic myonecrosis usually occur 1 to 4 days after the precipitating event, although the range is 8 hours to 3 weeks. The initial symptom is pain that is often sudden and severe at the site of surgery or trauma. The involved skin has intense edema and is initially pale before progressing to a bronze or magenta color, followed by the formation of bullae. The bullae contain fluid that may be clear or hemorrhagic. The discharge has an odor that is described as "foul-sweet."

Circulatory collapse and hypotension unresponsive to fluid challenge are common and may reflect the effect of α-toxin, which suppresses cardiac contractility. About 15% of patients have bacteremia that is usually complicated by rapid hemolysis with a dramatic drop in the hematocrit, which may even decrease to 0%. Common complications include jaundice, hypotension, hepatic failure, and renal failure. The renal failure is often due to hemoglobulinuria and myoglobulinuria, but it may also be due to acute tubular necrosis from hypotension. Despite the severity of the illness, the patient's mental status is usually remarkably good until very late in the disease. Surgical intervention shows necrotic muscle that does not contract with stimulation. Deeper dissection reveals beefy red necrotic muscle that becomes black and extremely friable in the late stages.

Uterine gas gangrene, which was once common after septic abortions, is now rare but may complicate normal delivery, amniocentesis, cesarean section, or abortion. The onset is usually sudden, with fever, tachycardia, hypotension, renal failure, and jaundice. Radiography may show gas in the uterine wall. The urine is often "port wine" in color as a result of hemoglobulinuria, and there is often jaundice because of massive intravascular hemolysis. The usual causes are *C. perfringens* and *C. sordellii.*

Spontaneous myonecrosis occurs in the absence of trauma and is usually caused by *C. septicum*. One distinctive association is colon cancer or neutropenic enterocolitis, which represent portals of entry for hematogenous seeding of *C. septicum*. This infection is also seen with acute leukemia and is most common with chemotherapy for solid tumors and after stem cell transplantation. The usual portals of entry are the terminal ileum, cecum, and ascending colon, hence the term *typhlitis*. The usual manifestation is a necrotizing infection in an extremity or in the abdominal wall, accompanied by hypotension and renal failure. Examination shows spreading crepitations with rapid clinical deterioration over a period of hours, and imaging reveals gas.

DIAGNOSIS

The diagnosis of gas gangrene is usually based on a constellation of characteristic clinical features, including myonecrosis, shock, and renal failure. The patient typically complains of very severe pain. Early recognition is important, because early institution of treatment may strongly influence the prognosis. The diagnosis is established by examination of the muscle, which shows putrid discharge, characteristic bullae, and crepitations. Gram stain demonstrates abundant gram-positive bacilli and no inflammatory cells. Histopathologic examination of the lesion shows myonecrosis without polymorphonuclear leukocytes, a finding that is remarkably different from most soft tissue infections, which do not feature necrosis and have abundant inflammatory cells. Gas is present in the tissue and may be detected by physical examination, radiography, or other imaging methods.

PREVENTION

The basic principle of prevention is adequate management of traumatic wounds—establishing adequate drainage, removing foreign bodies, draining hematomas, and ensuring good hemostasis.

TREATMENT

Rx

The most important facet of treatment is prompt surgical débridement. Many cases require extensive, often mutilating surgery. Penicillin and clindamycin are recommended but are rarely adequate without radical surgery, except in patients with neutropenic enterocolitis, who can often be managed with antibiotics. The rationale for penicillin combined with clindamycin is that some strains of clostridia are resistant to clindamycin, but clindamycin is probably the superior drug for reducing toxin formation. Other antibiotics that are generally effective include metronidazole and chloramphenicol. The use of hyperbaric oxygen is controversial, in part because the therapeutic trials have been either of poor quality or not convincing.

PROGNOSIS

Factors associated with a poor prognosis include elderly age, location on the trunk, association with severe underlying disease, leukopenia, renal failure, hemolysis, and shock. The best results are seen in young patients with involvement of a single extremity. Management plays an important role, particularly the use of early and aggressive surgery, as well as antibiotics. The overall mortality rate of patients with traumatic gas gangrene in tertiary centers is about 25%.

NEUROTOXIC CLOSTRIDIAL INFECTIONS

Botulism

DEFINITION

Botulism is a severe neuroparalytic disease characterized by a descending flaccid motor neuron paralysis. It is caused by botulinum toxin produced by *Clostridium botulinum.*

The Pathogen

C. botulinum is a gram-positive, spore-forming obligate anaerobe that is widely distributed in nature and is frequently found in soil, marine environments, and agricultural products. Each strain produces one of seven toxins designated by the letters A to G. Botulinum toxin may also be produced by related clostridial species, *Clostridium baratii* and *Clostridium butyricum*. All these neurotoxins produce the same syndrome, and the causes of disease in humans are types A, B, and E, with rare cases caused by type F.

EPIDEMIOLOGY

Botulism in humans is generally one of three types: food-borne botulism, infant botulism, or wound botulism. Rarely, botulism may be acquired as a result of iatrogenic misadventures with botulinum toxin, which is a potential bioterrorism agent if inhaled or ingested.

Food-borne botulism is the most common form of botulism in the world, but it is a distant second to infant botulism in the United States, with only 19 food-borne cases occurring in the United States in 2006. Foods most frequently implicated are home canned vegetables or fermented foods, and most cases are sporadic single cases occasionally involving two or three people. Commercially preserved and restaurant-prepared foods are also rare causes of food-borne botulism. Type A toxin is predominant in the United States. Alaska has the highest rate of any state, with approximately 35% of all cases; 80 to 90% of events and cases in Alaska are caused by type E and are most often associated with fermentation methods used to prepare fish and marine mammals by native Alaskans. Meat and meat products are frequently implicated in Europe, where the predominant toxin is type B. In China, the most frequent vehicle is a vegetable product, and type A predominates.

Infant botulism is the most frequently recognized form in the United States and is the most recently discovered type of botulism, first described in 1976. It is caused by production of botulinum toxin in the intestine after presumed spore ingestion and colonization in 2- to 36-week-old infants. Honey has been identified as the source of *C. botulinum* spores, but in most cases the source is never identified. Nearly all cases are caused by type A or B toxin. The symptoms usually begin with constipation followed by poor feeding, weak cry, lethargy, and generalized weakness characterized as the "floppy baby syndrome" due to loss of head control. This form of botulism is rare in adults, occurring most often in patients with anatomic or functional abnormalities of the intestines.

Wound botulism, first described in 1943, is the least frequent form of the disease and is usually caused by either type A or B toxin. Sporadic cases in traumatic wounds contaminated by soil are rarely reported. Outbreaks have been described in black tar heroin users in the western United States, particularly if they inject the drug intramuscularly or subcutaneously (skin popping). These drug users also develop other clostridial infections, including necrotizing fasciitis caused by *C. sordellii* and *C. novyi*, and tetanus caused by *Clostridium tetani.*

Inhalation or ingestion of botulinum toxin is considered one of the top six bioweapon agents in terms of probability of use. The presumed method would be contamination of the food supply, water supply, or commercial beverages or aerosolization in a highly populated area to cause inhalational botulism. It is estimated that a point-source aerosol release of the toxin could incapacitate or kill 10% of people within a 0.5-km radius.

Iatrogenic botulism results from the misuse of botulinum toxin for cosmetic or therapeutic purposes. Cosmetic treatment doses are far too low to cause systemic disease, but the use of unlicensed products with high concentrations of botulinum toxin can cause systemic symptoms. Higher doses used for the management of muscle movement disorders have caused occasional cases with systemic botulism-like symptoms.

PATHOBIOLOGY

Pathologic findings are due to absorption of toxins from the intestine (ingested preformed toxin in foods or in situ production in the intestine in infants), inhalation (aerosol from bioterrorism), absorption from cutaneous infection sources (wounds), or iatrogenic injection. The toxin is disseminated by the systemic circulation and causes flaccid paralysis by binding presynaptic motor neuron terminals and blocking acetylcholine transmission across the neuromuscular junction. The estimated lethal doses of purified botulinum toxin A for a 70-kg human are 0.09 to 0.15 μg when given intravenously, 0.8 to 0.9 μg when inhaled, and 70 μg when given orally.

CLINICAL MANIFESTATIONS

In contrast to Guillain-Barré syndrome (Chapter 428), which is an ascending paralysis, botulism is characterized by generalized weakness and a descending paralysis. Symptoms are due to absorption of botulinum toxin from the gut, lung, or a wound. Clinical symptoms consist of highly distinctive and usually symmetrical cranial nerve palsies, followed by a symmetrical descending flaccid paralysis. Prominently involved cranial nerves III, IV, and VI cause blurred vision and diplopia; involvement of cranial nerve VII causes the characteristic expressionless facies and dysphagia; and involvement of cranial nerve IX causes dysarthria. Thus, the initial symptoms include the "four Ds"—diplopia, dysarthria, dysphagia, and dysphonia—although the last is rarely reported, and blurred vision is reported more commonly than diplopia. These findings are followed by a descending upper extremity paralysis and respiratory paralysis. Neurologic examination shows bilateral cranial nerve VI paresis, ptosis, dilated pupils with a sluggish reaction, and diminished gag reflex, followed by descending involvement of motor neurons. Deep tendon reflexes are diminished or absent. Mentation remains clear, vital signs are normal, and the neurologic findings are symmetrical. The most common cause of death is respiratory failure. The tempo of the disease and the extent of paralysis in the absence of treatment are highly variable. The symptoms may be restricted to a few cranial nerves, or there may be complete paralysis of all voluntary muscles. Progression may occur over a period of hours or days. The timing and extent of neurologic deficits depend on the size of the botulinum toxin inoculum.

DIAGNOSIS

Botulism should be suspected in patients with an acute flaccid paralysis involving the cranial nerves, particularly in the presence of bilateral cranial nerve VI dysfunction, associated neurologic findings, and a 10-hour to 5-day history of consuming suspect food, such as preserved or home-canned foods. Nausea, vomiting, abdominal pain, and diarrhea are common early in the illness, with constipation present when paralysis develops. The finding of two or more cases that are epidemiologically linked is virtually diagnostic of food-borne botulism because other causes of paralysis are rare and sporadic. In the absence of a history of suspect food ingestion, potentially infected wounds should be sought, including injection sites in users of black tar heroin. With bioterrorism, the epidemiology may reflect a common source exposure, such as a local water supply or an aerosolized toxin, but it could also be widely distributed with a contaminated food source, such as the milk supply.

Laboratory tests for suspected food-borne botulism include analysis of serum, stool, gastric contents, or food for botulinum toxin and culture of stool and suspect food or wounds for *C. botulinum.* Toxin assay specimens should be collected before treatment with antitoxin. With wound botulism, recovery of *C. botulinum* from wound cultures or detection of toxin in serum is diagnostic. The toxin assays are generally available only at public health laboratories. The standard is a mouse bioassay for detection and quantification of toxin. Toxin type is determined by type-specific antibody neutralization. In general, adult patients with clinical evidence of botulism have detectable toxin in sera in a third of cases and detectable toxin in stool in a third of cases, but the organism is recovered from stool in about 60%.

The differential diagnosis includes myasthenia gravis, Guillain-Barré syndrome, tick paralysis, cerebrovascular accident, trichinosis, Eaton-Lambert syndrome, hypocalcemia, hypermagnesemia, organophosphate poisoning, atropine poisoning, and paralytic poisoning by shellfish or puffer fish. Electromyography using repetitive stimulation at 2 to 50/second may be helpful in distinguishing causes of flaccid paralysis. Electromyography patterns with slow and rapid supramaximal stimulation show similar responses in botulism and Eaton-Lambert syndrome. Cerebrospinal fluid analysis and cranial imaging are normal in botulism.

PREVENTION

The disease can be prevented by destroying spores in the original food source, inhibiting germination, or destroying preformed toxin, as follows:

- Spores can be destroyed by heat or irradiation. Spores of types A and B survive boiling for several hours, especially at high altitudes, such as in

Colorado. Spores are destroyed if the temperature is maintained at 120° C or higher for 30 minutes in pressure cookers. Spores of type E are more heat labile and are killed by heating at 80° C for 30 minutes. Modern industrial canning ("retort canning") predictably kills botulinum spores.

- Germination can be inhibited by reducing the pH, refrigerating, freezing, drying, or adding inhibitory substances such as salt, sugar, or sodium nitrate.
- Preformed toxin is inactivated by heating at 85° C for 5 minutes.

TREATMENT

Rx

Clinicians who suspect botulism should immediately seek clinical consultation, notify public health authorities, and administer antitoxin. The agency to contact in the United States is the state health department or the Centers for Disease Control and Prevention (24-hour emergency service at 404-329-2888); similar public health agencies should be contacted in other countries. Treatment consists of supportive care and passive neutralization with equine botulinum antitoxin.

The standard treatment of adults is trivalent antitoxin if the toxin type is not known or type-specific antitoxin for types A, B, or E; the standard dose is one vial (5500 to 8500 IU) diluted 1:10 in saline and delivered by slow intravenous infusion. An experimental heptavalent vaccine (A to G) from the U.S. Army may be available for unusual types associated with bioterrorism. The antitoxin should be given as early as possible and should not be delayed while awaiting microbiologic results. This treatment does not reverse paralysis or neutralize toxin already bound to nerve endings, but it does neutralize unbound toxin in the circulation to prevent progression. The antitoxin is horse serum, which is associated with anaphylaxis in 2% and other hypersensitivity reactions in 9% of patients when larger doses are used; patients should be given small doses to screen for reaction before receiving the full dose.

Respiratory failure is a major risk, and patients must be monitored carefully with liberal criteria for ventilatory support. The requirement for mechanical ventilation varies from about 20% in adults with food-borne disease to 60% in patients with infant botulism. Other forms of supportive care include enteral or parenteral feeding and positioning in the reverse Trendelenburg position.

Toxin can be removed from the gastrointestinal tract by gastric lavage, cathartics, and enemas early in the course. Antibiotic treatment is unnecessary, except for wound botulism. Infants should be given intravenous human botulism immune globulin as a single intravenous infusion of 50 mg/kg.

PROGNOSIS

The case-fatality rate for untreated food-borne botulism was once 60 to 70% but is currently 3 to 5% with treatment. Infant botulism in the United States now has a mortality rate of less than 1%; the use of human antitoxin has reduced the median duration of hospitalization from 6 to 3 weeks. Patients who survive any form of botulism generally have a complete recovery.

Tetanus

DEFINITION

Tetanus is a neurologic syndrome characterized by generalized rigidity and convulsive spasm of skeletal muscles caused by a neurotoxin elaborated at the site of injury by *C. tetani.*

The Pathogen

C. tetani is an anaerobic, gram-positive, slender, motile bacillus. When it sporulates, the terminal spore gives the organism a characteristic "drumstick" or "tennis racket" shape. The vegetative form produces tetanospasmin, a protein neurotoxin with a molecular weight of approximately 151 kD, including a heavy chain (100 kD) that binds neuronal cells and a light chain that blocks the release of neurotransmitters.

EPIDEMIOLOGY

C. tetani can be found in 2 to 23% of soil samples, with the highest yield in manure-treated soil. The organism can also be found in stool from a variety of domestic and farm animals and poultry. Tetanus is most common in warm climates and in highly cultivated rural areas. The greatest problem occurs in resource-limited countries because of high numbers of unimmunized mothers and unhygienic practices. The estimated annual toll from neonatal tetanus in developing countries is greater than 257,000, mostly secondary to inadequate passive immunity caused by absence of immunity in the mother. In the United States, an average of 31 cases of tetanus are reported annually, and almost all occur in unimmunized or inadequately immunized persons. The age of these patients is near 60 years in 58% and younger than 20 years in 6%; this age distribution reflects the impact of waning immunity with aging.

PATHOBIOLOGY

Tetanospasmin ranks with botulinum toxin as one of the most potent known microbial toxins; 2.5 ng/kg is a lethal human dose. Clinical tetanus usually results from entry of the organism into a wound and low oxygen conditions that allow spore germination and survival of the vegetative organism to produce toxin. Entry is usually through a traumatic or surgical wound, injection site, burn, skin ulcer, or infected umbilical cord. Tetanospasmin binds the peripheral nerve terminals and is then carried intra-axonally within membrane-bound vesicles to spinal neurons at a transport rate of approximately 75 to 250 mm/day. The light chain passes to the presynaptic terminals, where it blocks the release of neurotransmitters in inhibitory afferent motor neurons. Loss of the inhibitory influence results in sustained muscular contraction. Binding of the toxin is irreversible, so recovery requires the generation of new axon terminals.

CLINICAL MANIFESTATIONS

Forms of tetanus include generalized, local, cephalic, and neonatal. Generalized tetanus, which is the most common form, accounts for 80 to 90% of reported cases in the United States. The usual incubation period is 3 to 21 days (mean, 8 days), depending largely on the distance between the site of injury and the central nervous system. A short incubation period is associated with more severe symptoms. Generalized tetanus is characterized by a persistent tonic spasm with brief exacerbations. The neck and jaw are almost always involved. Trismus is the initial complaint in 75% of cases, so the patient is often initially seen by a dentist or oral surgeon. Other early features include irritability, restlessness, diaphoresis, and dysphagia with hydrophobia and drooling. Persistent spasm of the back musculature may cause opisthotonos. These early manifestations reflect involvement of the paraspinous muscles. With progression, all muscles contract, with stronger muscles overtaking weaker muscles. Noise or tactile stimuli may precipitate spasms and generalized convulsions. Involvement of the autonomic nervous system may result in severe arrhythmias, blood pressure oscillation, profound diaphoresis, hyperthermia, rhabdomyolysis, laryngeal spasm, and urinary retention. In most cases, the patient remains lucid and afebrile. The condition may continue for 3 to 4 weeks, despite antitoxin therapy, because of the time required for intra-axonal toxin transport. Complications include fractures from sustained contractions, pulmonary emboli, bacterial infections, and dehydration.

Local tetanus, in which the patient has persistent muscle contractions in the extremity involving a contaminated wound, is rare and shows considerable variation in severity. In mild cases, a patient may simply have spasms of the involved extremity; in more severe cases, local painful spasms progress to generalized tetanus. This relatively unusual form of tetanus has an excellent prognosis, with only about 1% mortality.

Cephalic tetanus is also rare and generally follows a head injury or occurs with *C. tetani* infection of the middle ear. Clinical symptoms consist of isolated or combined dysfunction of the cranial motor nerves, most frequently cranial nerve VII. This dysfunction may remain localized or progress to generalized tetanus. The incubation period is only 1 or 2 days, and the prognosis for survival is usually poor.

Neonatal tetanus is generalized tetanus resulting from *C. tetani* infection in neonates and occurs primarily in underdeveloped countries, where it accounts for up to half of all neonatal deaths. The usual cause is infection of the umbilical cord in newborns of unimmunized mothers. The usual incubation period after birth is 3 to 10 days, and the child typically shows irritability, facial grimacing, and severe spasms with touch. The mortality rate exceeds 70%.

DIAGNOSIS

The diagnosis of tetanus is usually based on clinical observations. The putative agent, *C. tetani,* is recovered from wound culture only about 30% of the time. Results of cerebrospinal fluid analysis are entirely normal. Diagnostic testing is usually not necessary except in cases lacking an identified portal of entry. The differential diagnosis depends on the dominant clinical features and includes dystonic reactions as a result of neuroleptic toxicity, seizure disorders, hypocalcemic or alkalotic tetany, alcohol withdrawal, and strychnine poisoning. Strychnine also antagonizes glycine, and strychnine

TABLE 304-1 GUIDE TO TETANUS PROPHYLAXIS IN ROUTINE WOUND MANAGEMENT

*Such as (but not limited to) wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite.
†For children younger than 7 years, DTaP (pediatric diphtheria–tetanus toxoid plus acellular pertussis vaccine) is recommended; if pertussis vaccine is contraindicated, DT (pediatric diphtheria–tetanus toxoid) is given. For persons aged 7 to 9 years or 65 years or older, Td (adult tetanus–diphtheria toxoid) is recommended. For persons 10 to 64 years, Tdap (adult tetanus–diphtheria toxoid plus acellular pertussis vaccine) is preferred to Td if the patient has never received Tdap and has no contraindication to pertussis vaccine. For persons 7 years and older, if Tdap is not available or not indicated because of age, Td is preferred to TT (tetanus toxoid alone). Note that pediatric formulations (DT and DTaP) contain a similar amount of tetanus toxoid as adult Td, but they contain three to four times as much diphtheria toxoid. DTaP and Tdap vaccines do not contain thimerosal as a preservative.
‡TIG is human tetanus immune globulin. Equine tetanus antitoxin should be used when TIG is not available.
§Yes, if more than 10 years since the last dose.
‖Yes, if more than 5 years since the last dose.

poisoning is the only condition that truly mimics tetanus. Strychnine levels in blood and urine establish the diagnosis. Dystonic reactions may resemble tetanus and are distinguished by rapid response to anticholinergic agents.

PREVENTION

Immunization with tetanus toxoid is virtually 100% effective, so nearly all cases of tetanus occur in unimmunized or inadequately immunized individuals. The Immunization Practices Advisory Committee recommends active immunization of infants and children with DPT (diphtheria, tetanus toxoids, and pertussis adsorbed) at 2 months, 4 months, 6 months, 15 to 18 months, and 4 to 6 years of age. Protective levels of serum antitoxin in persons who complete the primary series persist for at least 10 years. Td (tetanus and diphtheria toxoids adsorbed for adult use) is recommended every 10 years, but this recommendation is commonly neglected, as demonstrated by serosurveys showing that 40% of persons older than 60 years in the United States lack protective levels of tetanus antitoxin. The recommended primary immunization series for unimmunized persons older than 7 years is Td at time 0, 4 to 8 weeks, and 6 to 12 months after the second dose, and then every 10 years. Nearly all states now require DPT immunization for school enrollment. Immunization of childbearing women confers protection to their infants through transplacental maternal antibody.

Prevention of tetanus after injury (Table 304-1) requires appropriate wound management, assurance of adequate immunity, and consideration of antibiotic prophylaxis. The aim of surgery is to eliminate necrotic tissue, purulent collections, and foreign bodies that promote the environmental conditions necessary for spore germination. Passive immunization with tetanus immune globulin (TIG) is recommended only for "tetanus-prone" wounds in patients with an inadequate or unknown primary immunization status. The determination of whether a wound is tetanus prone depends on the interval between injury and treatment, the degree of contamination, the extent of devitalized tissue or foreign bodies at the site of injury, and the depth of injury. Antimicrobial agents such as penicillin or metronidazole may be given to inhibit replication of the vegetative forms of *C. tetani,* but immunization and wound cleansing are considered more important.

TREATMENT

Rx

Patients with tetanus require intensive care, with particular attention to respiratory support; treatment with benzodiazepines; autonomic nervous system support; passive and active immunization; surgical débridement; and antibiotics directed against *C. tetani.* There may be clinical progression for 2 to 4 weeks, despite antitoxin treatment, because of the time required to complete the transport of toxin. The severity of disease may be reduced by partial immunity, so some patients have mild disease with minimal mortality, whereas others have mortality rates as high as 60% despite expert care.

Supportive Care

It is most important to assess airway function. Many patients require endotracheal intubation with benzodiazepine sedation and neuromuscular blockade; a tracheostomy should be placed if the endotracheal tube causes spasms. A feeding tube is usually required for nutritional support.

Control of Muscle Spasms

Benzodiazepines have become the mainstay of therapy to control spasms and provide sedation. The most extensively studied is diazepam given in 5-mg increments; lorazepam and midazolam are equally effective. Patients with tetanus may have high tolerance for the sedative effects of these drugs and may require exceptionally high doses. When tetanus symptoms resolve, the drugs must be tapered over at least 2 weeks to prevent withdrawal reactions. If control of spasms cannot be achieved by benzodiazepines, long-term neuromuscular blockade is performed with vecuronium (6 to 8 mg/hour).

Passive Immunization

Human TIG should be given as soon as possible to neutralize toxin that has not entered neurons. The usual dose is 500 IU intramuscularly. Higher doses or intrathecal administration does not appear to be more effective. An alternative to TIG is pooled intravenous immunoglobulin. Equine TIG is equally effective, but the rate of allergic reactions is high because of the equine source; this preparation should not be used if human TIG is available.

Active Immunization

The standard three-dose schedule of immunization with tetanus toxoid should be given at an injection site separate from that used for immunoglobulin.

Antibiotic Therapy

C. tetani is susceptible in vitro to penicillins, cephalosporins, imipenem, macrolides, metronidazole, and tetracyclines. Clinical studies favor the use of metronidazole, which should be given in an intravenous dose of 2 g/day for 7 to 10 days.

Autonomic Nervous System Dysfunction

This complication generally reflects excessive catecholamine release and is usually treated with labetalol (0.25 to 1.0 mg/minute) for blood pressure control. Hypotension may require norepinephrine infusion. Bradycardia may require a pacemaker.

Surgery

Any wounds should be appropriately débrided.

PROGNOSIS

The overall mortality rate for generalized tetanus is 20 to 25%, even in modern medical facilities with extensive resources. Patients with moderate or severe generalized tetanus generally require treatment for 3 to 6 weeks. The highest mortality rates are at the extremes of age. The most frequent cause of death is pneumonia, but many patients have no obvious findings at autopsy, suggesting that death was directly due to the neurotoxin. Patients who recover usually recover completely.

OTHER CLOSTRIDIAL INFECTIONS

Clostridium perfringens Type C Enteritis

C. perfringens type C enteritis, also called *enteritis necroticans*, is a necrotizing disease involving the proximal small intestine caused by β-toxin–producing strains of *C. perfringens.* Enteritis necroticans occurs as sporadic cases or in outbreaks, most often in underdeveloped countries. This disease has often been given colorful appellations based on its dramatic clinical presentation or its cultural associations. For instance, it was called Darmbrand, or "fire bowels," in Germany in the post–World War II period and pigbel in Papua New Guinea, where it was recognized following pork feasts by aboriginal people in the highlands. Pigbel was the most common cause of death among highland children older than 1 year throughout the 1960s and 1970s, before the introduction of an effective toxoid vaccine. The disease still occurs sporadically throughout the highlands. There were outbreaks among Khmer refugees in Thailand in the 1980s and in Sri Lanka in 2007. Enteritis necroticans also occurs rarely in isolated cases in the developed world, particularly among patients with diabetes mellitus.

PATHOBIOLOGY

Experimental and clinical evidence supports infection with *C. perfringens* type C and β-toxin as the causative agent of and key virulence factor in enteritis necroticans. The organism has been identified at the site of necrotic

lesions, the disease can be reproduced in guinea pigs, isogenic β-toxin gene null mutants are avirulent, and vaccination with a toxoid preparation of β-toxin is protective. What is not satisfactorily explained is the means of infection and the unusual location of the necrotic lesions. Segmental, full-thickness necrosis of the upper small bowel separated by bands of normal bowel wall is the hallmark of the pathology. Some have suggested that the organism is part of the normal flora in some populations and that ingestion of a high-protein meal on top of a steady diet of trypsin inhibitor–containing sweet potatoes overwhelms the tryptic capacity of the gut and causes increased local availability of β-toxin. A more likely explanation is that this is a food-borne infection and that contamination of foods is more likely in underdeveloped settings. Intestinal helminthic coinfection is common in patients at risk for enteritis necroticans, and the proximal small intestine is the preferential site of infection with helminths such as *Strongyloides* (Chapter 365). This has led to a hypothesis of subclinical helminthic infestation facilitating local clostridial infection or intoxication with β-toxin following the ingestion of a contaminated meal.

CLINICAL MANIFESTATIONS

In Papua New Guinea, affected patients usually develop severe abdominal pain 12 hours to several days after a ritual pork feast (or, presumably, other infected food). Vomiting and bloody diarrhea are frequently associated findings. The abdomen becomes distended, and thickened bowel loops are sometimes appreciated on palpation. Disease severity and whether the patient experiences spontaneous recovery or bowel perforation and death depend on the extent of intestinal involvement.

DIAGNOSIS

Recognition of the clinical syndrome is critical to making the diagnosis. Culture to identify specific β-toxin–producing strains of *C. perfingens* remains a research tool and is not helpful in the management of patients. Plain radiographs of the abdomen may show dilated small bowel loops and ileus.

PREVENTION

An effective toxoid vaccine is available and has been used in Papua New Guinea (where the disease is endemic) as well as in the Khmer refugee camp outbreak in 1986.

TREATMENT

Rx

Treatment is primarily supportive, including nasogastric suction and intravenous hydration. Surgical resection of the infected bowel is often required for those who do not initially respond to supportive measures. Antibiotics (penicillin, chloramphenicol, metronidazole) are almost always given empirically, but their role has not been defined. Prognosis depends on the extent of disease and the availability of surgery for those with more extensive intestinal involvement.

Clostridium perfringens Type A Diarrhea

C. perfringens type A is a well-recognized cause of food poisoning due to the ingestion of food, usually meat, heavily contaminated with enterotoxin-producing *C. perfringens.* The incubation period is 7 to 15 hours following ingestion, and the most prominent symptoms are diarrhea and abdominal pain. The syndrome is usually mild and self-limited.

In contrast to food poisoning due to *C. perfringens* type A, a more severe and protracted infectious diarrhea syndrome due to this organism has been recognized among hospitalized or institutionalized patients. These patients often have a history of prior or concomitant antibiotic use, and an EIA for *C. perfringens* enterotoxin is commercially available for investigative use. Metronidazole treatment is recommended for those with protracted diarrhea. As with CDI, diarrhea may recur following successful treatment.

DISEASES CAUSED BY NON–SPORE-FORMING ANAEROBIC BACTERIA

ITZHAK BROOK AND ELLIE J GOLDSTEIN

DEFINITION

Anaerobic bacteria are the main members of the indigenous, normal human flora, including the skin and the oral, gastrointestinal, and vaginal mucosa (Fig. 305-1; Table 305-1). However, the types of predominant anaerobes are different at each site.

The Pathogens

Recent advances in taxonomics have led to reclassification of many anaerobic species (E-Table 305-1). The genus *Bacteroides* is used only for species of the *Bacteroides fragilis* group. The "oral" *Bacteroides* and "pigmented" *Bacteroides* species have been reclassified as *Prevotella* (saccharolytic, pigmented species), *Porphyromonas* (asaccharolytic species), and other genera. Capnophilic organisms (which require an elevated concentration of carbon dioxide for growth), sometimes referred to as microaerophiles, are not true anaerobes and are often more related to *Campylobacter*, *Capnocytophaga*, and other genera. In addition, many new genera and several new species have been created to accommodate pathogens such as *Bilophila wadsworthia*, *Sutterella wadsworthensis*, *Centipeda periodontii*, and *Anaerobiospirillum thomasii*. *Fusobacterium nucleatum* is the predominant *Fusobacterium* species from clinical specimens.

TABLE 305-1 LOCATION OF VARIOUS GROUPS OF ANAEROBES AS NORMAL MICROFLORA IN HUMANS

LOCATION	No. of Organisms Per Gram		PREDOMINANT ANAEROBIC BACTERIA
	AEROBES	ANAEROBES	
Skin	—	—	*Propionibacterium acnes* *Peptostreptococcus* spp
Mouth/upper respiratory tract (in saliva)	10^8-10^9	10^9-10^{11}	Pigmented *Prevotella* and *Porphyromonas* spp *Fusobacterium* spp *Peptostreptococcus* spp *Actinomyces* spp
Gastrointestinal tract (in fecal material)			
Upper	10^2-10^5	10^3-10^7	*Bacteroides fragilis* group *Clostridium* spp
Lower	10^5-10^9	10^{10}-10^{12}	*Peptostreptococcus* spp *Bifidobacterium* spp *Eubacterium* spp
Female genital tract (in vaginal secretions)	10^8	10^9	*Peptostreptococcus* spp *Prevotella bivia* *Prevotella disiens*

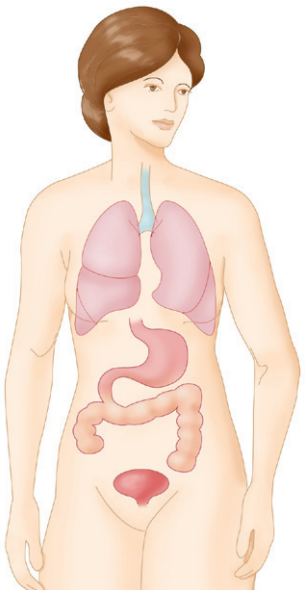

FIGURE 305-1. Anaerobes as the predominant normal microflora of the human body by general anatomic location. (Adapted from Finegold SM, Sutter VL. *Diagnosis and Management of Anaerobic Infections.* Kalamazoo, MI: Upjohn; 1976. Copyright by Dr. Finegold.)

EPIDEMIOLOGY

Although these organisms perform beneficial functions as part of the gastrointestinal flora, they are also consummate opportunistic pathogens that can cause serious infections, typically in synergistic infections in combination with aerobic bacteria. Because the microbiology of these infections is often complex and culture results may be delayed, knowledge of the normal flora at the location of infection is an indispensable guide for selecting and instituting empirical antimicrobial therapy.

PATHOBIOLOGY

Anaerobic bacteria range from those that die with very brief exposure to oxygen to those that can survive even in the presence of atmospheric oxygen (e.g., *B. fragilis*). Most anaerobes require an environment with a low oxidation-reduction potential (E_h gradient), which can be achieved in association with low pH, tissue destruction, byproducts from aerobic bacterial metabolism, or low oxygen content. Though not true anaerobes, some organisms such as microaerophilic streptococci and other capnophilic or hard-to-grow organisms are sometimes lumped together with anaerobes because of their fastidious nature. Some genera such as *Lactobacillus* and *Actinomyces* contain both aerobic and anaerobic species.

Anaerobic bacteria possess a variety of virulence factors that differ among species (Table 305-2).

CLINICAL MANIFESTATIONS

Bacteremia

Transient anaerobic bacteremia occurs in approximately 85% of patients immediately after dental cleaning or manipulation. More than 200 cases of endocarditis from anaerobes are reported annually in the United States, usually in association with anatomic abnormalities or damaged cardiac valves (Chapter 76). The majority of anaerobic bacteremias are intermittent and associated with serious intra-abdominal or female genital tract, skin, and soft tissue infections, often near the fecal stream. Which organisms are involved depends on their portal of entry and the underlying disease. The common isolates are the *B. fragilis* group (60 to 75% of isolates). Overall, about 5 to 15% of bacteremias are due to anaerobes, and they are the sole isolates in two thirds of such infections. *B. fragilis* group bacteremia is associated with a 15 to 30% mortality rate. Bacteremia with the *B. fragilis* group is mostly associated with a gastrointestinal source; bacteremia with pigmented *Prevotella, Porphyromonas,* and *Fusobacterium* spp, with oropharyngeal and pulmonary sources; *Fusobacterium* spp with the female genital tract; and *Propionibacterium acnes* with foreign bodies. Bacteremia with peptostreptococci is associated with all sources, but especially with the oropharyngeal, pulmonary, and female genital tracts.

TABLE 305-2 POTENTIAL VIRULENCE FACTORS IN VARIOUS ANAEROBES

FACTOR	SPECIES
ADHESION	
Capsule	*Bacteroides fragilis* group, *Prevotella melaninogenica*

Central Nervous System Infections

Anaerobes can cause brain abscess, subdural empyema, epidural abscess, and meningitis. The main source of brain abscess is an adjacent, generally chronic infection in the ears, mastoids, sinuses, oropharynx, teeth, or lungs. Rarely, bacteremia of another origin or endocarditis can lead to such infection.

Meningitis caused by anaerobes is rare and can follow respiratory infection or develop as a complication of a cerebrospinal fluid shunt. The isolates generally recovered from brain abscesses that complicate respiratory and dental infections include *Prevotella, Porphyromonas, Bacteroides, Fusobacterium,* and *Peptostreptococcus* spp. Microaerophilic and other streptococci are also often isolated. *P. acnes* is common in shunt infections.

Head and Neck

Dental infections (Chapter 433) associated with a variety of oral anaerobic bacteria include periodontal disease, gingivitis, pulpitis, acute necrotizing ulcerative gingivitis, localized juvenile periodontitis, adult periodontitis, pericoronitis, endodontitis, periapical and dental abscesses, and postextraction infection. Peritonsillar, retropharyngeal, and parapharyngeal abscesses (Chapter 437) are deep-seated, potentially life-threatening infections that may extend into the various potential spaces of the neck or mediastinum and cause jugular vein thrombosis. Oral anaerobes may be isolated in more than 50% of such cases, usually in mixed culture with aerobes. Other regional infections include cervicofacial actinomycosis (Chapter 337), Ludwig's angina, *Fusobacterium necrophorum* sepsis with metastatic infection (Lemierre's syndrome), suppurative sialoadenitis (including parotitis), neck space infections, thyroiditis and chronic sinusitis (Chapter 434), otitis media (Chapter 434), and mastoiditis. Management involves surgical drainage and appropriate antimicrobial therapy.

Pleuropulmonary

Anaerobes are the predominant "normal flora" of the oral cavity and upper respiratory tract, and most pneumonias are due to aspiration of this flora (Chapter 97). Aspiration may be a result of altered consciousness, dysphagia, or mechanical devices such as intubation equipment. Poor oral hygiene is associated with an increased anaerobic bacterial burden, and the presence of aerobes or necrotic tissue lowers the pH, which in turn facilitates the growth of anaerobes. Anaerobes are involved in 90% of patients with community-acquired aspiration pneumonia and in about a third of patients with nosocomial aspiration pneumonia, empyema, lung abscess, and pneumonia associated with tracheostomy. If the anaerobic component of aspiration pneumonia is not treated, the anaerobes can cause a lung abscess. Management requires good pulmonary toilet and antimicrobial therapy.

Intra-abdominal

Anaerobes outnumber aerobes by 1000 : 1 in the large intestine, so it is not surprising that they play an important role in almost all intra-abdominal infections. Most visceral abscesses (e.g., hepatic; Chapter 154), chronic cholecystitis (Chapter 158), perforated and gangrenous appendicitis (Chapter 144), postoperative wound infections and abscesses, diverticulitis (Chapter 144), and any infection associated with fecal contamination of the abdominal cavity involve both aerobes and anaerobes. *B. fragilis* group members are especially important pathogens because they are encapsulated and resist phagocytosis, are often resistant to many commonly used antibiotics, and promote abscess formation. They may also be associated with concomitant bacteremia and sepsis.

Obstetric-Gynecologic

A variety of obstetric-gynecologic diseases involve anaerobes (Table 305-3). These infections are polymicrobial and include the following: bacterial vaginosis; soft tissue perineal, vulvar, and Bartholin gland abscesses; endometritis; pyometra; salpingitis; tubo-ovarian abscesses; adnexal abscess; pelvic inflammatory disease, which may include pelvic cellulitis and abscess; chorioamnionitis; vaginal cuff cellulitis; septic pelvic thrombophlebitis; intrauterine contraceptive device–associated infection; septic abortion; and postsurgical obstetric and gynecologic infections. Bacterial vaginosis has been associated with preterm labor or delivery, chorioamnionitis, low birthweight, postpartum endometritis, and postabortal pelvic inflammatory disease. Bacterial vaginosis can increase the risk for infection with human immunodeficiency virus (HIV) type 1 and the development of other sexually transmitted diseases (Chapter 293).

Skin and Soft Tissue

Cutaneous infections include infected ulcers, cellulitis (including synergistic necrotizing cellulitis), pyoderma, paronychia, hidradenitis suppurativa, and a variety of secondarily infected sites. Such sites include secondarily infected gastrostomy or tracheostomy site wounds, subcutaneous sebaceous or inclusion cysts, eczema, psoriasis, poison ivy, atopic dermatitis, eczema herpeticum, scabies or kerion, and postsurgical wounds.

Subcutaneous infections include abscesses, decubitus ulcers, infected diabetic (vascular or trophic) ulcers, human and animal bite wounds, anaerobic cellulitis and gas gangrene, bacterial synergistic gangrene, Fournier's gangrene, infected pilonidal cyst or sinus, and burn wounds. Anaerobic soft tissue infections that occur deeper are necrotizing fasciitis, necrotizing synergistic cellulitis, and gas gangrene. These infections can involve the fascia and can induce myositis and myonecrosis.

Cultures frequently yield isolates that are members of the "normal flora" of the region of the infection. In addition to oral and skin flora, human bite infections often contain *Eikenella* species and animal bites harbor *Pasteurella multocida*.

The infections are generally polymicrobial, and some (e.g., decubitus ulcers, diabetic foot ulcers) are often complicated by osteomyelitis or bacteremia. Deep tissue infections such as necrotizing cellulitis, fasciitis, and myositis often involve *Clostridium* species, *Streptococcus pyogenes*, or a polymicrobic aerobic and anaerobic flora. They are often associated with gas in the tissues and putrid-like pus with a gray thin quality and have a high rate of bacteremia and mortality. Management of deep-seated soft tissue infection includes surgical débridement, drainage, and vigorous surgical management.

TABLE 305-3 CLINICAL INDICATORS OF ANAEROBIC INFECTION

Infection adjacent to a mucosal surface
Foul-smelling discharge
Necrotic gangrenous tissue and abscess formation
Free gas or crepitus in tissue
Bacteremia or endocarditis with no growth on aerobic blood cultures
Infection related to the use of antibiotics effective against aerobes only (e.g., trimethoprim-sulfamethoxazole, aminoglycosides, older quinolones)
Infection related to tumors or other destructive processes
Infected thrombophlebitis
Infection after bites
Black discoloration of exudates containing *Prevotella melaninogenica*, which may fluoresce under ultraviolet light
"Sulfur granules" in discharges caused by actinomycosis
Clinical finding of gas gangrene or necrotizing fasciitis
Clinical condition predisposing to anaerobic infection (e.g., after maternal amnionitis, fistulous tracts, bites, dental infection, bowel perforation)

Osteomyelitis and Septic Arthritis

Anaerobes are notable in osteomyelitis of the long bones after trauma and fracture, osteomyelitis related to peripheral vascular disease, decubitus ulcers, and osteomyelitis of the cranial and facial bones. Most of these infections are polymicrobial.

Cranial and facial bone osteomyelitis is generally caused by spread from a contiguous soft tissue source or from sinus, ear, or dental infection. Intestinal anaerobes originating from decubitus ulcers are involved in pelvic osteomyelitis. Osteomyelitis of long bones and septic arthritis are generally caused by hematogenous spread, trauma, or the presence of a prosthetic device.

The predominant isolated anaerobes are peptostreptococci and *P. acnes* (often in prosthetic joint infection), *B. fragilis* group and fusobacteria (often of hematogenous origin), and clostridia (associated with trauma).

DIAGNOSIS

Anaerobic infections should be suspected in a number of specific clinical scenarios (Table 305-3). An appropriately collected microbiologic specimen (Table 305-4) is critical for accurate diagnosis.

TREATMENT

Rx

General principles of treatment (Table 305-5) include appropriate antimicrobial therapy coupled with prompt drainage, decompression of closed-space infections, relief of obstructions, and surgical débridement. The various clinically important anaerobes can be characterized by reasonably predictable susceptibility patterns to antimicrobial agents (Table 305-6), but culture and sensitivity results should ultimately guide therapy. The efficacy of hyperbaric oxygen is unproved, but its use in conjunction with other therapeutic measures is not contraindicated.

When choosing antimicrobials for the treatment of mixed infections, their aerobic and anaerobic antibacterial spectra and their availability in oral or

parenteral form should be considered. Some antimicrobials have a limited range of activity. For example, metronidazole is active only against anaerobes and therefore cannot be administered as a single agent for the treatment of mixed infections. Others (i.e., carbapenems, tigecycline) have wide spectra of activity against aerobes and anaerobes.

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on normal flora, and their bactericidal activity. Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram stain preparation of the specimen may indicate the types of anaerobes present in the infection and the nature of the infectious process.

Even though the duration of therapy for anaerobic infections is generally longer than that for aerobic and facultative infections, the length of treatment must be individualized, depending on the response. In some cases, treatment may require 6 to 8 weeks, but therapy may be shortened with proper surgical drainage. An anti–gram-negative enteric agent is generally added to treat Enterobacteriaceae when managing intra-abdominal infections.

The available parenteral antimicrobials for most infections are clindamycin, metronidazole, chloramphenicol, cefoxitin, a penicillin (i.e., ticarcillin, ampicillin, piperacillin) and a β-lactamase inhibitor (i.e., clavulanic acid, sulbactam, tazobactam), a carbapenem (i.e., imipenem, meropenem, doripenem, ertapenem), or tigecycline.

An agent effective against gram-negative enteric bacilli (e.g., an aminoglycoside, fluoroquinolone) or an antipseudomonal cephalosporin (e.g., cefepime) is generally added to metronidazole and, occasionally, cefoxitin when treating intra-abdominal infections. Penicillin can be added to metronidazole for the treatment of intracranial, pulmonary, or dental infections to cover microaerophilic streptococci and *Actinomyces* species. Penicillin is added to clindamycin to supplement its coverage against *Peptostreptococcus* species and other gram-positive anaerobic organisms. For *Chlamydia* and *Mycoplasma* species, doxycycline is added to most regimens when treating pelvic infections. Oral therapy is often substituted for parenteral therapy. The agents available for oral therapy are clindamycin, amoxicillin and clavulanate, and metronidazole.

TABLE 305-4 SPECIMEN ACCEPTABILITY FOR ANAEROBIC CULTURE

SPECIMENS THAT SHOULD NOT BE CULTURED FOR ANAEROBES
Feces or rectal swabs
Throat or nasopharyngeal swabs
Sputum or bronchoscopic specimens
Routine or catheterized urine
Vaginal or cervical swabs
Material from superficial wounds or abscesses not collected properly to exclude surface contamination
Material from abdominal wounds obviously contaminated with feces, such as an open fistula
SPECIMENS APPROPRIATE FOR ANAEROBIC CULTURE
All normally sterile body fluids other than urine, such as blood, pleural, and joint fluids
Urine obtained by suprapubic bladder aspiration
Percutaneous transtracheal aspiration, direct lung puncture, or double-lumen catheter bronchial brushing and bronchoalveolar lavage (both cultured quantitatively)
Culdocentesis fluid obtained after decontamination of the vagina
Material obtained from closed abscesses
Material obtained from sinus tracts or draining wounds

TABLE 305-5 GENERAL PRINCIPLES OF THERAPY FOR ANAEROBIC INFECTIONS

- Decompression of closed spaces
- Débridement
- Drainage
- Relief of obstructions
- Irrigation
- Provision of adequate circulation when possible
- Removal of foreign bodies
- Antimicrobials
  - Activity against most likely pathogen or pathogens: location dependent, minimal effect on normal flora
  - Absorption, appropriate route of administration (intravenous, oral)
  - Penetration into site of infection
  - Dosage appropriate for local tissue levels, body mass of patient, renal and liver function
  - Duration appropriate for condition
  - Susceptibility testing of isolate to guide specific therapy

306 *NEISSERIA MENINGITIDIS* INFECTIONS

DAVID S. STEPHENS

DEFINITION

Neisseria meningitidis (the meningococcus) is the cause of epidemic meningitis, a fulminant sepsis (meningococcemia), milder bacteremia, and, less commonly, other focal infections.

The Pathogen

N. meningitidis is an aerobic, gram-negative β-proteobacterium and a member of the family Neisseriaceae, which also includes *Neisseria gonorrhoeae* (Chapter 307), another important human pathogen. The meningococcus is a common commensal of the human upper respiratory tract, but it can also cause local and devastating invasive human disease. Human mucosal surfaces, most commonly the nasopharynx, are the only known reservoir. There are 13 known serogroups of *N. meningitidis,* based on different capsular polysaccharide structures, but only 6 serogroups (A, B, C, W-135, X, and Y) cause the majority of invasive meningococcal disease (Fig. 306-1). Highly pathogenic meningococci are also distinguished by genetically defined clonal complexes that can emerge and spread worldwide. Dissecting the basis of meningococcal disease has provided important scientific lessons for bacterial emergence and pathogenesis, antibiotic resistance mechanisms, innate and adaptive human immune responses, and vaccine strategies.

EPIDEMIOLOGY

For at least 200 years, *N. meningitidis* has inflicted rapid death, disability, and fear on disparate human populations. Beginning with the initial descriptions of outbreaks in Geneva in 1805 and New Bedford, Massachusetts, in 1806, the meningococcus has caused endemic cases, case clusters, epidemics, and pandemics of meningitis and septicemia. An estimated 500,000 cases occur worldwide each year. The greatest burden of disease occurs in Africa and in parts of Asia, where endemic rates of disease are 5 to 10 per 100,000 population. Especially in sub-Saharan Africa, seasonal epidemics occur yearly, and cyclic pandemics have occurred every 8 to 10 years since 1905. During the epidemics and cyclic pandemics, the incidence can climb to 1 per 1000 population for weeks before the frequency of disease declines in the immediate outbreak area. For example, despite partially effective vaccines, the dry seasons in Burkina Faso, located in the sub-Saharan meningitis belt, can be accompanied by more than 5000 cases of meningitis per week (>680/100,000 population), an almost yearly occurrence in the country. Meningococcal epidemics in developing countries cause catastrophic expense, which contributes to the cycle of poverty and hence the disorganization of social structures.

The disease remains endemic, with focal outbreaks, in the United States, Canada, Europe, Japan, Australia, and other industrialized countries, with a lower overall incidence of 0.3 to 2 per 100,000 population. The introduction and widespread use of new meningococcal conjugate vaccines in North America, Australia, and Europe have lowered the incidence. Endemic disease and outbreaks continue to occur in China, eastern Europe, Russia, South America, India, and Southeast Asia. Before and during World War II, large epidemic outbreaks (mainly due to serogroup A) affected the United States, Europe, Japan, and Australia; after the war these outbreaks disappeared, for reasons that are not clear. Meningococcal disease has the highest incidence in children younger than 4 years and in adolescents, but in endemic settings, half of all cases occur in adults.

PATHOBIOLOGY

N. meningitidis is transmitted among humans through close contact via large respiratory droplets. Colonization of the upper respiratory mucosal surfaces (e.g., nasopharynx) by *N. meningitidis* is the first step in establishment of a human carrier state and invasive meningococcal disease. Acquisition of meningococci through contact with respiratory secretions or saliva can be transient, lead to colonization (carriage), or result in invasive disease. The inoculum size needed for transmission is unknown. Meningococcal disease usually occurs within 1 to 14 days of acquisition. Rarely, meningococci are transmitted sexually.

Initial contact of meningococci with mucosal epithelial cells is mediated by type IV pili. These structures provide mobility to penetrate mucus and are the initial adhesins for epithelial cells; the receptor for pili may be the I-domain of integrin α chains or possibly CD46. Meningococci proceed to proliferate on the surface of human nonciliated epithelial cells, forming small microcolonies at the site of attachment; they can disseminate from colonies by post-translational modification of pili and migrate to adjacent cells via pili-mediated "twitching" motility. Meningococci can also spread from the nasopharynx to adjacent epithelial surfaces and can infrequently cause local infections, including pneumonia, sinusitis, or otitis media. Close adherence of meningococci to the host epithelial cells results in the formation of epithelial cell cortical plaques and leads to the recruitment of factors ultimately responsible for the formation and extension of pseudopodia that can surround the meningococcus. Intimate meningococcal association with the epithelial cell is mediated by the bacterial opacity proteins Opa and Opc with CD66/carcinoembryonic antigen–related cell adhesion molecules (CEACAMs) and integrins, respectively, on the surface of the cell. However, other meningococcal epithelial cell mediators include the meningococcal adhesin NadA and meningococcal lipo-oligosaccharide. The formation of epithelial cell membrane protrusions and pseudopodia stems from the organization of specific molecular complexes involving the linkers ezrin and moesin, along with the clustering of several membrane-integral proteins, including CD44, intracellular adhesion molecule 1, and cortical actin polymerization. These events can lead to internalization of *N. meningitidis* in epithelial cells (Fig. 306-2). Intracellular meningococci reside within a membranous vacuole and are capable of translocating through the epithelial layers within 18 to 40 hours. Meningococci are capable of intracellular replication, due in part to the protective capsule and the organism's capacity to acquire iron through specialized transport systems.

Meningococci cross mucosal surfaces, enter the blood stream, and, in some individuals, produce systemic infection. Damage to the mucosal surface by coinfection, drying (e.g., very low humidity), or smoke exposure may increase this risk of invasion. The molecular interactions noted for epithelial cells also occur with endothelial cells, and meningococci can translocate across the blood-meninges barrier, possibly at the choroid plexus or by opening of intercellular junctions, and proliferate in the subarachnoid space, resulting in meningitis. In vasculature and cerebrospinal fluid (CSF), high levels of multiplying bacteria lead to an intense inflammatory response, with pronounced increases in concentrations of tumor necrosis factor-α (TNF-α), interleukins (IL-1β, IL-6, IL-8, and IL-10), different chemokines, and other inflammatory mediators.

Resistance to complement-mediated lysis and phagocytosis is due to the expression of the capsule and lipo-oligosaccharide. Meningococcal endotoxin released in blebs plays a major role in the inflammatory events of meningococcemia and meningococcal meningitis. Meningococcal lipid A is responsible for much of the biologic activity and toxicity of meningococcal endotoxin. The Toll-like receptor 4 (TLR4) is critical to the innate immune response to bacterial endotoxins, and meningococcal endotoxin is no exception. Activation of TLR4 by endotoxin requires association with the accessory protein MD-2, an *N*-glycosylated 19- to 27-kD protein expressed in both a soluble and a membrane-bound form. Binding of endotoxin to MD-2 in association with TLR4 leads to dimerization or oligomerization of two or more TLR4s, subsequent cellular activation, and cytokine and chemokine release.

In contrast, an asymptomatic *N. meningitidis* carrier state is found in 8 to 25% of healthy individuals. Meningococcal carriage is affected by age, intimate personal contact, crowding (e.g., bars, dormitories), and vaccination or chemoprophylaxis interventions in the community. Variable carriage rates have been reported, even during epidemics. Meningococcal carriage is a dynamic process, is less common in young children than in adults (<3%; *N. lactamica* predominates), is highest in adolescents (7 to 37%), and increases in closed populations (e.g., military recruits, hajj pilgrims). Rates as high as 36 to 71% have been reported in military recruits. Damage to the

upper respiratory tract by coinfections (e.g., mycoplasma, influenza, other respiratory viral infections), smoking, very low humidity, drying of mucosal surfaces, and trauma induced by dust predisposes to both carriage and meningococcal disease. Carriage has been linked to status as a secretor of glycoprotein ABO blood group antigens, which are water soluble, and to ethnic background. In a large U.K. study, social behavior (e.g., attendance at pubs or clubs, intimate kissing, cigarette smoking or exposure to passive smoke) was highly associated with the risk of meningococcal carriage. Carriage can last for days, weeks, or months and is an immunizing event leading to protective immunity against the organism.

The absence of protective bactericidal antibodies is the most important predisposing factor for systemic meningococcal disease, but genetic polymorphisms and other host cofactors can contribute to disease and disease severity. Disappearance of protective maternal antibodies increases the risk in older infants and young children. Congenital and acquired antibody deficiencies also increase risk. Opsonization and phagocytic function are important host defense mechanisms, as shown by disease reduction after polysaccharide vaccination in individuals with complement deficiencies. Rapidly progressive, fatal meningococcemia can arise in patients without properdin, and there is an increased risk of recurrent meningococcal infections in those with defects in the terminal complement pathway (C5–C9).

Polymorphisms in genes coding for the Fcγ-receptor II (CD32), Fcγ-receptor III (CD16), mannose-binding lectin, and TLR4 have been associated with increased risk. Mannose-binding lectin is a plasma opsonin that initiates complement activation; specific polymorphisms in the gene are identified more frequently in children with meningococcal disease than in controls. Plasminogen activator inhibitor-1 concentrations appear to affect the severity and mortality of meningococcal sepsis, suggesting that impaired fibrinolysis is an important factor in its pathophysiology. Meningococcal disease is occasionally linked to immunosuppressive disorders such as nephrotic syndrome, congenital or acquired hypogammaglobulinemia, splenectomy, and HIV/AIDS (about a 10-fold increased risk for sporadic disease). However, there has been no documented increase in epidemic outbreaks of meningococcal disease in countries with very high rates of HIV infection.

Meningococci can multiply rapidly in the vascular compartment, with an estimated doubling time of 30 to 45 minutes in some patients, or in the CSF. The release of high levels of inflammatory mediators such as endotoxin in the circulation or the CSF triggers an exaggerated release of chemokines, cytokines, bradykinin, and nitric oxide. Vascular dilation, hypovolemia, capillary leak, and a pronounced reduction in myocardial function are the result. At a later stage, substantial complement activation contributes to the altered endothelial barrier function and relaxation of the smooth muscles in the vessel wall through the generation of high levels of anaphylatoxins (C3a and C5a). The capillary leak syndrome results in an increased flux of albumin and water across the altered capillary wall to the extravascular space. A patient with fulminant meningococcemia accumulates a large amount of fluid in the extravascular tissue. Circulatory collapse and multiorgan dysfunction are the primary causes of death due to meningococcemia. In meningitis, morbidity and death are due predominantly to cerebral edema.

Unraveling the pathogenic mechanisms of this devastating, evolutionarily successful obligate human pathogen has significance for other new vaccines directed at mucosal pathogens and vaccine adjuvants, as well as for the understanding of human sepsis and the design of sepsis antagonists.

CLINICAL MANIFESTATIONS

The meningococcus causes meningitis (~50% of cases); septicemia (meningococcemia) or, less commonly, a mild bacteremia pneumonia; and much less commonly (<5% of cases), septic arthritis, pericarditis, chronic bacteremia, or conjunctivitis. Very rarely, meningococci can cause urethritis. In endemic and epidemic disease outbreaks, hemorrhagic skin lesions (petechiae, purpura; Fig. 306-3) are present in 28 to 77% of patients with invasive meningococcal disease on admission; these lesions can be difficult to see in patients with dark skin. Hemorrhagic lesions sometimes occur on mucous membranes and sclera, but they are especially prevalent on the limbs. Petechiae of meningococcemia are usually larger and bluer than the pinpoint petechiae caused by thrombocytopenia, leukocytoclastic vasculitis induced by other infections or drugs, or vomiting or coughing. A nonblanching macular rash can also be a manifestation of meningococcal bacteremia. Evolving ecchymoses or purpura (diameter >10 mm) are noted mainly in patients with meningococcemia and disseminated intravascular coagulation (Chapter 178), but they may not appear until 12 hours into the illness. In addition to vasculitis, other conditions in the differential diagnosis of meningococcemia include Rocky Mountain spotted fever and enteroviral infections.

Meningitis is the most common clinical presentation of invasive meningococcal disease. Headache, fever, and rash with meningismus and altered mental status are the characteristic features; however, the rash may be absent, and the presentation can resemble pneumococcal or bacterial meningitis of other causes, viral meningitis, or early-stage encephalitis. Bacteremic meningococcal pneumonia has been linked most often to serogroup Y and is more common in adolescents, adults, and especially older adults (approximately one third of cases occur in those older than 65 years). Isolated septic pericarditis or septic arthritis can also be a presentation, and an autoimmune- or antibody-mediated polyarthritis can be seen in the recovery phase following invasive meningococcal disease. Chronic meningococcemia can present with low-grade fever and a polyarticular arthritis that can be confused with rheumatoid arthritis.

DIAGNOSIS

The clinical diagnosis of meningococcal meningitis relies on the recognition of fever, rash, meningeal signs, and altered mental status and is confirmed by CSF pleocytosis; Gram stain and/or polymerase chain reaction (PCR) of CSF, with or without growth in culture; or culture of blood or skin lesions.

FIGURE 306-3. Clinical manifestations of meningococcal disease. A and **B,** Macular and petechial rashes of meningococcal bacteremia. **C,** Fulminant meningococcal sepsis with ecchymoses. **D,** Digital necrosis of meningococcemia sepsis. **E,** Hemorrhagic adrenals in fulminant meningococcal sepsis. (Modified from Stephens DS, Greenwood B, Brandtzaeg P. Epidemic meningitis, meningococcemia and *Neisseria meningitidis*. *Lancet.* 2007; 369:2196-2210.)

The early clinical diagnosis of meningococcemia is a challenge because a rash, meningeal signs, and high fever may not be present. Blood cultures are diagnostic, but the course can be quite fulminant (<24 hours), and the early stages of disease can mimic viral infections such as influenza. Thus, it can be difficult to identify and treat the disease quickly. General symptoms of sepsis (nausea and vomiting, drowsiness, irritability, leg pains, cold hands and feet, abnormal skin color) are present. However, these symptoms (in contrast to fever and rash) are not likely to be specific markers. Parents and relatives should be instructed to undress and inspect a febrile child, adolescent, or young adult for a rash, and physicians and other health care providers should be alert to the concerns of parents or relatives about the abrupt or rapid deterioration of a patient.

PCR is increasingly used for the diagnosis of meningococcal meningitis, including serogrouping and genomic typing. Improved antigen and nucleic acid detection systems are leading to better meningococcal disease surveillance and molecular epidemiology. Biopsy samples from dermis show that meningococci are present in and around the microvascular endothelial cells. Meningococci in these lesions can be cultured up to 12 hours after effective antibiotic treatment is started. In two studies, the sensitivity of culture and Gram stain of the aspiration and biopsy samples of skin lesions was 62 and 56%, respectively.

TREATMENT

Rx

Early antibiotic administration is most important because effective antibiotics immediately stop the growth of *N. meningitidis*. Ceftriaxone, cefotaxime, and penicillin are all effective antibiotics, as are meropenem and chloramphenicol. Fluoroquinolones have excellent in vitro activity, but clinical experience is limited, and meningococcal resistance is now emerging to quinolones. Meningococci in CSF are killed within 3 to 4 hours after intravenous treatment with an adequate dose of a third-generation cephalosporin or penicillin, and concentrations of endotoxin in plasma fall by 50% within 2 hours. The concentrations of key cytokines and chemokines fall in parallel. Antibiotic treatment does not induce a large release of meningococcal endotoxin or lead to an increased inflammatory response.

Prehospital antibiotic treatment is advocated if the disease is suspected. One goal is to reduce the case-fatality rate for patients with fulminant meningococcal sepsis or meningitis with rapidly increasing concentrations of meningococci and inflammatory mediators in the circulation or CSF. If antibiotic treatment is initiated before admission, ceftriaxone or another effective antibiotic should be injected intravenously or intramuscularly. During epidemics in developing countries, a single injection of ceftriaxone or long-acting chloramphenicol may be sufficient for patients with meningitis,■ and this simple treatment has saved many thousands of lives. Although the sensitivity of meningococci to penicillin is decreasing worldwide because of a reduced affinity for penicillin–binding protein 2, high-level penicillin resistance remains rare. Ceftriaxone and cefotaxime can achieve CSF concentrations 45- to 8750-fold higher than the minimal inhibitory concentrations for meningococci.

Patients with suspected bacterial meningitis of unknown cause are often given ceftriaxone or cefotaxime, often combined with vancomycin, until the causative agent has been identified. When *N. meningitidis* is identified, antibiotic treatment can be continued with a third-generation cephalosporin or penicillin alone. Traditionally, patients were treated for 7 days, but 3 or 4 days of intravenous treatment can provide a cure without relapses.

Recognition of the different pathophysiologic processes associated with meningococcal meningitis (which causes death and morbidity predominantly by cerebral edema) and meningococcal septic shock (which causes death and morbidity predominantly through hypovolemia, capillary leak, myocardial dysfunction, and multiorgan failure) has led to improved management strategies for these two different forms of disease. Early and aggressive management of shock through the use of volume expansion, intensive care monitoring, and inotropic support can reduce fatality rates of meningococcal sepsis from higher than 30% to 5 to 10%. In meningococcemia with hypotension, the primary goal is to increase the circulating blood volume by aggressive fluid treatment. Both colloids and crystalloids (saline 0.9%) can be used. Adults are given saline starting with 1 L infused intravenously over 15 to 20 minutes, followed by several liters at a reduced rate. Some patients require two to three times their own blood volume during the first 24 hours. The total fluid volume needed per 24 hours is determined by response to treatment—tissue perfusion, blood pressure, urine output, and evidence of intravascular volume overload. The volume treatment may be combined with a vasopressor such as dopamine, norepinephrine, epinephrine, or dobutamine. Fluid treatment may be complicated in patients with reduced renal function. They may need dialysis or hemofiltration to compensate for renal failure and to reduce the substantial edema that accumulates.

Patients with meningitis or mild meningococcemia should be given the normal daily fluid requirement, supplemented with the volume lost before admission. Excessive volume treatment in patients with meningitis can induce fatal brain edema and herniation. Management of raised intracranial pressure (hyperosmolar solutions, diuretics, mechanical ventilation), seizures, and hyponatremia is indicated.

Anticoagulant treatment of patients with meningococcemia and disseminated intravascular coagulation has not been documented to improve outcome. A phase III study of recombinant activated protein C in children with sepsis of all causes, including meningococcemia, was stopped because no benefit was noted.■ Administration of activated protein C is associated with an increased risk of cerebral hemorrhage. The use of recombinant human tissue plasminogen activator does not appear to be beneficial. Randomized controlled clinical trials using hyperimmune serum, antibodies, or recombinant bactericidal or permeability-increasing protein designed to inactivate *N. meningitidis* endotoxin have not demonstrated a beneficial effect on survival. Blockade of other specific inflammatory mediators has not been adequately tested in meningococcal septic shock.

Patients with fulminant meningococcal septicemia can develop adrenal hemorrhage (Waterhouse-Friderichsen syndrome). The corticotropin concentration is higher, the cortisol concentration is lower, and the corticotropin to cortisol ratio is higher in patients with fatal meningococcal shock than in survivors. Adults with septic shock and indications of inadequate adrenal function are given low doses of steroids.■ Although the benefit has not been documented in children, many intensive care specialists use stress replacement doses of hydrocortisone in children with shock caused by *N. meningitidis*.

Plasmapheresis, blood exchange, and extracorporeal membrane oxygenation have been used in patients with meningococcemia; however, no controlled trial to assess the results has been done. Plasmapheresis and blood exchange appear to have little additive effect on the endogenous clearance of endotoxin and cytokines from the circulation. Extracorporeal membrane oxygenation has been used in several centers, with better results in children with acute pulmonary failure than in those with refractory septic shock. The use of insulin to control mild hyperglycemia in critically ill adults has not shown benefits (Chapter 108).

Pharmacologic doses of dexamethasone have been shown to reduce morbidity in pneumococcal and *Haemophilus influenzae b* meningitis.■ The use of dexamethasone to reduce death caused by brain edema or to prevent sequelae such as deafness in patients with meningococcal meningitis remains unproved based on randomized controlled trials, but large studies have not been performed, and its early use in suspected bacterial meningitis is a consideration.

PREVENTION

Chemoprophylaxis to eliminate meningococcal carriage is recommended for close contacts of patients to prevent further transmission and disease (Table 306-1). The occurrence of meningococcal disease in household contacts is approximately 100-fold higher than in the general population.

TABLE 306-1 CHEMOPROPHYLAXIS AGAINST MENINGOCOCCAL DISEASE*

DRUG	AGE GROUP	DOSAGE	DURATION AND ROUTE OF ADMINISTRATION
Rifampin†	Children <1 mo	5 mg/kg body weight q12h	2 days, oral
	Children ≥1 mo	10 mg/kg body weight q12h	2 days, oral
	Adults	600 mg q12h	2 days, oral
Azithromycin	<15 yr	10 mg/kg body weight	Single oral dose
	>15 yr	500 mg	Single oral dose
Ceftriaxone	<15 yr	125 mg	Single IM dose
	>15 yr	250 mg	Single IM dose
Ciprofloxacin‡	Adults	500 mg	Single oral dose

*Modified from guidelines issued by the Centers for Disease Control and Prevention.
†Not recommended for pregnant women; teratogenic in laboratory animals. Because the reliability of oral contraceptives might be affected by rifampin therapy, consider alternative contraceptive measures while rifampin is being administered. Secretions (e.g., tears) may be stained red.
‡Not usually recommended for persons younger than 18 years or for pregnant or lactating women because it causes cartilage damage in immature laboratory animals; however, it may be considered for chemoprophylaxis in children when no acceptable alternative is available. Note that meningococcal resistance to quinolones has been reported in the United States, India, and other locations.
IM = intramuscular.

Chemoprophylaxis can be helpful to control localized outbreaks in residential schools and barracks, but it is generally not recommended for the control of large epidemics (see the discussion of vaccines, later). Rifampin, ceftriaxone, azithromycin, and quinolones (but not penicillin) all have the ability to eradicate meningococci in the nasopharynx. Most meningococci are now resistant to sulfonamides; resistance to rifampin can develop rapidly, and quinolone resistance in meningococci is occurring.

Prevention through vaccination is the best option for the long-term control of meningococcal disease. Capsular polysaccharide vaccines to decrease serogroup A, C, Y, and W-135 meningococcal disease were introduced in the 1970s and 1980s. These vaccines are safe, with mild local adverse events; they are effective (>85%) in children older than 2 years and adults but are less immunogenic in younger children. Immunity to the polysaccharide vaccines is limited to 3 to 5 years of protection, and immunologic hyporesponsiveness is induced by repeated doses of the polysaccharide. Meningococcal polysaccharide vaccines do not induce immunologic memory and have little or no effect on nasopharyngeal carriage. Although these vaccines have been used extensively to control epidemics in the African meningitis belt, they are usually deployed too late in the course of an outbreak to achieve maximal effect. There is no evidence that widespread use of polysaccharide vaccines has reduced the frequency of epidemics in Africa.

A major advance in the past decade has been the development of meningococcal polysaccharide-protein conjugate vaccines and their introduction into the United Kingdom, other parts of Europe, Canada, Australia, and the United States.■ These vaccines are safe and immunogenic in young children, induce immunologic memory, and can decrease nasopharyngeal carriage of meningococci. In the United Kingdom, introduction of the C conjugate meningococcal vaccine in 2000 to all children and young adults greatly reduced the rate of serogroup C disease (90% vaccine effectiveness at 3 years for patients aged 11 to 18 years). A major protective effect of the C conjugate vaccine is mediated through herd immunity. Rates of serogroup C carriage and disease in nonvaccinated individuals were reduced by more than 50%. Serogroup A, C, Y, and W-135 polysaccharide-protein conjugate meningococcal vaccines were introduced for adolescents in the United States in 2005 and extended to children aged 2 to 10 years at increased risk for meningococcal disease. In addition to children and adolescents, populations that should benefit from the new conjugate vaccines are military recruits, patients with immunoglobulin or complement deficiencies (inherited or chronic deficiencies such as C3, properdin, factor D, or late complement components), anatomic or functional asplenia, microbiologists who are routinely exposed to isolates of *N. meningitidis*, and people who travel to or reside in countries where *N. meningitidis* is epidemic. The development of additional meningococcal conjugate vaccines holds great promise for controlling meningococcal disease in highly endemic and epidemic areas (e.g., sub-Saharan Africa), where serogroup A, C, and W-135 epidemics continue to occur. Further, serogroup X outbreaks have recently appeared in Africa.

The development of vaccines for serogroup B *N. meningitidis* remains a challenge. Serogroup B has caused prolonged outbreaks, such as those seen over the past 2 decades in the Pacific Northwest (Oregon, parts of Washington), Brazil, Norway, and New Zealand. The serogroup B capsule has an identical structure to polysialic structures expressed in fetal neural tissue and does not induce a protective bactericidal immunoglobulin G response. Thus, strategies are focused on noncapsular antigens, such as outer membrane proteins and vesicles and lipo-oligosaccharides. The diversity of major outer membrane structures in meningococci has limited these approaches, but success in controlling serogroup B epidemics that are strain specific (e.g., in New Zealand), the identification of conserved novel surface proteins for use in combination vaccines, and the discovery of novel group B capsule-specific epitopes are paths for new vaccines to prevent serogroup B meningococcal disease.

PROGNOSIS

Historically, the mortality of untreated systemic meningococcal disease was 70 to 90%. Despite highly effective antibiotics and aggressive supportive care, the mortality of invasive meningococcal disease remains at about 10%. The failure to recognize disease early and the very rapid development of disease, especially meningococcemia, remain the most significant challenges. The chance of surviving shock is directly correlated to plasma concentrations of endotoxin, and half the nonsurviving patients with shock die within the first 12 hours of hospital admission.

Morbidity includes limb loss (single amputation, 2%; multiple amputations, 1%), hearing loss (≈9%), and significant long-term neurologic disability (>2%), including cognitive dysfunction, visual impairment, educational difficulties, developmental delays, motor nerve deficits, seizure disorders, and behavioral problems. If parents and health care professionals recognize the importance of fever and headache with a nonblanching rash and seek treatment early, morbidity and mortality can be reduced with prehospital antibiotic treatment, rapid transportation to medical facilities, and stabilization in an intensive care unit. Prevention of meningococcal disease with new vaccines and vaccine strategies remains the major worldwide goal.

307 *NEISSERIA GONORRHOEAE* INFECTIONS

MATTHEW R. GOLDEN AND H. HUNTER HANDSFIELD

DEFINITION

Neisseria gonorrhoeae is a sexually transmitted organism that infects primarily the columnar epithelia of mucosal surfaces and causes urethritis in men and endocervicitis and urethritis in women. Other sites of primary infection include the rectum, pharynx, and conjunctiva, and vulvovaginitis can occur in prepubertal girls. The most common complication of gonococcal infection is pelvic inflammatory disease (PID), which can lead to infertility, ectopic pregnancy, and chronic pelvic pain. Other much less common complications include epididymitis, posterior urethritis, urethral stricture, Bartholin's gland abscess, and perihepatitis. Bacteremia may occur, with the production of characteristic cutaneous lesions, arthritis, and, rarely, endocarditis or meningitis. Neonatal conjunctivitis (ophthalmia neonatorum) was formerly a common cause of blindness. Gonococcal infections are also thought to increase the risk of human immunodeficiency virus (HIV) transmission from persons dually infected with HIV and *N. gonorrhoeae* and to increase the risk of HIV acquisition among persons with gonorrhea who are exposed to HIV.

The Pathogen

The gonococcal envelope is similar in its basic structure to that of other gram-negative bacteria and is composed of an inner cytoplasmic membrane, a middle peptidoglycan cell wall, and an outer membrane. The outer membrane contains several surface components that play a central role in the organism's interaction with the host and its pathogenicity. Pili, hair-like projections also referred to as *fimbriae*, are composed of several different protein subunits and, along with other outer membrane adhesins (i.e., opacity-related proteins), facilitate attachment and invasion of host cells. Gonococci vary the composition of these proteins and surface lipo-oligosaccharides over time, allowing the organism to elude host defenses. This phase variation has also been a barrier to successful vaccine development.

EPIDEMIOLOGY

Gonorrhea is the second most commonly reported infectious disease in the United States, with 336,742 cases reported to the Centers for Disease Control and Prevention (CDC) in 2008. The incidence of gonorrhea in the United States in 2008 was 111.6 per 100,000 population, although this number, which is based on cases reported to U.S. health departments, is certainly an underestimate. The overall incidence of gonorrhea in the United States has been relatively stable for more than a decade, and current rates are more than 70% lower than the incidence observed in the mid-1970s. The prevalence of gonorrhea varies widely, depending on the population tested. The Ad Health study tested a representative sample of U.S. 18- to 26-year-olds in 2001 and 2002 and found that 0.43% were infected, with wide variations geographically and among population groups. Among women aged 15 to 24 tested for gonorrhea in family planning clinics in 43 U.S. states and territories in 2008, the overall prevalence of gonorrhea was 0.9%, but it varied from 0 to 3.8%. By comparison, the prevalence of chlamydial infection in the Ad Health study was 4.19%, and among 15- to 24-year-old females tested in U.S. family planning clinics in 2008, it was 7.4% (range, 3.1 to 15%).

Like virtually all other sexually transmitted infections (STIs; Chapter 293), gonorrhea rates vary widely with age, geographic location, sexual orientation, and race or ethnicity. In the United States, the rate of reported infection is highest among 15- to 24-year-olds, and rates in the South are more than twice those observed in the West and Northeast. However, the most glaring disparities are observed when comparing rates of infection among different racial and ethnic groups and when comparing heterosexuals to men who have sex with men (MSM).

Rates of reported gonorrhea among U.S. African Americans are more than 20 times higher than those among non-Hispanic whites, and rates among American Indians/Alaska Natives and Hispanics are 3.6 and 2.2 higher, respectively, than those among non-Hispanic whites. Variations in reporting probably account for some of these observed differences, because low socioeconomic status is associated with receiving care in public health clinics and other venues where there is more complete reporting than in the private health care sector. However, the marked disparity in reported rates is also apparent in population-based studies, clearly establishing that the different rates of infection in different racial and ethnic groups are not simply a result of reporting bias. Comparing the prevalence of gonorrhea among African Americans and whites, the Ad Health study reported a prevalence ratio of 21.76, and the National Health and Nutrition Examination Survey found that gonorrhea was 17 times more prevalent among non-Hispanic blacks than among whites. The reasons for this profound disparity are certainly multifactorial and are not entirely clear. Different racial groups in the United States vary little in terms of their number of sex partners, so this cannot explain the different rates of STIs. Although inadequate access to medical care likely plays a role in the racial disparities in STI rates, profound racial and ethnic disparities are also observed in the United Kingdom and the Netherlands, nations with nationalized health care systems in which access to care should be more uniform than it is in the United States. Recent research has highlighted the importance of concurrency (i.e., partnerships that overlap in time) and patterns of sexual mixing based on age, race, and level of sexual activity as critical determinants of a population's risk of STI. These factors are thought to be shaped by social factors (e.g., poverty, incarceration, joblessness, racism) that play a central role in defining the epidemiology of all STIs worldwide.

Gonorrhea also disproportionately affects gay and bisexual men and other MSM. MSM constitute approximately 5% of the male population of the United States. National estimates of the rate of gonorrhea among MSM are not available. However, the public health department in King County, Washington, estimated that the rate of gonorrhea among MSM in 2008 was 719 per 100,000, 14-fold higher than the reported rate in heterosexual men (51 per 100,000) and more than 7 times the reported rate among men nationwide. Numerous cities in the United States, western Europe, and Australia have reported increases in the rate and number of gonorrhea cases among MSM since the mid-1990s.

Gonorrhea is highly transmissible. Though not precisely defined, the risk of transmission from a man to a woman during a single episode of unprotected vaginal intercourse is thought to be 50 to 70%, and the risk of transmission from a woman to a man is 20%. The transmission risks associated with anal sex, fellatio, or cunnilingus are not well defined, but anal intercourse is likely a relatively efficient mode of transmission. Transmission by fellatio also occurs frequently, especially from the insertive to the receptive partner. Although the transmission and acquisition of gonorrhea by cunnilingus were traditionally thought to be uncommon, recent data suggest that gonococcal infection may be relatively common in some populations of men who perform cunnilingus. Gonococci die rapidly on drying, and with the exception of occasional acquisition by laboratory personnel working with the organism, nonsexual transmission does not occur in adults. Perinatal transmission causing neonatal ophthalmitis or pharyngeal infection is now rare.

PATHOBIOLOGY

Following attachment to host epithelial cells, gonococci are endocytosed into the cell in a process thought to be facilitated by Por (or protein 1). Gonococci then replicate within the host cell and are released into the subepithelial space.

Typical urethral infections result in prominent inflammation, probably as a result of the release of toxic lipo-oligosaccharide and peptidoglycan fragments, as well as the release of chemotactic factors that attract neutrophilic leukocytes. The reasons why some gonococcal strains selectively cause asymptomatic genital infection are poorly understood, but this propensity may be related to differences in the organism's ability to bind complement-regulatory proteins that downregulate the production of chemotactic peptides. In particular, gonococcal strains that express PorB1A appear to bind factor H and complement-binding protein and have an increased propensity for causing disseminated gonococcal infections.

Although the gonococcus is not highly mutable, many gonococci possess conjugative plasmids and are consequently able to efficiently transfer other, nontransferable plasmids, such as those conferring resistance to penicillin and tetracycline. Gonococci are also capable of efficiently transferring naked DNA (transformation). These characteristics are important in the organism's ability to develop resistance to antimicrobials.

CLINICAL MANIFESTATIONS

Gonococcal infections can result in a number of specific clinical syndromes, each of which has its own manifestations, differential diagnosis, and
